17    **Abstract:**

18    Land surface emissions are an important source of atmospheric total gaseous mercury (TGM),  
19    however, its role on the variations of TGM isotopic compositions and concentrations has not been  
20    properly evaluated. In this study, TGM isotope compositions, a powerful tracer for sources and  
21    transformation of Hg, were measured at ten urban sites and one rural site in China. TGM  
22    concentrations were higher in summer than in winter in most cities except in Guiyang and  
23    Guangzhou in the low latitudes. The summertime high TGM concentrations were coincided with  
24    prevailing low TGM  $\delta^{202}\text{Hg}$  and high TGM  $\Delta^{199}\text{Hg}$  signatures. These seasonal patterns were in  
25    contrast with those typically observed in rural areas in the Northern Hemisphere, suggesting  
26    atmospheric oxidation chemistry, vegetation activity as well as residential coal combustion were not  
27    likely the dominant mechanisms contributing to the TGM concentration and isotopic composition  
28    seasonality in Chinese cities. The amplitudes of seasonal variations in TGM concentrations and  
29     $\Delta^{199}\text{Hg}$  (or TGM  $\delta^{202}\text{Hg}$ ) were significantly positively (or negatively) correlated with that of the  
30    simulated soil GEM emission flux. These results suggest that the seasonal variations in TGM  
31    isotopic compositions and concentrations in the ten Chinese cities were likely controlled by land  
32    surface emissions that were observed or reported with highly negative  $\delta^{202}\text{Hg}$  signatures.

33  
34    **1. Introduction**

35    Mercury (Hg) is a toxic heavy metal pollutant of global concerns for ecological and human  
36    health. Hg in the atmosphere includes three major forms: gaseous elemental mercury (GEM),  
37    gaseous oxidized mercury (GOM), and particulate bound mercury (PBM). According to global Hg  
38    models, GEM is the dominant form of total gaseous mercury (TGM = GEM + GOM, 88.8~92.9%)  
39    and total Hg (88.8~92.8%) in the troposphere (Selin et al., 2007; Holmes et al., 2010; Horowitz et  
40    al., 2017), and the fraction of GEM in total atmospheric Hg is thought to be much higher in the  
41    planetary boundary layer (PBL) (e.g., on average >95%) than that in the free troposphere  
42    (Swartzendruber et al., 2009; Lyman and Jaffe, 2012; Shah et al., 2016). GEM has a long  
43    atmospheric residence time and can transport globally through the atmosphere (Obrist et al., 2018).  
44    GEM can be deposited onto earth's surface by dry deposition or atmospheric oxidation followed by  
45    wet and dry deposition. Once deposited, it could be transformed to methylmercury and subsequently  
46    bio-accumulated in the food web, posing a threat to human health and the environment (Obrist et  
47    al., 2018). GEM in the atmosphere can be derived from primary anthropogenic, natural and legacy  
48    emissions. Land surface emissions are an important source of atmospheric GEM. Total GEM  
49    emissions from global land surfaces, although not well constrained, are estimated to range from 600  
50    to 2000 Mg/yr, which are in the similar magnitude as the global primary anthropogenic GEM  
51    emissions (Selin et al., 2007; Holmes et al., 2010; Pirrone et al., 2010; Agnan et al., 2016). However,  
52    to what extent the land surface emissions can contribute to the variations of GEM at local, regional,  
53    and global scales has not been well understood.

55 TGM or GEM concentrations in urban areas are generally elevated as compared to rural areas  
56 (Fu et al., 2015; Mao et al., 2016), which could be attributed to strong Hg emissions from primary  
57 anthropogenic sources, urban surfaces (soil, pavement, building surface, dominantly referred to as  
58 “legacy” emissions), and indoor Hg-containing products (Carpi and Chen, 2001; Feng et al., 2005;  
59 Eckley and Branfireun, 2008; Rutter et al., 2009). A previous study in Mexico City, Mexico, based  
60 on pollution rose and Concentration Field Analysis (CFA), suggested that highly elevated GEM  
61 concentrations (mean = 7.2 ng m<sup>-3</sup>) were dominantly (81%) attributed to anthropogenic sources  
62 (Rutter et al., 2009). The large percentage of anthropogenic source contributions, however, might  
63 have been supplemented by volcanic emissions and re-emission of Hg previously deposited to urban  
64 surfaces in anthropogenic source regions (Rutter et al., 2009). On the other hand, TGM  
65 concentrations in New York, USA (mean = 3.90 ng m<sup>-3</sup>) and Nanjing, China (mean = 7.9 ng m<sup>-3</sup>)  
66 were observed to be positively correlated with air temperature and/or the intensity of solar radiation,  
67 implying that land surfaces emissions contributed to elevated TGM levels (Carpi and Chen, 2002;  
68 Zhu et al., 2012). This hypothesis has not considered the atmospheric transport patterns and  
69 temporal variations in anthropogenic emissions at local and regional scales and needs to be further  
70 validated. GOM is a potential proxy of anthropogenic sources. However, GOM has a short  
71 atmospheric residence time and could be also produced via in situ oxidation of GEM, making it  
72 challenging to identify the contributions of anthropogenic source to TGM or GEM in many urban  
73 areas using GOM observations (Lynam and Keeler, 2005; Peterson et al., 2009; Rutter et al., 2009).  
74 Relative contributions from specific sources in urban areas could be also assessed by development  
75 of TGM or GEM emission inventories of different source categories. For example, total GEM  
76 emissions from soils in Guiyang, China were scaled up based on an empirical model and were in  
77 the similar magnitude as that from anthropogenic sources (Feng et al., 2005). Such approaches,  
78 however, are very limited in many urban areas in China and other countries worldwide. Therefore,  
79 the understanding of the sources of TGM or GEM in urban areas is essentially limited and there is  
80 a need to develop an additional tracer to identify the controls of specific sources on the variations  
81 of TGM or GEM in urban areas.

