28 **Abstract**

29 In the aqueous phase, fine particulate matter can form reactive species (RS) that influence the aging,
30 properties, and health effects of atmospheric aerosols. In this study, we explore the RS yields of aerosol
31 samples from remote forest (Hyytiälä, Finland) and polluted urban locations (Mainz, Germany; Beijing,
32 China), and we relate the RS yields to different chemical constituents and reaction mechanisms. Ultrahigh-
33 resolution mass spectrometry was used to characterize organic aerosol composition, electron paramagnetic
34 resonance (EPR) spectroscopy with a spin-trapping technique was applied to determine the concentrations
35 of $\bullet\text{OH}$, $\text{O}_2\bullet^-$, and carbon- or oxygen-centered organic radicals, and a fluorometric assay was used to quantify
36 H_2O_2 . The aqueous H_2O_2 -forming potential per mass unit of ambient $\text{PM}_{2.5}$ (particle diameter $< 2.5 \mu\text{m}$)
37 was roughly the same for all investigated samples, whereas the mass-specific yields of radicals were lower
38 for sampling sites with higher concentration of $\text{PM}_{2.5}$. The abundances of water-soluble transition metals
39 and aromatics in ambient $\text{PM}_{2.5}$ were positively correlated with the relative fraction of $\bullet\text{OH}$ and negatively
40 correlated with the relative fraction of carbon-centered radicals. In contrast, highly oxygenated organic
41 molecules (HOM) were positively correlated with the relative fraction of carbon-centered radicals and
42 negatively correlated with the relative fraction of $\bullet\text{OH}$. Moreover, we found that the relative fractions of
43 different types of radicals formed by ambient $\text{PM}_{2.5}$ were comparable to surrogate mixtures comprising
44 transition metal ions, organic hydroperoxide, H_2O_2 , and humic or fulvic acids. The interplay of transition
45 metal ions (e.g., iron and copper ions), highly oxidized organic molecules (e.g., hydroperoxides), and
46 complexing or scavenging agents (e.g., humic or fulvic acids), leads to non-linear concentration
47 dependencies in the aqueous-phase RS production. A strong dependence on chemical composition was also
48 observed for the aqueous-phase radical yields of laboratory-generated secondary organic aerosols (SOA)
49 from precursor mixtures of naphthalene and β -pinene. Our findings show how the composition of $\text{PM}_{2.5}$
50 can influence the amount and nature of aqueous-phase RS, which may explain differences in the chemical
51 reactivity and health effects of particulate matter in clean and polluted air.

52 **1 Introduction**

53 Atmospheric fine particulate matter with a particle diameter $< 2.5 \mu\text{m}$ ($\text{PM}_{2.5}$) can form reactive species
54 (RS) upon dissolution in the aqueous phase (Bates et al., 2015;Lakey et al., 2016;Park et al., 2018;Li et al.,
55 2018;Tong et al., 2019). The umbrella term RS comprises reactive oxygen species (e.g., $\bullet\text{OH}$, $\text{O}_2\bullet^-$, $^1\text{O}_2$,
56 H_2O_2 , and ROOH) as well as C- and O-centered organic radicals (Halliwell and Whiteman, 2004;Sies et al.,
57 2017), which influence the chemical aging of atmospheric aerosols and their interaction with the biosphere
58 (Pöschl and Shiraiwa, 2015;Reinmuth-Selzle et al., 2017;Shiraiwa et al., 2017). For example, Fenton-like
59 reactions of hydroperoxides with transition metal ions contribute to the formation of aqueous-phase radicals
60 including $\bullet\text{OH}$ (Jacob, 2000;Enami et al., 2014;Anglada et al., 2015;Tong et al., 2016a), enhancing the
61 conversion of organic precursors to secondary organic aerosols (SOA) (Donaldson and Valsaraj,
62 2010;Ervens et al., 2011;Gligorovski et al., 2015;Gilardoni et al., 2016). Moreover, $\text{PM}_{2.5}$ may generate
63 excess concentrations of RS in human airways, causing antioxidant depletion, oxidative stress, and
64 respiratory diseases (Nel, 2005;Cui et al., 2015;Lakey et al., 2016;Qu et al., 2017;Lelieveld and Pöschl,
65 2017;Rao et al., 2018).

66 The formation pathways and yields of RS from ambient PM and laboratory-generated SOA have been
67 investigated in a wide range of studies (Valavanidis et al., 2005;Ohyama et al., 2007;Chen et al., 2010;Wang
68 et al., 2011a;Wang et al., 2011b;Verma et al., 2014;Badali et al., 2015;Bates et al., 2015;Verma et al.,
69 2015;Arangio et al., 2016;Tong et al., 2016a;Kuang et al., 2017;Tong et al., 2017;Zhou et al., 2018;Tong
70 et al., 2019;Chowdhury et al., 2019;Fang et al., 2019;Liu et al., 2020). The mass, surface area, and chemical
71 composition of PM were discussed as key factors influencing the reactivity of atmospheric aerosols (Møller
72 et al., 2010;Fang et al., 2015;Jin et al., 2019;Lammel et al., 2020). Among the substance groups associated
73 with RS formation by PM in water are black carbon (Baumgartner et al., 2014), transition metals (Yu et al.,
74 2018), oxidized aromatic compounds including quinones and environmentally persistent free radicals
75 (EPFR) (Xia et al., 2004;Gehling et al., 2014;Charrier et al., 2014;Xiong et al., 2017), humic-like substances
76 (HULIS) (Lin and Yu, 2011;Page et al., 2012;Fang et al., 2019), and peroxide-containing highly oxygenated

77 organic molecules (HOM) (Chen et al., 2010;Wang et al., 2011b;Tong et al., 2016a;Tong et al., 2018;Tong
78 et al., 2019;Fang et al., 2020;Qiu et al., 2020). Moreover, the HULIS and other multifunctional compounds
79 containing carboxyl, carboxylate, phenolic, and quinoid groups may influence the redox activity of PM via
80 chelating transition metals (Laglera and van den Berg, 2009;Kostić et al., 2011;Catrouillet et al.,
81 2014;Gonzalez et al., 2017;Wang et al., 2018c;Win et al., 2018;Wei et al., 2019).

82 To assess the oxidative potential of ambient PM, the following cellular or acellular assays have been
83 used: dichloro-dihydro-fluorescein diacetate (DCFH-DA), dithiothreitol (DTT), ascorbic acid (AA),
84 macrophage, electron paramagnetic resonance (EPR), and surrogate lung fluids (SLF) (Landreman et al.,
85 2008;Charrier and Anastasio, 2012;Kalyanaraman et al., 2012;Charrier et al., 2014;Charrier and Anastasio,
86 2015;Fang et al., 2016;Tong et al., 2018;Bates et al., 2019;Fang et al., 2019;Molina et al., 2020;Crobeddu
87 et al., 2020). However, the interplay of different PM constituents often results in non-additive
88 characteristics of the RS yields or oxidative potential of PM (Charrier et al., 2014;Lakey et al., 2016;Wang
89 et al., 2018b). Thus, unraveling the adverse health effects of ambient PM requires systematic investigations
90 of the RS formation and chemical reactivity of PM from different sources and environments (Shiraiwa et
91 al., 2017).