82 Hg stable isotope is a rapidly growing tool for studying the biogeochemical cycle of Hg in the  
83 environments (Blum and Johnson, 2017). Hg isotopes in surface-earth system can undergo both  
84 mass-dependent fractionation (MDF,  $\delta^{202}\text{Hg}$  signature) and mass-independent fractionation (MIF,  
85  $\Delta^{199}\text{Hg}$ ,  $\Delta^{201}\text{Hg}$  and  $\Delta^{200}\text{Hg}$  signatures), which might be caused by specific or multiple sources and  
86 transformation processes (Blum et al., 2014). [Previous studies found that Chinese coal-fired power](#)  
87 [plants \(CFPP\) emitted GEM with slightly negative  \$\delta^{202}\text{Hg}\$  \(mean = -0.26‰\) and significantly](#)  
88 [negative  \$\Delta^{199}\text{Hg}\$  \(mean = -0.26‰\) values \(Tang et al., 2017; Liu et al., 2019a\)](#). Based on the  
89 observed isotopic compositions of global source materials, fractionation of Hg isotopes during

90 industrial processes, and global Hg emission inventory, Sun et al. (2016b) predicted a mean  $\delta^{202}\text{Hg}$   
91 of  $-0.59\text{\textperthousand}$  and a mean  $\Delta^{199}\text{Hg}$  of  $-0.02\text{\textperthousand}$  for the global primary anthropogenic GEM emissions in  
92 2010. On the other hand, isotopic compositions of indoor GEM and GEM emitted from urban  
93 building surface were characterized by highly negative  $\delta^{202}\text{Hg}$  (means =  $-1.54$  to  $-1.56\text{\textperthousand}$ ,  $n = 2$ ) and  
94 near-zero to slightly positive  $\Delta^{199}\text{Hg}$  values (means =  $0.00$  to  $0.17\text{\textperthousand}$ ,  $n = 2$ ) (Jiskra et al., 2019a).  
95 Isotopic compositions of GEM emitted from urban soils currently remain unknown. Global Hg  
96 isotope models proposed this source would have highly negative  $\delta^{202}\text{Hg}$  (e.g.,  $\sim-3.0\text{\textperthousand}$ ) and positive  
97  $\Delta^{199}\text{Hg}$  signatures (e.g.,  $\sim 1.7\text{\textperthousand}$ ) (Sonke, 2011; Sun et al., 2019). Therefore, GEM emitted from  
98 anthropogenic sources is probably isotopically distinguishable from that emitted from land surfaces  
99 and indoor Hg-containing products, which provide an useful tracer for identification of TGM or  
100 GEM sources in urban areas.

101 Previous studies have measured the isotopic compositions of TGM or GEM at many rural and  
102 fewer urbanized sites in the Northern Hemisphere (Gratz et al., 2010; Sherman et al., 2010; Demers  
103 et al., 2013; Demers et al., 2015; Enrico et al., 2016; Fu et al., 2016; Yu et al., 2016; Obrist et al.,  
104 2017; Xu et al., 2017; Fu et al., 2018; Fu et al., 2019; Jiskra et al., 2019a; Jiskra et al., 2019b).  
105 According to these studies, TGM or GEM isotopic compositions in urban areas showed a mean  
106  $\delta^{202}\text{Hg}$  of  $0.49 \pm 0.28\text{\textperthousand}$  and a mean  $\Delta^{199}\text{Hg}$  of  $0.02 \pm 0.04\text{\textperthousand}$  ( $1\sigma$ ,  $n = 4$ ), which were much lower  
107 and higher, respectively, than the mean values observed in rural areas (mean  $\delta^{202}\text{Hg} = 0.56 \pm 0.45\text{\textperthousand}$ ,  
108 mean  $\Delta^{199}\text{Hg} = -0.18 \pm 0.06\text{\textperthousand}$ ,  $1\sigma$ ,  $n = 10$ ). The lower TGM  $\delta^{202}\text{Hg}$  and higher  $\Delta^{199}\text{Hg}$  signatures  
109 in urban areas relative to rural areas were previously hypothesized to be mainly related to primary  
110 anthropogenic emissions, whereas the effect of emission and re-emission of GEM from urban  
111 surfaces was frequently neglected mainly because of the strong primary anthropogenic Hg  
112 emissions and poor understanding of emission flux and isotopic signatures of GEM from land  
113 surfaces in urban areas. It should be noted that many observational TGM  $\delta^{202}\text{Hg}$  values in urban  
114 areas (e.g., Beijing and Guiyang of China) or in urbanized and industrial plumes were far more  
115 negative than that estimated for anthropogenic emissions ( $-0.59\text{\textperthousand}$ ) (Sun et al., 2016b; Yu et al.,  
116 2016; Fu et al., 2018). This indicates that primary anthropogenic emissions were not the exclusive  
117 explanation for the highly negative TGM  $\delta^{202}\text{Hg}$  signatures in the urban atmosphere.

118 In this study, TGM concentrations and isotopic compositions were measured in ten Chinese  
119 cities in summer and winter 2018, providing a unique opportunity for studying the spatial and  
120 seasonal variations in TGM concentrations and isotopic compositions in urban areas of China.  
121 Isotopic compositions of GEM emitted from soils were also measured in two Chinese cities, and  
122 together with data in literature were used to investigate the role of land surface emissions in the  
123 seasonal and spatial variations in TGM concentrations and isotopic compositions in major Chinese  
124 cities. The findings in this study are helpful for a better understanding of the sources of atmospheric

125 TGM in urban areas of China, and knowledge gained emphasizes the need to mitigate surface Hg  
126 emissions during implementation of the Minamata Convention.

127 **2. Methods**

128 **2.1 Study sites**

129 Ten cities including Beijing, Shijiazhuang, Jinan in northern China, Lanzhou in northwestern  
130 China, Zhengzhou and Wuhan in central China, Shanghai in eastern China, Chengdu and Guiyang  
131 in southwestern China, and Guangzhou in southern China were selected for measuring TGM  
132 concentrations and isotopic compositions (Figure S1). These cities are located in different  
133 geographical regions of China, which were potentially characterized by specific source emission  
134 patterns, climate, and atmospheric chemistry. The designated investigations in these cities may  
135 therefore provide a comprehensive information on the variations of TGM concentrations and  
136 isotopic compositions in mega cities of China, and help to explore the major factors influencing the  
137 atmospheric Hg in Chinese cities. Site locations, information of the ten cities, and sampling periods  
138 are given in Table S1. Briefly, these cities have populations of 3.75 to 21.54 million in urban areas.  
139 Fractions of the urban and buildup land area out of the total land area of a  $1^\circ \times 1^\circ$  grid surrounding  
140 the sampling sites ranged from 4.9% to 41.1% (mean = 22.5%), whereas the remaining land surfaces  
141 are mainly croplands, barren lands, open grassland, open shrublands, and open forests (range from  
142 35.6% to 82.3% with a mean of 57.5%) (Figure S2 and Table S1). In each of the ten cities, one  
143 sampling site was selected for measuring TGM concentrations and isotopic compositions. The  
144 sampling sites are generally located in heavily commercial and residential areas in all the cities and  
145 with no major industrial Hg emission sources within 2 km of the sampling sites. All the  
146 measurements were conducted on building roofs at elevations of  $>10$  m. In order to investigate the  
147 shift of GEM isotopic compositions in urban areas relative to that in remote areas due to local  
148 urbanized emissions, a same type of measurements was also conducted at the rural Waliguan  
149 Baseline Observatory in northwestern China (Mt. Waliguan), which belongs to the World  
150 Meteorological Organization's (WMO) Global Atmospheric Watch (GAW) network (Figure S1).

151 **2.2 Sampling of TGM**

152 In this study, chlorine-impregnated activated carbon (CLC, 0.5 g) traps were used to collect  
153 atmospheric TGM samples (Fu et al., 2014). A schematic diagram of the sampling system is shown  
154 in Figure S3. Briefly, particles in ambient air were firstly removed using a Teflon filter (47 mm  
155 diameter;  $0.2 \mu\text{m}$  pore size) at the inlet of the sampling system, and then ambient TGM were trapped  
156 onto the CLC traps at a flow rate of  $\sim 2.5 \text{ L min}^{-1}$  using a Teflon coated Mini diaphragm vacuum  
157 pump (N89 KTDC, KNF Inc.). The sampling flow rate was adjusted using a needle valve installed  
158 at the outlet of the vacuum pump. The inlet of the sampling system was about 1.5 m above surface  
159 ground. Daily (24 h) continuous sampling of TGM at each urban site lasted for approximately one

160 week in the winter and summer of 2018, respectively (Daily samples, Table S1). The wintertime  
161 samplings were conducted from 5 to 15 January 2018 simultaneously in Beijing, Shijiazhuang, Jinan,  
162 Lanzhou, and Zhengzhou, and from 18 to 27 January 2018 simultaneously in Shanghai, Chengdu,  
163 Wuhan, Guiyang, and Guangzhou. The summertime samplings were conducted from 29 June to 7  
164 July 2018 simultaneously in Shijiazhuang, Jinan, Zhengzhou, Guiyang, and Guangzhou, and from  
165 27 July to 10 August 2018 simultaneously in Beijing, Lanzhou, Shanghai, Wuhan, and Chengdu.  
166 TGM samples were also continuously collected from 19 November 2014 to 19 February 2015 at Mt.  
167 Waliguan with a sampling duration of 10 day. After field sampling, CLC traps were sealed carefully  
168 and kept in sealed polypropylene crisper before sample processing for Hg isotope analysis.

169 GOM concentrations are generally elevated in Chinese urban areas due to local primary  
170 anthropogenic emissions (Fu et al., 2015). Previous studies showed that GOM measured using  
171 Tekran 2537/1130/1135 system on average accounted for 0.37 to 0.50% of TGM in Guiyang, Beijing,  
172 and Shanghai, China, while the daily GOM fractions in TGM ranged from 0.04 to 1.58% in Guiyang  
173 (Table S2) (Fu et al., 2011; Duan et al., 2017; Zhang et al., 2019). It is likely that the Tekran system  
174 could underestimate GOM concentrations by approximately 3-fold with respect to that measured by  
175 other recently developed methods (e.g., cation exchange membranes (CEM) or nylon membranes)  
176 (Huang et al., 2013; Gustin et al., 2015; Gustin et al., 2019). To date, GOM has not been measured  
177 by CEM or nylon membranes in Chinese urban areas. If adjusting GOM concentrations by a factor  
178 of 3, the above-mentioned mean GOM fractions would be increased to 1.1-1.5% in Guiyang, Beijing,  
179 and Shanghai, and these values are similar to those observed in Reno, Nevada, USA based on the  
180 CEM method (mean GOM fraction of 2.7%) (Gustin et al., 2019). Mean  $\delta^{202}\text{Hg}$  and  $\Delta^{199}\text{Hg}$  of TGM  
181 in urban areas of this study ranged from -0.96 to -0.24‰ and -0.12 to -0.01‰, respectively.  
182 Assuming that the isotope composition of GOM resemble those of primary anthropogenic emissions  
183 (e.g.,  $\delta^{202}\text{Hg} = -0.77\text{\textperthousand}$ ,  $\Delta^{199}\text{Hg} = -0.06\text{\textperthousand}$ ) (Sun et al., 2016b), a maximum GOM fraction of TGM  
184 (5%) would lead to negligible shifts in TGM  $\delta^{202}\text{Hg}$  (-0.03 to 0.01‰) and  $\Delta^{199}\text{Hg}$  (-0.003 to  
185 0.003‰). Therefore, TGM isotopic composition measured in this study would not be biased  
186 significantly by GOM compounds. The interchange use of the terms “TGM” or ‘GEM’ in this and  
187 previous studies would not confound significantly the intercomparison of isotopic composition.