92 The concentration of PM_{2.5} and the composition of airborne organic matter vary considerably from clean
93 forest to polluted urban environments. For example, the PM_{2.5} concentrations at the Hyytiälä forest site are
94 typically below 10 µg m⁻³, with organic matter accounting for ~70% (Laakso et al., 2003;Maenhaut et al.,
95 2011), whereas the PM_{2.5} concentrations in Beijing during winter can reach and exceed daily average values
96 of 150 µg m⁻³, with organic matter accounting for ~40% (Huang et al., 2014). Moreover, anthropogenic
97 emissions can enhance the formation of biogenic SOA and HOM as well as the levels of particulate
98 transition metals, humic-like substances, and PM oxidative potential (Goldstein et al., 2009;Hoyle et al.,
99 2011;Liu et al., 2014;Xu et al., 2015;Ma et al., 2018;Pye et al., 2019;Shrivastava et al., 2019).

100 In this study, we compared the RS yields of PM_{2.5} in clean and polluted environments. We used three
101 approaches to explore the RS formation by PM_{2.5} from remote forest of Hyytiälä (Finland), intermediately
102 polluted city of Mainz (Germany), and heavily polluted megacity of Beijing (China) (Figure 1). To quantify

103 the abundances of redox-active PM constituents related to RS formation, we collected ambient PM_{2.5} and
104 measured the chemical composition of organic matter, the abundance of water-soluble transition metals,
105 and the yield of radicals and H₂O₂ in the liquid phase (Figure 1a). To assess the influence of anthropogenic-
106 biogenic organic matter interactions on the RS formation by ambient PM_{2.5}, we analyzed the radical yield
107 of SOA generated by oxidation of mixed anthropogenic and biogenic precursors in a laboratory chamber
108 (Figure 1b). To gain insights into the radical formation mechanism of ambient PM_{2.5} in water, we
109 differentiated the influence of transition metal ions, organic hydroperoxide (ROOH), water-soluble humic
110 acid (HA) and fulvic acid (FA) on the radical formation by Fenton-like reactions (Figure 1c).

111 **2 Materials and methods**

112 **2.1 Chemicals**

113 The following chemicals were used as received without further purification: β-pinene (99%, Sigma-
114 Aldrich), naphthalene (99.6%, Alfa Aesar GmbH&Co KG), cumene hydroperoxide (80%, Sigma-Aldrich),
115 H₂O₂ (30%, Sigma-Aldrich), FeSO₄•7H₂O (F7002, Sigma-Aldrich), CuSO₄•5H₂O (209198, Sigma-
116 Aldrich), NiCl₂ (98%, Sigma-Aldrich), MnCl₂ (≥ 99%, Sigma-Aldrich), VCl₂ (85%, Sigma-Aldrich), NaCl
117 (443824T, VWR International GmbH), KH₂PO₄ (≥ 99%, Alfa Aesar GmbH&Co KG), Na₂HPO₄ (≥
118 99.999%, Fluka), humic acid (53680, Sigma-Aldrich), fulvic acid (AG-CN2-0135-M005, Adipogen), 5-
119 tert-Butoxycarbonyl-5-methyl-1-pyrroline-N-oxide (BMPO, high purity, Enzo Life Sciences, Inc.), H₂O₂
120 assay kit (MAK165, Sigma-Aldrich), ultra-pure water (14211-1L-F, Sigma-Aldrich), 47 mm diameter
121 Teflon filters (JVWP04700, Omnipore membrane filter), and micropipettes (50 μL, Brand GmbH&Co KG).
122 The used neutral saline (pH=7.4) consists of 10 mM phosphate buffer (2.2 mM KH₂PO₄ and 7.8 mM
123 Na₂HPO₄) and 114 mM NaCl, which was used to simulate physiologically relevant condition.

124 **2.2 Collection and extraction of ambient fine PM**

125 Ambient fine particles were collected onto Teflon filters for all sites. The Hyytiälä PM_{2.5} was collected
126 using a three-stage cascade impactor (Dekati® PM10) at the Station for Measuring Forest Ecosystem-
127 Atmosphere Relations station (SMEAR II station, Finland) during 31 May-19 July 2017 (Hari and Kulmala,

128 2005). The Mainz fine PM was collected using a micro-orifice uniform deposit impactor (MOUDI, 122-R,
129 MSP Corporation) (Arangio et al., 2016) on the roof of the Max Planck Institute for Chemistry during 22
130 August-17 November 2017 and 23-31 August 2018. The Beijing winter PM_{2.5} was collected using a 4-
131 channel PM_{2.5} air sampler (TH-16, Wuhan Tianhong Instruments Co., Ltd.) in the campus of the Peking
132 University, an urban site of Beijing, during 20 December-13 January 2016 and 6 November-17 January
133 2018 (Lin et al., 2015). The sampling time for a single filter sample in Hyytiälä, Mainz, and Beijing are 48-
134 72, 25-54, and 5-24 h, respectively, depending on the local PM concentrations. More information about the
135 sampling is shown in Table S1. After sampling, all filter samples were put in petri dishes and stored in a -
136 80 °C freezer before analysis. To determine the mass of collected PM, each filter was weighed before and
137 after the collection using a high sensitivity balance ($\pm 10 \mu\text{g}$, Mettler Toledo XSE105DU). In Hyytiälä, the
138 PM₁ and PM_{1-2.5} were separately sampled, which were combined and extracted together to represent PM_{2.5}
139 samples. Mainz PM with cut-size range of 0.056-1.8 μm is taken as a proxy for PM_{2.5}. Particle
140 concentrations in aqueous extracts were estimated to be in the range of 200-6000 $\mu\text{g mL}^{-1}$ (Figure S1).

141 **2.3 Formation, collection, and extraction of laboratory-generated SOA**

142 To generate SOA from mixed anthropogenic and biogenic precursors, different concentrations of gas-phase
143 naphthalene and β -pinene were mixed and oxidized in a potential aerosol mass (PAM) chamber, i.e., an
144 oxidation flow reactor (OFR) (Kang et al., 2007; Tong et al., 2018). Naphthalene and β -pinene were used
145 as representative SOA precursors in Beijing and Hyytiälä, respectively (Hakola et al., 2012; Huang et al.,
146 2019). The concentrations of gas-phase O₃ and $\cdot\text{OH}$ in the PAM chamber were $\sim 1 \text{ ppm}$ and $\sim 5.0 \times 10^{11} \text{ cm}^{-3}$
147 (Tong et al., 2018), respectively. SOA was produced by adjusting the relative concentrations of
148 naphthalene to the sum of it with β -pinene (i.e., $[\text{naphthalene}] / ([\text{naphthalene}] + [\beta\text{-pinene}])$) to be $\sim 9\%$,
149 $\sim 23\%$, and $\sim 38\%$ (mass fraction), respectively. The concentrations of naphthalene and β -pinene were 0.2-
150 0.6 ppm and 1.0-2.5 ppm, respectively, which were determined on the basis of a calibration function
151 measured by gas chromatography mass spectrometry (Tong et al., 2018). The number and size distributions
152 of SOA particles were measured using a scanning mobility particle sizer (SMPS, GRIMM Aerosol Technik

153 GmbH&Co. KG). When the SOA concentration was stable, 47 mm diameter Teflon filters (JVWP04700,
154 Omnipore membrane filter) were used to collect SOA particles, which were extracted into water solutions
155 within 2 minutes after the sampling. More information about the SOA formation, characterization,
156 collection, and extraction can be found in previous studies (Tong et al., 2016a;Tong et al., 2017;Tong et al.,
157 2018;Tong et al., 2019).

158 **2.4 Surrogate mixtures**

159 We used cumene hydroperoxide (CHP), humic acid (HA), fulvic acid (FA), and H₂O₂ as model compounds
160 mimicking the redox-active substances in ambient particulate matter (Lin and Yu, 2011;Ma et al.,
161 2018;Tong et al., 2019). The following method was used to prepare HA or FA solutions. First, 0-1000 µg
162 mL⁻¹ HA or FA water suspensions were made. Then, the suspensions were sonicated for 3 minutes to
163 accelerate the dissolution of HA or FA. Afterwards, the sonicated suspensions were centrifuged at 6000
164 rpm (MiniStar, VWR International bvba) for 2 minutes. Finally, the supernatants were taken out from the
165 centrifuge tubes with pipettes and stored in glass vials under 4-8 °C condition before analysis. The HA or
166 FA solutions were prepared freshly day-to-day. To determine the concentrations of dissolved HA or FA,
167 aliquots of the supernatants were dried with pure N₂ flow (1-2 bar) and weighted with a high sensitivity
168 balance (± 0.01 mg, Mettler Toledo XSE105DU). The concentrations of Fe²⁺, Cu²⁺, HA, and H₂O₂ in the
169 surrogate mixtures are 43 µM, 3 µM, 4 mg L⁻¹, and 7 µM, which are based on the measurement of ambient
170 PM extracts (Fe²⁺ and Cu²⁺, Section 2.8) or the estimated abundance in ambient PM (CHP, HA, FA, and
171 H₂O₂, SI). To explore the influence of HA/FA on Fenton-like reactions, the radical formation in the
172 following aqueous mixtures was also analyzed: CHP+Fe²⁺, CHP+Cu²⁺, CHP+Cu²⁺+HA, CHP+Cu²⁺+FA.
173 The concentrations of Fe²⁺, Cu²⁺, HA, FA, and H₂O₂ in these solutions are 15-300 µM, 15-300 µM, 0-180
174 µg mL⁻¹, 0-180 µg mL⁻¹, 0-300 µM, respectively.

175 **2.5 Quantification of radicals by EPR**

176 5-tert-Butoxycarbonyl-5-methyl-1-pyrroline-N-oxide (BMPO) was used as a spin-trapping agent for
177 detecting different types of radicals formed in the extracts of PM. Ambient PM or laboratory-generated

178 SOA were extracted from Teflon filters into 10 mM BMPO neutral saline or water solutions by vortex
179 shaking for ~15 minutes (with Heidolph Reax 1). Around one fourth of each ambient PM filter or a whole
180 SOA-loaded filter was used for extraction. It was assumed that most of the short-lived radicals have reacted
181 with BMPO to form stable adducts during the extraction process.

182 A continuous-wave electron paramagnetic resonance (CW-EPR) X-band spectrometer (EMXplus-10/12;
183 Bruker Corporation) was applied for the identification and quantification of radical adducts (Tong et al.,
184 2016a;Tong et al., 2017;Tong et al., 2018;Tong et al., 2019). In order to increase the signal to noise ratio
185 of EPR spectra, some of the extracts were concentrated by a factor of 5 - 20 through 15 - 20 minutes drying
186 under 1-2 bar pure N₂ flow. The EPR spectra of BMPO-radical adducts were recorded by setting the
187 following operating parameters: a microwave frequency of 9.84 GHz, a microwave power of 0.017 mW
188 (20 dB), a receiver gain of 40 dB, a modulation amplitude of 1 G, a scan number of 50, a sweep width of
189 100 G, a modulation frequency of 100 kHz, a conversion time of 11 ms, and a time constant of 10 ms.

190 To average EPR spectra of different PM_{2.5} extracts for each site, the magnetic field values of each
191 spectrum was transformed to g-values. Then we used the Bruker software, Xenon to do the averaging,
192 irrespective of the concentrations of PM_{2.5} in extracts. The spin-counting method embedded in Xenon was
193 applied to quantify radical adducts. The spin-counting method was calibrated using the standard compound
194 4-hydroxy-2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPOL). To obtain the relative yields of •OH, O₂•⁻, C-
195 and O-centered organic radicals, EPR spectra were simulated and fitted using the Xenon software before
196 deconvolution (Arangio et al., 2016;Tong et al., 2018). The spin number of assigned species accounts on
197 average for more than 95% of totally observed radical adducts, which is characterized by the peak area
198 ratios of corresponding species. EPR spectra with low signal-to-noise ratio introduce uncertainty into the
199 parameters describing the lineshape of peaks representing radical adducts (Tseitlin et al., 2012), causing a
200 total quantification uncertainty of 0-19% for different types of radicals (•OH, O₂•⁻, C- and O-centered
201 organic radicals etc.). The hyperfine coupling constants used for spectrum fitting are shown in Table S2.

202 More information on the hyperfine coupling constants of different types of BMPO radical adducts can be
203 found in previous studies (Zhao et al., 2001;Arangio et al., 2016).

204 **2.6 Measurement of H₂O₂ yields**

205 We extracted ambient PM_{2.5} from one fourth of each Teflon filter into 1 mL ultra-pure water or neutral
206 saline by stirring it with a vortex shaker for ~15 minutes. Afterwards, the extracts were centrifuged at 9000
207 rpm (Eppendorf Minispin) for 3 minutes to remove the insoluble particles. Finally, the concentration of
208 H₂O₂ in the supernatant was measured using the MAK165 assay kit (Yan et al., 2017;Tong et al., 2018). 50
209 μL of supernatant and 50 μL of a Master Mix solution containing horseradish peroxidase and Amplex Red
210 substrate were mixed in a 96-well plate. The horseradish peroxidase catalyzed the oxidation of Amplex Red
211 by H₂O₂ to form fluorescent resorufin (Wang et al., 2017), which was consequently quantified using a
212 microplate reader (Synergy™ NEO, BioTek, excitation at 540 nm and emission at 590 nm) after 30 minutes
213 of incubation. The concentration of H₂O₂ in aqueous PM extracts was determined using an H₂O₂ calibration
214 curve based on standard H₂O₂ solutions and also corrected by blank measurements (Tong et al., 2018).

215 **2.7 Mass spectrometry of organic compounds**

216 By using a Q-Exactive Orbitrap mass spectrometer (Thermo Fisher Scientific, MA, USA) coupled with an
217 ultra-high performance liquid chromatography (UHPLC) system (Dionex UltiMate 3000, Thermo
218 Scientific, Germany) (Wang et al., 2018a;Wang et al., 2019;Tong et al., 2019), we characterized the HOM
219 and aromatic compounds in Hyytiälä, Mainz, and Beijing winter fine PM samples in negative ionization
220 mode. We processed the MS spectrum and UHPLC chromatogram of measured samples through a non-
221 target screening approach by using the commercially available software SIEVE® (Thermo Fisher Scientific,
222 MA, USA). Then, we blank-corrected the signals with peak intensity $> 1 \times 10^5$. Afterwards, we used the
223 following criteria to assign molecular formulae and filter out the irrational ones: (a) the number of atoms
224 of C, H, O, N, S, and Cl should be in the range of 1-39, 1-72, 0-20, 0-7, 0-4, and 0-2, respectively. (b)
225 Atomic ratios of H/C, O/C, N/C, S/C, and Cl/C should be in the range of 0.3-3, 0-3, 0-1.3, 0-0.8, and 0-0.8,
226 respectively.