### 188 2.3 Sample processing and TGM analysis

189 Before the analysis of Hg concentration and isotopic composition, TGM collected on CLC  
190 traps were preconcentrated into 5 mL of 2HNO<sub>3</sub>/1HCl mixed acid solution (40%) following  
191 previous studies (Biswas et al., 2008; Sun et al., 2013; Fu et al., 2014). Trapping solution Hg  
192 concentrations were measured by Tekran 2500 Hg analyzer following US EPA Method 1631  
193 (USEPA, 2002). TGM concentrations of the samples were calculated using Eq. (1):

$$194 \text{TGM} = \frac{C \times V_{\text{solution}}}{V_{\text{gas}}} \quad (1)$$

195 where TGM is the atmospheric TGM concentration in  $\text{ng m}^{-3}$ ,  $C$  is the Hg concentration in trap  
 196 solution in  $\text{ng mL}^{-1}$ ,  $V_{\text{solution}}$  is the volume of trap solution in mL, and  $V_{\text{gas}}$  is the cumulative sampling  
 197 air volume in  $\text{m}^3$ . Full procedural blanks of field sampling and preconcentration were measured at  
 198 each sampling site and in each season by combustion of sealed field CLC traps (containing 0.5 g  
 199 CLC) prepared before field sampling. The mean Hg concentration in these sealed field blanks was  
 200  $0.20 \pm 0.09 \text{ ng}$  ( $1\sigma$ ,  $n = 27$ , Table S3), which was negligible (<5%) compared to the Hg in trapping  
 201 solutions of samples. Breakthrough tests showed that 96.7 to 99.6% (mean =  $98.9 \pm 0.9\%$ ,  $1\sigma$ ,  $n =$   
 202 10) of TGM in ambient air could be collected by the CLC traps in our experiment setting (Table S3).  
 203 Recoveries of the preconcentration were tested by combustion of Lichen CRM (BCR 482), which  
 204 showed a mean value of  $92.5 \pm 3.9\%$  ( $1\sigma$ ,  $n = 6$ , Table S3). Standard additions of  $\text{Hg}^0$  vapor (5 to  
 205 25 ng, produced by  $\text{SnCl}_2$  reduction of diluted NIST 3133 solutions) to CLC traps at the  $2.5 \text{ L min}^{-1}$   
 206 sampling flow rate showed a mean recovery of  $93.2 \pm 11.8\%$  ( $1\sigma$ ,  $n = 11$ , Table S3) for the sampling  
 207 and preconcentration method. These tests indicate that the above method is reliable and efficient for  
 208 measuring TGM concentrations and isotopic compositions.

## 209 2.4 TGM isotope analysis

210 Prior to isotope analysis, the concentrations of Hg in trap solution were diluted to 0.5 or 1.0 ng  
 211  $\text{mL}^{-1}$  using the  $2\text{HNO}_3/1\text{HCl}$  mixed acid solution (20%). Isotope ratios of Hg in diluted trap  
 212 solutions were measured by cold vapor-multicollector inductively coupled plasma mass  
 213 spectrometry (CV-MC-ICPMS) using a Nu Plasma (Nu Instruments) and a Neptune (Thermo Fisher  
 214 Scientific) in the Institute of Geochemistry, CAS (Guiyang, China) (Fu et al., 2019). TGM Isotopic  
 215 compositions were calculated following Equation (2) and (3) (Blum and Bergquist, 2007):

$$216 \quad \delta^{xxx}\text{Hg}_{\text{TGM}}(\text{\textperthousand}) = \left[ \frac{\left( \frac{^{xxx}\text{Hg}}{^{198}\text{Hg}} \right)_{\text{sample}}}{\left( \frac{^{xxx}\text{Hg}}{^{198}\text{Hg}} \right)_{\text{NIST 3133}}} - 1 \right] \times 1000 \quad (2)$$

217 where  $\delta^{xxx}\text{Hg}_{\text{TGM}}$  are the MDF signatures of TGM in per mil (‰),  $xxx$  is the mass number of Hg  
 218 isotopes (199, 200, 201, 202, and 204),  $(^{xxx}\text{Hg}/^{198}\text{Hg})_{\text{sample}}$  is the isotope ratios for TGM samples,  
 219 and  $(^{xxx}\text{Hg}/^{198}\text{Hg})_{\text{NIST 3133}}$  is the isotope ratios for the bracketing NIST 3133 standard (concentrations  
 220 matched within 10% of the sample trapping solution Hg concentrations).

$$221 \quad \Delta^{xxx}\text{Hg}_{\text{TGM}}(\text{\textperthousand}) = \delta^{xxx}\text{Hg}_{\text{TGM}} - \beta \times \delta^{202}\text{Hg}_{\text{TGM}} \quad (3)$$

222 Where  $\Delta^{xxx}\text{Hg}_{\text{TGM}}$  are the MIF signatures of TGM isotopes  $^{199}\text{Hg}$ ,  $^{200}\text{Hg}$ ,  $^{201}\text{Hg}$ , and  $^{204}\text{Hg}$  in per mil  
 223 (‰), and  $\beta$  values are 0.252, 0.5024, 0.752, and 1.493 for isotopes  $^{199}\text{Hg}$ ,  $^{200}\text{Hg}$ ,  $^{201}\text{Hg}$ , and  $^{204}\text{Hg}$ ,  
 224 respectively (Blum and Bergquist, 2007).

225 Isotopic compositions of NIST 3177 Hg standard ( $n = 30$ ), Lichen CRM (BCR 482,  $n = 6$ ), and  
226 standard additions of NIST 3133 Hg to CLC traps ( $n = 11$ ) (Table S3) were analyzed periodically  
227 during TGM isotope analysis, and the results were consistent with previously reported values or the  
228 original values of the NIST 3133 Hg standard (Table S3) (Enrico et al., 2016; Sun et al., 2016a;  
229 Blum and Johnson, 2017). In the present study, we report the analytical uncertainties ( $2\sigma$ ) of TGM  
230 isotopic compositions as the  $2\sigma$  values of the sample replicates when they are higher than the  $2\sigma$   
231 values of standard addition of NIST 3133 Hg to CLC traps. When the  $2\sigma$  values of the sample  
232 replicates were lower than the standard additions of NIST 3133 Hg to CLC traps,  $2\sigma$  values of the  
233 standard additions of NIST 3133 Hg to CLC traps were used to represent the  $2\sigma$  of TGM isotopic  
234 compositions.

235

## 236 **2.5 Ancillary Parameters and statistical methods**

237 Data for concentrations of ozone ( $O_3$ ) and carbon monoxide (CO) during the sampling periods  
238 were extracted from national air quality monitoring stations (<http://106.37.208.233:20035/>) located  
239 within 1.5 km of the sites, with the exception of the sampling site in Guangzhou (4.1 km).  
240 Normalized difference vegetation index (NDVI) around the sampling sites ( $1^\circ \times 1^\circ$ ) was obtained  
241 from the NASA Earth Observations (NEO, <https://neo.sci.gsfc.nasa.gov/>).