227 The HOM is defined as formulae in the following chemical composition range of $C_xH_yO_z$: monomers
228 with $x = 8-10$, $y = 12-16$, $z = 6-12$, and $z/x > 0.7$; dimers with $x = 17-20$, $y = 26-32$ and $z = 8-18$ (Ehn et
229 al., 2014;Tröstl et al., 2016;Tong et al., 2019). Aromatics in this study are defined to be compounds with
230 aromaticity index (AI) > 0.5 and aromaticity equivalent (X_c) > 2.5 , with the parameters accounting for the
231 fraction of oxygen and sulfur atoms involved in π -bond structures of a compound to be set as 1 (Koch and
232 Dittmar, 2006;Yassine et al., 2014;Tong et al., 2016b). Beyond this, the relative abundance of HOM or
233 aromatic compounds is defined to be the sum chromatographic area of HOM or aromatics divided by the
234 sum chromatographic area of all assigned organic compounds, with $< 30\%$ of totally detected organic
235 compounds not assigned (Wang et al., 2018a).

236 **2.8 Determination of water-soluble transition metal concentrations**

237 Based on the same extraction method as the H_2O_2 analysis in section 2.6, the concentrations of five selected
238 water-soluble transition metal species (Fe, Cu, Mn, Ni and V) in the supernatants of $PM_{2.5}$ extracts were
239 quantified using an inductively coupled plasma mass spectrometer (ICP-MS, Agilent 7900). These five
240 transition metal species were chosen for analysis due to their prominent concentrations and higher oxidative
241 potential (Charrier and Anastasio, 2012). A calibration curve for the ICP-MS analysis was made by
242 measuring standard multi-element stock solutions (Custom Grade, Inorganic Ventures). An aliquot of the
243 supernatants was diluted and acidified using a mixture of nitric acid (5%) and hydrofluoric acid (1%), which
244 was finalized to be 5 mL before analysis. The measured transition metal concentrations were blank-
245 corrected and shown in corresponding figures. The detection limit of the ICP-MS analysis in this study was
246 typically $< 40 \text{ ng L}^{-1}$. The $PM_{2.5}$ samples collected on 2 June, 7 June, 9 June, 12 June in 2017 in Hyttiälä,
247 on 22 August, 26 August, 28 August, 25 September, 25 October, 14 November in 2017 in Mainz, and all
248 the 12 $PM_{2.5}$ samples from Beijing winter were used for transition metal analysis. Temporal evolution of
249 water-soluble transition metal concentrations in water extracts of Mainz $PM_{2.5}$ were also measured, and we
250 found that the total ion concentration of Fe, Cu, Mn, Ni, and V showed a rapid rise during the first 15 min
251 (Figure S2a), but at a much slower rate afterwards (Figure S2b).

252 **3 Results and discussion**

253 **3.1 Aqueous-phase radical formation from ambient PM_{2.5}**

254 Figure 2a shows averaged EPR spectra of BMPO-radical adducts in neutral saline extracts of PM_{2.5} samples
255 from Hyytiälä, Mainz, and Beijing (Table S1). Each spectrum is composed of multiple peaks attributable
256 to different types of BMPO-radical adducts. The dotted vertical lines with different colors indicate the peaks
257 attributable to adducts of BMPO with •OH (green), O₂•⁻ (orange), C- (blue) and O-centered organic radicals
258 (purple) (Zhao et al., 2001; Arangio et al., 2016), respectively. The spectrum of Hyytiälä PM_{2.5} is dominated
259 by peaks attributable to C-centered radicals, the spectrum of Mainz PM_{2.5} exhibits strong peaks attributable
260 to C-centered radicals and •OH, and the spectrum of Beijing winter PM_{2.5} is dominated by four peaks
261 attributable to •OH.

262 Figure 2b shows the relative fractions (RF_{spin}) of •OH, O₂•⁻, C- and O-centered organic radicals averaged
263 over multiple samples from each site. The mean RF of C- and O-centered organic radicals, respectively,
264 were found to decrease from clean forest air samples (Hyytiälä, 66% and 11%) to polluted urban air samples
265 (Mainz, 46% and 10%; Beijing, 39% and 5%). The high yield of C-centered radicals can be explained by
266 rapid trapping of C-centered organic radicals (R•) by BMPO in the liquid phase (De Araujo et al., 2006). In
267 the aqueous extracts, we applied a large excess of BMPO (10 mM of BMPO vs. ~1 μM of trapped radicals),
268 and the estimated pseudo-first-order rate coefficient for R• reacting with BMPO ($9 \times 10^5 \text{ s}^{-1}$, (Tong et al.,
269 2018)) is much higher than the estimated R• recombination rate coefficient (2.4×10^3 , (Simic et al.,
270 1969; Tong et al., 2018)). Moreover, rearrangement reactions in water can convert RO• into R• (Chevallier
271 et al., 2004), which may warrant further investigation. The detected organic radicals are likely to comprise
272 different molecular sizes and structures, as supported by our recent observations of organic radicals with
273 up to 20 carbon atoms (C1-C20) formed by laboratory-generated SOA in water (Tong et al., 2018). The
274 mean RF of •OH was found to increase from clean forest air samples (Hyytiälä, 21%) to polluted urban air
275 samples (Mainz 38%, Beijing 53%). The mean RF of O₂•⁻ varied in the range of 2-6%, showing no clear
276 trend beyond the standard errors indicated in Figure 2b.

277 The formation of organic radicals, $\bullet\text{OH}$, $\text{O}_2\bullet^-$, and H_2O_2 can be attributed to Fenton-like reactions and
278 redox chemistry of organic and inorganic particulate matter, including environmentally persistent free
279 radicals (EPFR), highly oxygenated organic molecules (HOM), humic-like substances (HULIS), and
280 transition metal ions (Chevallier et al., 2004;Valavanidis et al., 2005;Li et al., 2008;Page et al.,
281 2012;Gehling et al., 2014;Tong et al., 2016a;Tong et al., 2017;Tong et al., 2018;Tong et al., 2019;Qiu et
282 al., 2020;Arangio et al., 2016). We speculate that hydrolytic or thermal decomposition of ROOH may play
283 a major role in the formation of RS by $\text{PM}_{2.5}$ from remote forest locations like Hyytiälä, where large
284 fractions of peroxide-containing HOM have been detected (Mutzel et al., 2015;Tröstl et al., 2016;Tong et
285 al., 2019;Pye et al., 2019;Roldin et al., 2019;Bianchi et al., 2019). ROOH can generate $\bullet\text{OH}$ and O-centered
286 organic radicals through decomposition ($\text{ROOH} \rightarrow \text{RO}\bullet + \bullet\text{OH}$) and Fenton-like reactions ($\text{Fe}^{2+} + \text{ROOH}$
287 $\rightarrow \text{Fe}^{3+} + \text{RO}\bullet + \text{OH}^-$; $\text{Fe}^{2+} + \text{ROOH} \rightarrow \text{Fe}^{3+} + \text{RO}\bullet + \text{OH}\bullet$) (Tong et al., 2016a). Interconversion of $\text{RO}\bullet$, $\text{R}\bullet$
288 and $\text{ROO}\bullet$ radicals can lead to the formation of $\text{O}_2\bullet^-$ and H_2O_2 (Chevallier et al., 2004;Tong et al., 2018),
289 which can further react with Fe^{2+} to form $\bullet\text{OH}$ ($\text{Fe}^{2+} + \text{H}_2\text{O}_2 \rightarrow \text{Fe}^{3+} + \bullet\text{OH} + \text{OH}^-$). In $\text{PM}_{2.5}$ from urban areas,
290 transition metal ions and HULIS are expected to play a major role in aqueous-phase formation and
291 interconversion of $\bullet\text{OH}$, $\text{O}_2\bullet^-$ and H_2O_2 (Lloyd et al., 1997;Valavanidis et al., 2000;Zheng et al.,
292 2013;Hayyan et al., 2016;Lakey et al., 2016;Tan et al., 2016;Kuang et al., 2017;Ma et al., 2018;Li et al.,
293 2019).

294 Environmentally persistent free radicals (EPFR), are known to pre-exist in $\text{PM}_{2.5}$ at mass-specific
295 concentration levels of ~ 0.2 to ~ 2 $\text{pmol } \mu\text{g}^{-1}$, which are an order of magnitude higher than the typical mass-
296 specific aqueous-phase radical yields of ~ 0.02 to ~ 0.2 $\text{pmol } \mu\text{g}^{-1}$ (Arangio et al., 2016;Vejerano et al.,
297 2018;Tong et al., 2019;Chen et al., 2020). While some EPFR may be water-insoluble (Chen et al., 2018),
298 others may directly contribute to the C-centered and O-centered radicals trapped by BMPO or participate
299 in redox reactions yielding $\bullet\text{OH}$ and $\text{O}_2\bullet^-$ radicals (Khachatryan et al., 2011;Arangio et al., 2016). The latter
300 have such short chemical lifetimes that they have to be formed upon dissolution of the investigated samples
301 immediately prior to trapping by BMPO.

302 The experiments and data presented in this study provide exploratory perspectives of the pathways of
303 formation and interconversion of reactive species formed by PM_{2.5} in the aqueous-phase, including highly
304 reactive radicals and less reactive reservoir species like H₂O₂ as discussed below. A quantitative assessment,
305 mechanistic elucidation, and full understanding will require comprehensive further experimental
306 investigations and model calculations.

307 **3.2 Yields of aqueous-phase radicals and H₂O₂ from ambient PM_{2.5}**

308 Figure 3 shows the average air volume-specific yields and PM_{2.5} mass-specific yields of aqueous-phase
309 reactive species (RS), including radicals and H₂O₂, plotted against the PM_{2.5} mass concentrations observed
310 during the sampling periods in Hyytiälä, Mainz, and Beijing, respectively. The volume-specific yields refer
311 to the sampled air volume and are given in units of pmol m⁻³. They represent the absolute amounts of RS
312 that are formed when the particulate matter is deposited in an aqueous phase such as cloud water or
313 epithelial lining fluid, where they can contribute to atmospheric multiphase chemistry, oxidative stress and
314 adverse health effect of PM respectively (Lakey et al., 2016; Tong et al., 2018). The mass-specific yields
315 are normalized by the sampled mass of PM_{2.5} and given in units of pmol µg⁻¹. They represent the relative
316 amounts of aqueous RS formed per mass unit PM_{2.5}, enabling a direct comparison of the relative reactivity
317 and aqueous RS-forming potential of the fine particulate matter from different sampling sites.

318 As illustrated in Figure 3a, the PM_{2.5} concentration increased by more than an order of magnitude
319 between the samples from Hyytiälä and Beijing (from ~5 to ~200 µg m⁻³), and the volume-specific yield of
320 aqueous-phase H₂O₂ exhibited a similarly strong increase (from ~10 to ~200 µg m⁻³), while the volume-
321 specific yield of aqueous-phase radicals exhibited a much smaller increase (from ~3 to ~7 pmol m⁻³; Tables
322 S1, S4, and S5). The strong increase of H₂O₂ with increasing PM_{2.5} concentration is consistent with earlier
323 studies identifying a wide range of redox-active organic and inorganic aerosol components that can produce
324 H₂O₂ in the aqueous phase (Gunz and Hoffmann, 1990; Anastasio et al., 1994; Zuo and Deng,
325 1997; Arellanes et al., 2006; Chung et al., 2006; Hua et al., 2008; Möller, 2009; Wang et al., 2010; Wang et al.,
326 2012; Anglada et al., 2015; Herrmann et al., 2015; Lakey et al., 2016; Tong et al., 2018; Bianco et al., 2020).

327 As illustrated in Figure 3b, the average mass-specific yields of aqueous-phase H_2O_2 were similar for the
328 investigated urban and forest $\text{PM}_{2.5}$ samples (around 2-4 $\text{pmol } \mu\text{g}^{-1}$). In contrast, the mass-specific yield of
329 aqueous-phase radicals was highest for the forest samples ($\sim 0.6 \text{ pmol } \mu\text{g}^{-1}$) and decreased steeply with
330 increasing $\text{PM}_{2.5}$ mass concentration for the urban samples ($\sim 0.3 \text{ pmol } \mu\text{g}^{-1}$ for Mainz, $\sim 0.06 \text{ pmol } \mu\text{g}^{-1}$ for
331 Beijing). Accordingly, the relative fraction of radicals compared to H_2O_2 formed and detected in the
332 aqueous phase decreased from 22% for the $\text{PM}_{2.5}$ samples from Hyytiälä to 8% for Mainz and 3% for
333 Beijing. In other words, the aqueous H_2O_2 -forming potential per mass unit of $\text{PM}_{2.5}$ was roughly the same
334 for all investigated samples, whereas the aqueous radical-forming potential varied widely between the
335 different samples.

336 The observed negative correlation with $\text{PM}_{2.5}$ mass concentration suggests that the mass-specific yield
337 of aqueous-phase radicals from fine particulate matter may be influenced by the sample load and level of
338 concentration in aqueous extracts, e.g., through enhanced re-combination of radicals at elevated
339 concentration. Experiments performed at different dilutions, i.e., with varying aqueous extract volumes and
340 concentration levels, however, suggest that observed differences in radical forming potential were not just
341 due to different sample loads but influence by differences in the chemical composition and reactivity of the
342 investigated $\text{PM}_{2.5}$ samples (Figure S1d and S1e). For example, the particularly high mass-specific yields
343 of total radicals and C-centered radicals in the aqueous phase appears associated with particularly high mass
344 fractions of organic matter in $\text{PM}_{2.5}$ from Hyytiälä ($\sim 70\%$, (Jimenez et al., 2009;Maenhaut et al., 2011)).