242 In order to investigate the effect of soil emissions on the variations in TGM concentrations and  
243 isotopic compositions, GEM exchange flux between soil and atmosphere at  $1^\circ \times 1^\circ$  resolution at  
244 each sampling site in July and January were extracted from the gridded land surface emission  
245 inventory in China simulated for 2013, which has a spatial resolution of  $\sim 36$  km and a monthly  
246 temporal resolution (Figure S1) (Wang et al., 2016). This model established a new scheme for  
247 estimating soil-atmosphere GEM flux which have taken account the effect of photochemical and  
248 nonphotochemical reduction of Hg(II) in soil, diffusion of  $Hg^0$  from soil to atmosphere, as well as  
249 the temperature, moisture, organic matter contents, PH, Hg concentration, bulk density, and land  
250 cover of soils, etc. [more details in Wang et al., 2016]. Note that the simulated surface emission  
251 inventory does not include GEM emissions from pavement, building surface and indoor Hg-  
252 containing products. These sources are in close proximity to the sampling sites (Figure S2), and  
253 their effect is also interpreted in Section 3.4.

254 Daily isotopic compositions of GEM emitted from hillslope barren soil in Guiyang ( $114.269^\circ$   
255 E,  $30.488^\circ$  N) and from agricultural soil in Wuhan ( $114.269^\circ$  E,  $30.488^\circ$  N) from 29 July to 3 August  
256 2019 and from 24 to 27 August 2019, respectively, by measuring the GEM isotopic compositions at  
257 the inlet and outlet of a dynamic flux chamber, followed by a calculation based on the binary mixing  
258 model (Eq. 4 and 5):

$$259 \delta^{xxx}GEM_{emission} = (\delta^{xxx}GEM_{outlet} \times GEM_{outlet} - \delta^{xxx}GEM_{inlet} \times GEM_{inlet}) \div (GEM_{outlet} - GEM_{inlet}) \quad (4)$$

260  $\Delta^{xxx}\text{GEM}_{\text{emission}} = (\Delta^{xxx}\text{GEM}_{\text{outlet}} \times \text{GEM}_{\text{outlet}} - \Delta^{xxx}\text{GEM}_{\text{inlet}} \times \text{GEM}_{\text{inlet}}) \div (\text{GEM}_{\text{outlet}} - \text{GEM}_{\text{inlet}})$  (5)

261 where  $xxx$  corresponds to the mass number of Hg isotopes (199, 200, 201, 202 (not for MIF  
262 signature), and 204),  $\delta^{xxx}\text{GEM}_{\text{outlet}}$  and  $\Delta^{xxx}\text{GEM}_{\text{outlet}}$  are the MDF and MIF values of GEM at the  
263 outlet, respectively,  $\delta^{xxx}\text{GEM}_{\text{inlet}}$  and  $\Delta^{xxx}\text{GEM}_{\text{inlet}}$  are the MDF and MIF values of GEM at the inlet,  
264 respectively, and  $\text{GEM}_{\text{outlet}}$  and  $\text{GEM}_{\text{inlet}}$  are the GEM concentrations measured at the outlet and  
265 inlet, respectively.

266 Linear regression analysis was performed with IBM SPSS Statistics using the forced entry  
267 method.

### 268 **3. Results and Discussion**

#### 269 **3.1 TGM concentrations**

270 Mean TGM concentrations at the urban sites during the study periods ranged from 2.34 to 4.56  
271 ng m<sup>-3</sup> (n = 10) with a mean ( $\pm 1\sigma$ ) of  $3.08 \pm 0.79$  ng m<sup>-3</sup> (Figure 1). These values were 1.5 to 3.0  
272 times higher than the mean background value of 1.51 ng m<sup>-3</sup> in 2014 in the Northern Hemisphere  
273 obtained from the Global Mercury Observation System (GMOS) (Sprovieri et al., 2016), and 1.2 to  
274 2.4 times higher than the mean value of  $1.94 \pm 0.64$  ( $\pm 1\sigma$ ) ng m<sup>-3</sup> at urban sites in North America  
275 and Europe (Mao et al., 2016). Mean TGM concentrations observed at some urban sites were,  
276 however, 44-55% lower than previously reported mean values for earlier years, e.g., 4.19 ng m<sup>-3</sup> in  
277 Shanghai in 2014, 8.88 ng m<sup>-3</sup> in Guiyang in 2010, and 4.60 ng m<sup>-3</sup> in Guangzhou in 2011 (Chen et  
278 al., 2013; Fu and Feng, 2015; Duan et al., 2017), likely due to a combination of several factors such  
279 as decreased anthropogenic emissions (Liu et al., 2019b), different sampling locations even inside  
280 the same city, and different sampling times and durations of the year. The declining TGM  
281 concentration (by 40%) in recent years (2014-2016) has indeed been reported in Chongming Island,  
282 Shanghai (Tang et al., 2018), which has been mostly attributed to reduced anthropogenic Hg  
283 emissions in China. Such emission reductions would impact more on urban than rural areas in  
284 atmospheric TGM (Liu et al., 2019b).