345 Figure 4 shows how the relative fractions (RF_{spin}) of C-centered radicals and $\bullet\text{OH}$ in the aqueous phase
346 varied with the abundance of HOM, aromatic compounds, and water-soluble transition metal ions in the
347 investigated $\text{PM}_{2.5}$ samples (Hyytiälä and Mainz) or $\text{PM}_{2.5}$ collected at different times (Beijing). As
348 illustrated in Figure 4a, C-centered radicals exhibited a pronounced increase with increasing HOM; whereas
349 $\bullet\text{OH}$ radicals showed a near-linear decrease. The observed increase of C-centered radicals with HOM is
350 consistent with earlier studies indicating that peroxide-containing HOM may play an important role in
351 organic radical formation (Tong et al., 2016a;Tong et al., 2019). In contrast, the C-centered radicals did not

352 exhibit an increase but a decrease with increasing abundance of aromatic compounds (Figure 4b). This is
353 consistent with ability of certain aromatic compounds like quinones and semiquinones to enhance redox
354 cycling and the formation of $\bullet\text{OH}$ radicals in analogy to Fenton reactions (Chung et al., 2006;Zhang and
355 Tao, 2009;Khachatryan et al., 2011;Elser et al., 2016;Fan et al., 2016;Lakey et al., 2016;An et al., 2019).
356 As illustrated in Figure 4c, C-centered radicals exhibited a pronounced decrease with transition metal ions,
357 whereas $\bullet\text{OH}$ radicals exhibited a near-linear increase. These findings are consistent with the role of
358 transition metal ions in Fenton-like reactions efficiently converting H_2O_2 and hydroperoxides into $\bullet\text{OH}$
359 radicals, and with studies reporting that metal-organic interactions may alter the oxidative potential
360 particulate matter under atmospheric and physiological conditions (Zuo and Hoigne, 1992;Lakey et al.,
361 2016;Singh and Gupta, 2016;Cheng et al., 2017;Wang et al., 2018b;Wei et al., 2019;Lin and Yu, 2020). To
362 gain further insights into the complex interactions of organic particulate matter, transition metal ions, and
363 reactive species in the aqueous phase, we performed experiments with laboratory-generated secondary
364 organic aerosols and surrogate mixtures of atmospherically relevant substance classes as detailed in the
365 following sections.

366 **3.3 Aqueous-phase radical yields of laboratory-generated SOA**

367 To investigate the influence of biogenic and anthropogenic secondary organic aerosols (SOA) on aqueous-
368 phase radical formation, we performed experiments with SOA from naphthalene and β -pinene oxidized by
369 O_3 and $\bullet\text{OH}$ in a PAM chamber (Sect. 2.3).

370 As illustrated in Figure 5a, we found a steep non-linear increase of the mass-specific radical yield with
371 increasing precursor mass fraction of β -pinene from $\sim 2 \text{ pmol } \mu\text{g}^{-1}$ for pure naphthalene SOA to $\sim 8 \text{ pmol}$
372 μg^{-1} for pure β -pinene SOA, which is consistent with related earlier investigations that found higher radical
373 yields for biogenic SOA compared to anthropogenic SOA (Tong et al., 2016a;Tong et al., 2017;Tong et al.,
374 2018;Tong et al., 2019).

375 Figure 5b shows that β -pinene SOA mainly generates $\bullet\text{OH}$ ($\sim 86\%$), whereas naphthalene SOA and
376 mixtures of naphthalene and β -pinene SOA mainly generate $\text{O}_2^{\bullet-}$ (60-77%) and C-centered radicals (18-

377 34%). Substantial formation of $O_2^{\bullet-}$ by terpene SOA is consistent with a recent study, showing that $O_2^{\bullet-}$
378 formation via $\bullet OH$ oxidation of primary or secondary alcohols followed by unimolecular decomposition of
379 α -hydroxyperoxyl radicals (Wei et al., 2021). The small RF of $\bullet OH$ generated by naphthalene SOA may
380 appear in contrast to the high RF of $\bullet OH$ generated $PM_{2.5}$ from Beijing that contains substantial amounts of
381 aromatics (Figure 4b). Note, however, that the composition of $PM_{2.5}$ from Beijing is much more complex
382 than that of laboratory-generated naphthalene SOA. For example, Fenton-like reactions of transition metal
383 ions are expected to generate $\bullet OH$ in ambient $PM_{2.5}$ (Kehrer, 2000; Tong et al., 2016a), whereas the
384 laboratory-generated SOA does not contain significant amounts of transition metals.

385 **3.4 Aqueous-phase radical yields of surrogate mixtures**

386 To investigate the influence of different types of redox-active components in $PM_{2.5}$ on the total yield of
387 radicals in the aqueous phase and on the relative fractions (RF_{spin}) of different types of radicals, we
388 performed experiments with aqueous surrogate mixtures of Fe^{2+} , Cu^{2+} , humic acid (HA), fulvic acid (FA),
389 cumene hydroperoxide (CHP), and H_2O_2 in varying concentrations. Figure 6 shows that increasing
390 concentrations of organic hydroperoxide (here CHP) can lead to a near-linear increase of total radical
391 concentration in the aqueous phase (Figure 6a), and to a strong increase of RF_{spin} for C-centered radicals
392 (Figure 6b). The increase of R^{\bullet} with CHP is consistent with the high RF_{spin} for C-centered radicals in $PM_{2.5}$
393 from Hyytiälä (Figure 2b), which contains a large fraction of HOM (Tong et al., 2019). Increasing
394 concentrations of H_2O_2 also led to a near-linear increase of increase of total radical concentration in the
395 aqueous phase (Figure 6c) as well as a strong increase of $\bullet OH$ (Figure 6d). The strong increase of aqueous-
396 phase $\bullet OH$ with H_2O_2 indicates that gas-particle partitioning and multiphase chemical reactions of gas-
397 phase oxidants can substantially influence the generation of radicals and oxidative stress by ambient $PM_{2.5}$.

398 For increasing concentrations of humic acid (HA), we observed a strong non-linear decrease of total
399 radical concentration in the aqueous phase (Figure 6e), and to a strong increase of RF_{spin} for C-centered
400 radicals (Figure 6f). The decreasing radical concentration is likely due to the ability of HA to bind/chelate
401 iron and other metal ions (Graber and Rudich, 2006; Laglera and van den Berg, 2009; Scheinhardt et al.,

402 2013;Tang et al., 2014;Yang et al., 2017), which may lead to a suppression of radical formation via Fenton-
403 like reactions. Moreover, humic substances can act as antioxidants and radical scavengers (Aeschbacher et
404 al., 2012). The fractional increase of C-centered radicals reflects the involvement of HA in complex radical
405 chemistry (Shi et al., 2020). Compared to HA, the effects of fulvic acid (FA) were qualitatively similar but
406 quantitatively less pronounced (Figures. 6g and 6h), which is consistent with earlier studies investigating
407 the metal ion binding capacity and redox chemistry of FA (Wang et al., 1996;Graber and Rudich,
408 2006;Scheinhardt et al., 2013;Tang et al., 2014;Gonzalez et al., 2017;Yang et al., 2017). Different
409 reactivities of HA and FA are also reflected by the different RF values of $O_2^{\cdot-}$ and C-centered radicals
410 observed at high concentrations of FA and HA (Figure 6h vs. Figure 6f) as well as in reactions mixtures
411 with copper instead of iron ions (Figure S6). Further investigations will be required to resolve the
412 underlying reaction mechanisms and kinetics.

413 **4 Conclusions and implications**

414 In this study, we investigated the formation of aqueous-phase H_2O_2 and radicals by aerosol samples from
415 remote forest and polluted urban air. The aqueous H_2O_2 -forming potential per mass unit of $PM_{2.5}$ was
416 roughly the same for all investigated samples, whereas the mass-specific yields of radicals were lower for
417 sampling sites with higher concentration of ambient $PM_{2.5}$.

418 The abundances of water-soluble transition metals in ambient $PM_{2.5}$ were positively correlated with the
419 relative fraction of $\cdot OH$ and negatively correlated with the relative fraction of carbon-centered radicals,
420 which can be attributed to Fenton-like reactions. In contrast, HOM was negatively correlated with the
421 relative fraction of $\cdot OH$ and positively correlated with the relative fraction of carbon-centered radicals,
422 which is consistent with related earlier studies indicating that peroxide-containing HOM may play an
423 important role in organic radical formation (Tong et al., 2016a;Tong et al., 2019).

424 We found that the relative fractions of different types of radicals formed by ambient $PM_{2.5}$ were
425 comparable to surrogate mixtures comprising transition metal ions, organic hydroperoxide, H_2O_2 , and
426 humic or fulvic acids. Our results show that the interplay of transition metal ions (e.g., iron and copper

427 ions), highly oxidized organic molecules (e.g., hydroperoxides), and complexing or scavenging agents (e.g.,
428 humic or fulvic acids) leads to non-linear concentration dependencies in the aqueous-phase RS production.
429 A strong dependence on chemical composition was also observed for the aqueous-phase radical yields of
430 laboratory-generated SOA from precursor mixtures of naphthalene and β -pinene.

431 Overall, our findings show how the composition of $PM_{2.5}$ can influence the amount and nature of
432 aqueous-phase RS, which may explain differences in the chemical reactivity and health effects of particulate
433 matter in clean and polluted air. Further investigations will be required to resolve the influence of biogenic
434 and anthropogenic pollutants on atmospheric chemistry, air quality, and public health in the Anthropocene
435 (Pöschl and Shiraiwa, 2015; Cheng et al., 2016; Shiraiwa et al., 2017; An et al., 2019; Roldin et al.,
436 2019; Daellenbach et al., 2020; Fang et al., 2020; Lelieveld et al., 2020; Lin and Yu, 2020; Pöschl, 2020; Su et
437 al., 2020; Tao et al., 2020; Yun et al., 2020; Zheng et al., 2020; Wang et al., 2021).

853 ***Data availability***

854 The dataset for this paper is available upon request from the corresponding author (h.tong@mpic.de).

855 ***Supporting Information***

856 Supporting material consists of seven figures and five tables.

857 ***Author contributions***

858 HT and UP designed the experiment and wrote up the original draft together with FL. CX, SY, and HK
859 involved in the collection of ambient particles. HT, FL, AF, and YZ participated in laboratory
860 measurements and data analysis. All other co-authors participated in results discussion and manuscript
861 editing.

862 ***AUTHOR INFORMATION***

876 This work was funded by the Max Planck Society, ACTRIS, ECAC, the Finnish Centre of Excellence under
877 Academy of Finland (projects no. 307331 and 272041), and PolyU (P0036313). Siegfried Herrmann and
878 Steve Galer from Climate Geochemistry Department of Max Planck Institute for Chemistry are gratefully
879 acknowledged for ICP-MS analysis. Technical staffs at SMEARII station are acknowledged for the
880 impactor maintenance. MS acknowledges funding from the National Science Foundation (CHE-1808125).

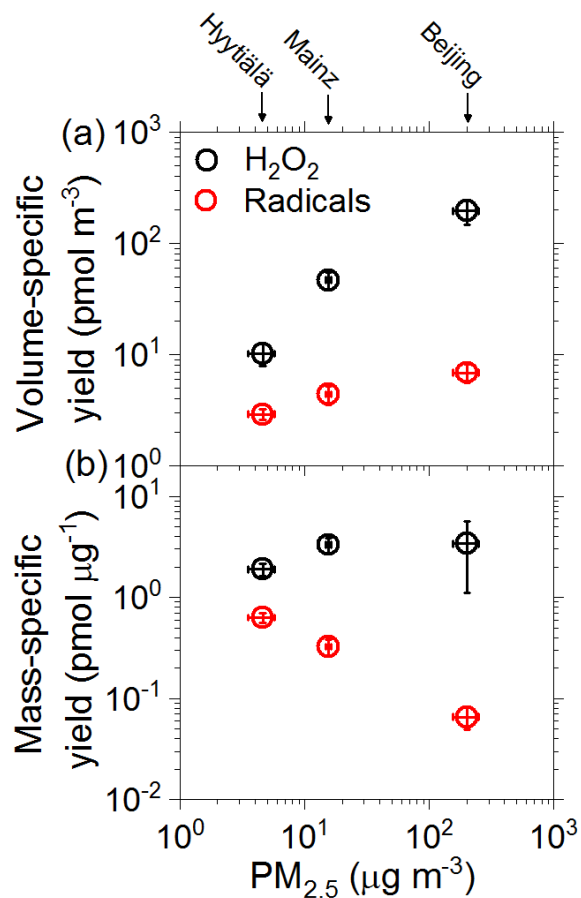

881

882 **Figure 1.** Schematic illustration of research approach and comparison of aqueous-phase reactive species
 883 (RS) formed in aqueous extracts of ambient fine particulate matter (PM_{2.5}), and laboratory generated
 884 secondary organic aerosols (SOA), and surrogate mixtures. ROOH: organic hydroperoxide. HA: humic
 885 acid. FA: fulvic acid. R[•] and RO[•]: C- and O-centered organic radicals, respectively.