#### 285 **3.2 TGM isotopic compositions**

286 Figure 2 shows the isotopic compositions of daily TGM samples collected at the ten urban and  
287 one rural sites. Large variations in daily TGM isotopic compositions were observed with values  
288 ranging from  $-1.68$  to  $0.63\text{\textperthousand}$  for  $\delta^{202}\text{Hg}$  and from  $-0.23$  to  $0.10\text{\textperthousand}$  for  $\Delta^{199}\text{Hg}$  (Figure 2 and Table  
289 S4). Mean TGM  $\delta^{202}\text{Hg}$  values were the lowest in Guiyang ( $-0.96 \pm 0.42\text{\textperthousand}$ ,  $1\sigma$ ), Lanzhou ( $-0.70 \pm$   
290  $0.35\text{\textperthousand}$ ,  $1\sigma$ ), and Chengdu ( $-0.68 \pm 0.44\text{\textperthousand}$ ,  $1\sigma$ ) in southwestern and northwestern China, followed  
291 by Wuhan (mean =  $-0.68 \pm 0.23\text{\textperthousand}$ ,  $1\sigma$ ) and Zhengzhou (mean =  $-0.55 \pm 0.24\text{\textperthousand}$ ,  $1\sigma$ ) in central China,  
292 Shijiazhuang ( $-0.54 \pm 0.44\text{\textperthousand}$ ,  $1\sigma$ ) and Jinan ( $-0.50 \pm 0.42\text{\textperthousand}$ ,  $1\sigma$ ) in northern China, coastal  
293 Guangzhou ( $-0.44 \pm 0.17\text{\textperthousand}$ ,  $1\sigma$ ) in southern China, coastal Shanghai ( $-0.32 \pm 0.35\text{\textperthousand}$ ,  $1\sigma$ ) in eastern

294 China, and was the highest in Beijing ( $-0.24 \pm 0.24\text{\textperthousand}$ ,  $1\sigma$ ) in Northern China (Figure 1 and Table  
295 S5). Much smaller spatial variations were seen in mean TGM  $\Delta^{199}\text{Hg}$  than TGM  $\delta^{202}\text{Hg}$ . The highest  
296 mean TGM  $\Delta^{199}\text{Hg}$  were observed in Guiyang ( $-0.01 \pm 0.06\text{\textperthousand}$ ,  $1\sigma$ ) and Chengdu ( $-0.01 \pm 0.03\text{\textperthousand}$ ,  
297  $1\sigma$ ), whereas values at the other urban sites ranged from  $-0.12$  to  $-0.04\text{\textperthousand}$  ( $n = 8$ ). Mean TGM  $\delta^{202}\text{Hg}$   
298 ( $-0.16 \pm 0.16\text{\textperthousand}$ ,  $1\sigma$ ) (or  $\Delta^{199}\text{Hg} = -0.10 \pm 0.04\text{\textperthousand}$ ,  $1\sigma$ ) value measured at rural Mt. Waliguan in  
299 winter were higher (or lower) than that in most cities in winter, with the exception of  $\delta^{202}\text{Hg}$  in  
300 Beijing and Shanghai (means =  $-0.09$  to  $-0.07\text{\textperthousand}$ ,  $n = 2$ ) and  $\Delta^{199}\text{Hg}$  in Shijiazhuang, Jinan, and  
301 Shanghai (means =  $-0.11$  to  $0.17\text{\textperthousand}$ ,  $n = 3$ ), where TGM concentrations were low (means =  $1.88$  to  
302  $2.12 \text{ ng m}^{-3}$ ) and comparable to that at rural Mt. Waliguan (Table S5). Mean TGM  $\Delta^{200}\text{Hg}$  values at  
303 the urban sites were all indistinguishable from zero ( $-0.03$  to  $0.02\text{\textperthousand}$ ,  $n = 10$ , Table S5), a  
304 phenomenon that is similar to previous observations in urban areas in China and USA (means =  $-0.01$  to  $0.01\text{\textperthousand}$ ,  $n = 4$ ) (Gratz et al., 2010; Yu et al., 2016; Xu et al., 2017). Therefore, we do not  
305 further interpret the MIF of even-mass Hg isotopes in this study.

307 Mean values of TGM  $\delta^{202}\text{Hg}$  and  $\Delta^{199}\text{Hg}$  in this study were similar to those reported at urban  
308 sites of China in previous studies, e.g., negative  $\delta^{202}\text{Hg}$  (means =  $-0.73$  to  $-0.08\text{\textperthousand}$ ,  $n = 3$ ) and close  
309 to zero  $\Delta^{199}\text{Hg}$  (means =  $-0.03$  to  $0.04\text{\textperthousand}$ ,  $n = 3$ ) in Beijing, Xi'an, and Guiyang (Yu et al., 2016; Xu  
310 et al., 2017). On the other hand, mean TGM  $\delta^{202}\text{Hg}$  values in this study were  $0.44$  to  $1.60\text{\textperthousand}$  lower  
311 than the values reported for rural areas of China (mean =  $0.20 \pm 0.40\text{\textperthousand}$ ,  $1\sigma$ ,  $n = 3$ ) and North  
312 America and Europe (mean =  $0.71 \pm 0.39\text{\textperthousand}$ ,  $1\sigma$ ,  $n = 7$ ), whereas mean TGM  $\Delta^{199}\text{Hg}$  values were  
313  $0.02$  to  $0.18\text{\textperthousand}$  higher than the means in rural areas of China (mean =  $-0.14 \pm 0.05\text{\textperthousand}$ ,  $1\sigma$ ) and North  
314 America and Europe (mean =  $-0.20 \pm 0.05\text{\textperthousand}$ ,  $1\sigma$ ) (Figure 2) (Gratz et al., 2010; Demers et al., 2013;  
315 Demers et al., 2015; Enrico et al., 2016; Fu et al., 2016; Obrist et al., 2017; Fu et al., 2018; Fu et al.,  
316 2019; Jiskra et al., 2019b). Apparently, atmospheric TGM is isotopically distinguishable between  
317 urban and rural sites and between different regions of the world, providing a potentially valuable  
318 tracer for understanding the sources and transformations of atmospheric Hg at local, regional, and  
319 global scales. As shown in Figure 2, some of the daily TGM isotopic compositions (i.e.,  $\delta^{202}\text{Hg}$  and  
320  $\Delta^{199}\text{Hg}$  signatures) fell in-between the end-member TGM isotopic compositions estimated for  
321 anthropogenic TGM emissions and observed from background areas, suggesting mixed influences  
322 on TGM isotopic compositions between anthropogenic emissions and background atmospheric pool  
323 (Demers et al., 2015; Fu et al., 2016; Xu et al., 2017; Fu et al., 2018). There were, however, many  
324 exceptions with daily TGM isotopic compositions outside the above-mentioned range, e.g., with  
325  $\delta^{202}\text{Hg}$  lower than  $-0.75\text{\textperthousand}$  or  $\Delta^{199}\text{Hg}$  higher than  $-0.01\text{\textperthousand}$  (Figure 2). Thus, additional sources and  
326 environmental processes should have also contributed to the variations in TGM isotopic  
327 compositions in urban environments of China.

328 **3.3 TGM isotopic compositions estimated for urbanized source end-members and measured  
329 for soil emissions**

330 Mean TGM concentrations at the urban sites (2.37 to 4.56 ng m<sup>-3</sup>, n = 10) were highly elevated  
331 compared to the background value (~1.5 ng m<sup>-3</sup>) in the Northern Hemisphere (Sprovieri et al., 2016).  
332 This could be attributed to local and regional Hg sources including Hg emissions from primary  
333 anthropogenic sources, land surfaces (e.g., soil, building, and pavement), and indoor Hg-containing  
334 products. As shown in Figure 2, TGM isotopic compositions in the cities were probably controlled  
335 by a binary physical mixing between the regional-scale background and the key end-member  
336 sources in the cities, which could be likely associated with the local and regional emission sources.  
337 Here we use a linearized binary physical mixing diagram to estimate the mean isotopic signature of  
338 the urbanized source end-members by extrapolating the 1/TGM<sub>mean</sub> to zero (where TGM is mostly  
339 derived from urbanized sources) (Figure 3), which showed  $\delta^{202}\text{Hg}$  and  $\Delta^{199}\text{Hg}$  values of  
340 approximately  $-1.16 \pm 0.15\text{\textperthousand}$  and  $0.05 \pm 0.02\text{\textperthousand}$  ( $1\sigma$ ), respectively.

341 The estimated  $\delta^{202}\text{Hg}$  (or  $\Delta^{199}\text{Hg}$ ) for urbanized emissions was much lower (or much higher)  
342 than the  $\delta^{202}\text{Hg}$  of  $-0.26\text{\textperthousand}$  (or  $\Delta^{199}\text{Hg}$  of  $-0.26\text{\textperthousand}$ ) for GEM emitted from CFPP in China (Tang et  
343 al., 2017; Liu et al., 2019a). The isotopic signatures of other anthropogenic emission sectors in China  
344 have not been appropriately constrained. Sun et al. (2016b) estimated a mean  $\delta^{202}\text{Hg}$  of  $-0.59\text{\textperthousand}$  and  
345 a mean  $\Delta^{199}\text{Hg}$  of  $-0.02\text{\textperthousand}$  for the global anthropogenic GEM emissions in 2010. Our estimate of  
346  $\delta^{202}\text{Hg}$  and  $\Delta^{199}\text{Hg}$  for the urbanized sources were, however,  $0.57\text{\textperthousand}$  lower and  $0.07\text{\textperthousand}$  higher than  
347 their predicted value for anthropogenic emissions, respectively. A recent study by Jiskra et al. (2019a)  
348 showed highly negative  $\delta^{202}\text{Hg}$  (means =  $-1.54$  to  $-1.56\text{\textperthousand}$ , n = 2) and high  $\Delta^{199}\text{Hg}$  values (means =  
349 0.00 to  $0.17\text{\textperthousand}$ , n = 2) for GEM in air impacted by Hg emissions from building surface and indoor  
350 sources, and these values seemed to support, to some extent, the estimated negative  $\delta^{202}\text{Hg}$  and close  
351 to zero  $\Delta^{199}\text{Hg}$  signatures of urbanized sources in the present study.

352 Soil emissions are potentially an important source of atmospheric TGM in urban areas (Feng  
353 et al., 2005; Agnan et al., 2016), and GEM emission fluxes from urban soils were reported to be  
354 approximately one order of magnitude higher than that from pavement and building surface (Gabriel  
355 et al., 2006; Eckley and Branfireun, 2008). The sampling sites in the present study were largely  
356 surrounded by cropland and sparsely vegetated soils (Figure S2), and it is therefore important to  
357 investigate their effects on the variations in TGM concentrations and isotopic compositions. The  
358 measured mean GEM emission fluxes from soils in Guiyang and Wuhan in summer were  $35.9 \pm$   
359 32.6 ( $1\sigma$ , n = 5) and  $9.8 \pm 5.3$  ( $1\sigma$ , n = 3) ng m<sup>-2</sup> h<sup>-1</sup>, respectively. The mean  $\delta^{202}\text{Hg}$  and  $\Delta^{199}\text{Hg}$   
360 values of GEM emitted from soils were  $-2.16 \pm 0.60\text{\textperthousand}$  and  $-0.27 \pm 0.15\text{\textperthousand}$  ( $1\sigma$ , n = 5), respectively,  
361 in Guiyang, and were  $-1.07 \pm 0.86\text{\textperthousand}$  and  $-0.01 \pm 0.52\text{\textperthousand}$  ( $1\sigma$ , n = 3), respectively, in Wuhan (Figure  
362 S4). These values suggest that the isotopic compositions of soil GEM emissions in urban areas of  
363 China likely have highly negative  $\delta^{202}\text{Hg}$  values, similar to that of GEM emitted from building

364 surface and indoor Hg-containing products (Jiskra et al., 2019a). We thus hypothesize that soil,  
365 building surface, and indoor Hg-containing products emissions contributed to the highly negative  
366 TGM  $\delta^{202}\text{Hg}$  values observed in this study. Based on the estimated  $\delta^{202}\text{Hg}$  values of urbanized  
367 source end-member (mean = -1.16‰), anthropogenic emissions (mean = -0.59‰), and GEM  
368 emitted from soils, building surface and indoor Hg-containing products (mean = -1.57‰) in this  
369 and previous studies (Sun et al., 2016b; Jiskra et al., 2019a), we estimate that the contribution of  
370 soil, building surface and indoor Hg-containing products emissions to the TGM in the ten cities was  
371 approximately equal to that of primary anthropogenic emissions (48% versus 52%). We caution that,  
372 due to the fact that the isotopic signatures of GEM emitted from many anthropogenic sources and  
373 land surfaces in China have not been well constrained, such a preliminary assessment should have  
374 large uncertainties. However, our estimate is overall consistent with previous studies on GEM  
375 emission fluxes from land surfaces and anthropogenic sources in Chinese urban areas. For example,  
376 previous studies on GEM emission fluxes from urban surfaces in China showed a mean value of  
377  $83.2 \pm 170 \text{ ng m}^{-2} \text{ h}^{-1}$  ( $1\sigma$ ,  $n = 39$ ) (Fang et al., 2004; Feng et al., 2005; Wang et al., 2006; Fu et al.,  
378 2012), which was relatively higher than the mean anthropogenic GEM flux ( $48.4 \pm 48.1 \text{ ng m}^{-2} \text{ h}^{-1}$ ,  
379  $1\sigma$ ,  $n = 10$ ) in the ten investigated cities (Table S5) (AMAP/UNEP, 2013). The findings in this and  
380 previous studies therefore suggest that soil, building surface, and indoor Hg-containing products  
381 emissions would play an important role in regulating the TGM concentrations and isotopic  
382 compositions in urban areas of China, which is further discussed in the following section.