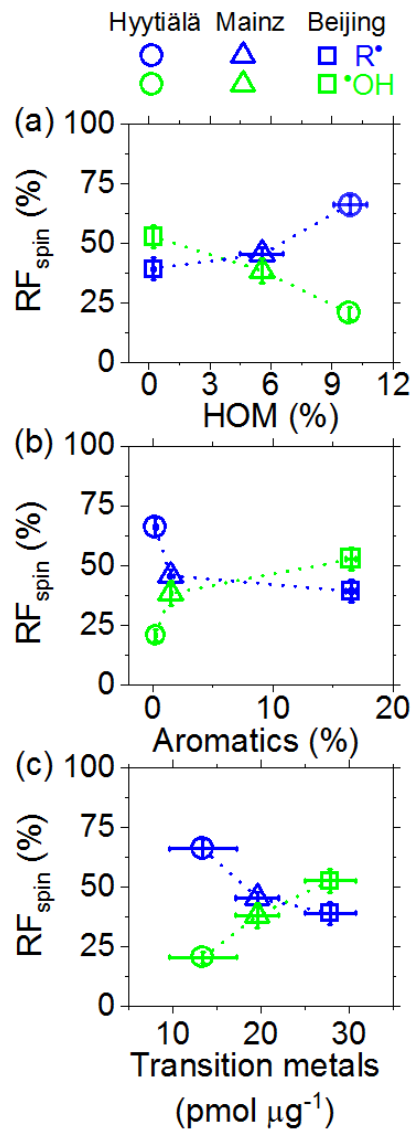

886

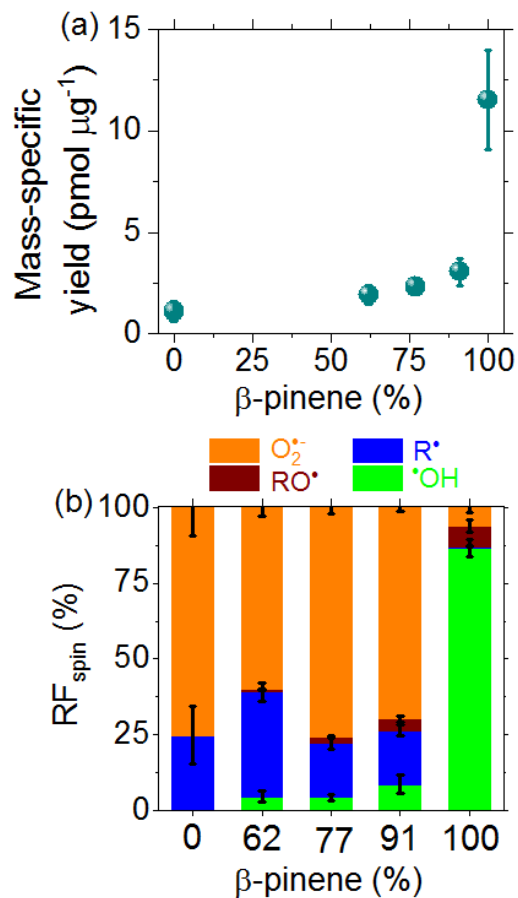

887 **Figure 2.** (a) Electron paramagnetic resonance (EPR) spectra and (b) relative fraction of unpaired electrons
 888 (RF_{spin}) attributed to different types of radicals formed in aqueous extracts of ambient $PM_{2.5}$ from Hyytiälä,
 889 Mainz, and Beijing. Dotted vertical lines in (a) indicate peak positions of different radical adducts. The
 890 spectra intensity in (a), RF_{spin} values and error bars in (b) represent arithmetic mean values and standard
 891 error (6-13 samples per location).

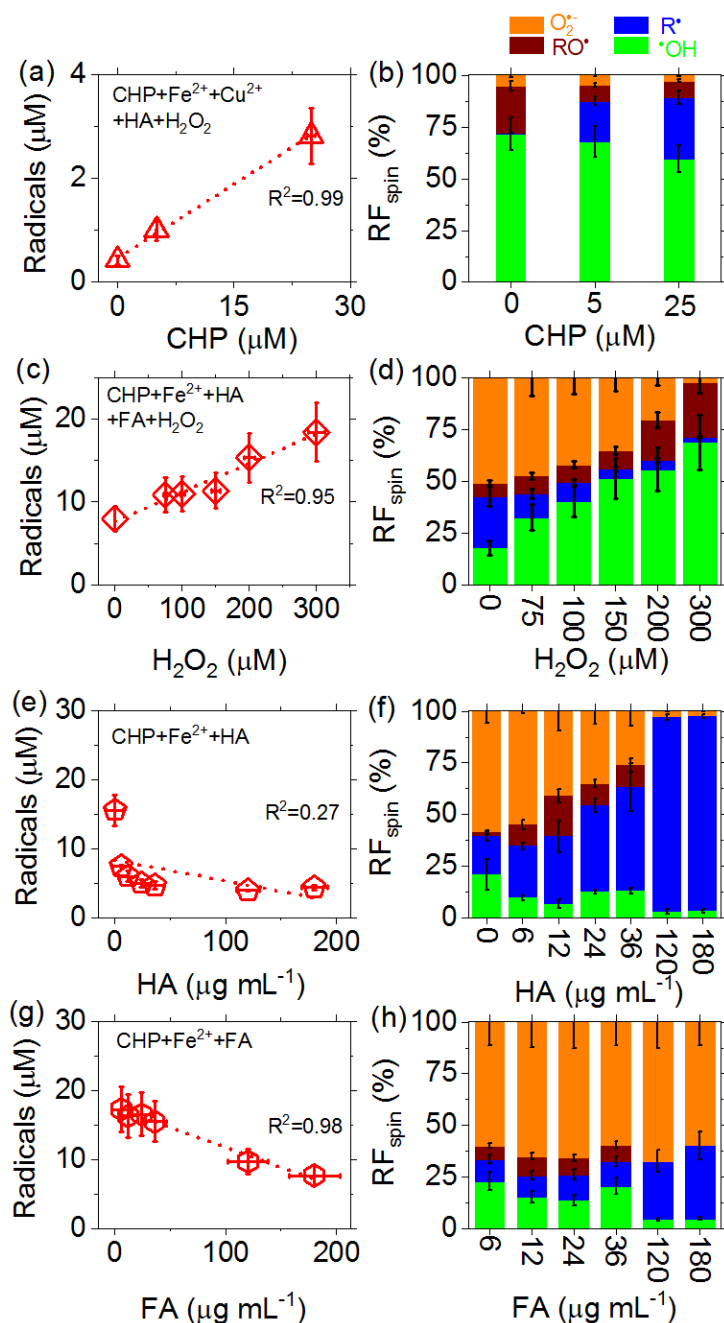

892
 893 **Figure 3.** (a) Air sample volume-specific yields and (b) mass-specific yields of aqueous-phase radicals (○) and H₂O₂ (○) formed in aqueous extracts of ambient PM_{2.5} from Hyytiälä, Mainz, and Beijing. plotted
 894 against PM_{2.5} mass concentration. The error bars represent standard errors of the mean (4-12 samples per
 895 location).
 896

897
 898 **Figure 4.** Relative fraction (RF_{spin}) of aqueous-phase C-centered (R^*) and $\bullet OH$ radicals plotted against the
 899 relative abundance of (a) highly oxygenated organic molecules (HOM), (b) aromatics, and (c) water-soluble
 900 transition metals in ambient $PM_{2.5}$ from Hyytiälä, Mainz, and Beijing. The relative abundances of HOM
 901 and aromatics in (a-b) represent the sum chromatographic area of HOM or aromatics divided by the sum
 902 chromatographic area of all assigned organic compounds. The abundances of HOM in (a) were adopted
 903 from a recent companion study (Tong et al., 2019). The error bars represent standard errors of the mean (4
 904 to 12 samples per location). The dashed lines are to guide the eye.

905
 906 **Figure 5.** (a) Mass-specific yields and (b) relative fractions (RF_{spin}) of different types of radicals formed
 907 upon aqueous extraction of laboratory-generated SOA from precursor mixtures of β -pinene and naphthalene
 908 plotted against the mass fraction of β -pinene (%) in the precursor mixture. The error bars represent standard
 909 errors (4-6 samples per data point).

910
 911 **Figure 6.** (a, c, e, g) Total concentrations and (b, d, f, h) relative fractions (RF_{spin}) of different types of
 912 radicals (spins) observed in aqueous mixtures of Fe²⁺, Cu²⁺, humic acid (HA), fulvic acid (FA), cumene
 913 hydroperoxide (CHP), and H₂O₂, serving as surrogate species for redox-active components of PM_{2.5}. (a, b):
 914 0-25 μM CHP, 43 μM Fe²⁺, 3 μM Cu²⁺, 4 μg mL⁻¹ HA, 7 μM H₂O₂ (CHP+Fe²⁺+Cu²⁺+HA+H₂O₂). (c, d):
 915 CHP: 100 μM. Fe²⁺: 300 μM. HA: 100 μg mL⁻¹. FA: 80 μg mL⁻¹. H₂O₂: 0-300 μM. (e, f): 100 μM CHP,
 916 300 μM Fe²⁺, 0-180 μg mL⁻¹ HA (CHP+Fe²⁺+HA). (g, h): 100 μM CHP, 300 μM Fe²⁺, 6-180 μg mL⁻¹ FA
 917 (CHP+Fe²⁺+FA). The error bars represent the uncertainties of EPR signal integration (y-axis) and solute
 918 concentration (x-axis), respectively.