### 383 **3.4 Effect of surface emissions on seasonal variations in TGM concentrations and isotopic 384 compositions**

385 Strong seasonal variations in the mean TGM concentrations and isotopic compositions were  
386 observed for most cities (Figure 4). The mean TGM concentrations and  $\Delta^{199}\text{Hg}$  values were  
387 relatively higher in summer than winter in most cities except for the two (Guiyang and Guangzhou)  
388 in the low latitudes that showed an opposite trend. On the contrary, the mean TGM  $\delta^{202}\text{Hg}$  showed  
389 lower values in summer than winter in all the cities except southernmost Guangzhou that showed  
390 no seasonal difference. The seasonal variations in TGM concentrations and  $\delta^{202}\text{Hg}$  in the present  
391 study were consistent with previous findings generated from year-round continuous observations in  
392 China, e.g., higher summertime TGM in Beijing and Shanghai (Zhang et al., 2013; Duan et al.,  
393 2017), higher wintertime TGM in Guiyang and Guangzhou (Feng et al., 2004; Chen et al., 2013),  
394 and lower summer  $\delta^{202}\text{Hg}$  in Guiyang and Xi'an (Yu et al., 2016; Xu et al., 2017).

395 The summertime higher TGM concentrations observed in most cities in the present study was  
396 in contrast to the observations in most rural areas in China as well as in other regions in the Northern  
397 Hemisphere, which frequently showed lower TGM or GEM concentrations in summer than in  
398 winter (Fu et al., 2015; Mao et al., 2016; Jiskra et al., 2018). Studies on the seasonal variations in

399 TGM or GEM isotopic compositions in rural areas are currently limited. A recent study at rural Mt.  
400 Changbai, northeastern China showed higher TGM  $\delta^{202}\text{Hg}$  values in summer than winter (Fu et al.,  
401 2019), which is opposite to the seasonal variations in TGM  $\delta^{202}\text{Hg}$  at most urban sites in the present  
402 study. Such a summertime lower TGM or GEM and higher  $\delta^{202}\text{Hg}$  pattern in rural areas should be  
403 mainly attributed to increasing atmospheric oxidation and vegetation uptake of GEM as well as  
404 decreasing residential coal combustion (Sprovieri et al., 2016; Horowitz et al., 2017; Jiskra et al.,  
405 2018; Fu et al., 2019; Sun et al., 2019). The seasonality in atmospheric oxidation chemistry,  
406 vegetation activity and residential coal combustion should be similar between urban and rural areas  
407 in China, as reflected by the seasonality in  $\text{O}_3$  (representing atmospheric oxidation chemistry),  
408 NDVI (representing vegetation activity), and CO (dominantly (40%) originates from residential coal  
409 combustion) (Jiskra et al., 2018; Zheng et al., 2018), which showed summertime higher  $\text{O}_3$   
410 concentrations and NDVI and lower CO concentrations at most urban sites (Figure S5). Therefore,  
411 the contrasting seasonal variations in TGM concentrations and isotopic compositions at most urban  
412 sites with respect to rural sites provided evidence that summertime enhanced emissions in these  
413 cities probably outbalanced the effect of seasonal variations in atmospheric oxidation chemistry,  
414 vegetation activity, and residential coal combustion.

415 Traditionally, local and regional anthropogenic emissions are thought to dominate the TGM or  
416 GEM pollution in urban areas of China (Lin et al., 2010). A recent study showed quantitatively  
417 comparable coal combustion Hg emission in China between winter and summer (Gao et al., 2019).  
418 Seasonal-resolution Hg emission inventories for other anthropogenic sources (e.g., productions of  
419 cement, iron and steel, aluminum and non-ferrous metals) in China have not been established. Based  
420 on the monthly production data of these source materials, we estimated that there is no strong  
421 seasonality in total Hg emissions from these sources (Table S6). [Prevailing wind directions during](#)  
422 [the wintertime and summertime sampling campaigns were similar Jinan, Lanzhou, Zhengzhou, and](#)  
423 [Shanghai, but were different in other remaining cities \(Figure S6\).](#) Variations in predominant wind  
424 directions would change the relationships between receptor and regional anthropogenic emissions,  
425 which could further influence the TGM levels and isotopic compositions in these cities. Given the  
426 similarity in wintertime and summertime prevailing wind directions in some cities and consistent  
427 summertime lower CO concentrations in most cities, it is postulated that the variations in local  
428 anthropogenic emissions and transport of regional anthropogenic emissions were not likely the main  
429 cause for the seasonal variations in TGM concentrations and isotopic compositions.

430 We found that the amplitudes of seasonal variations in TGM concentrations ( $(\text{TGM}_{\text{summer}} -$   
431  $\text{TGM}_{\text{winter}})/\text{TGM}_{\text{summer}}$ ) and  $\Delta^{199}\text{Hg}$  values ( $\Delta^{199}\text{Hg}_{\text{summer}} - \Delta^{199}\text{Hg}_{\text{winter}}$ ) were both significantly  
432 positively correlated with latitude of the cities (ANOVA,  $R^2$  were 0.85 and 0.66 for TGM and  
433  $\Delta^{199}\text{Hg}$ , respectively,  $p < 0.01$  for both, Figure 5A and C), whereas the seasonal  $\delta^{202}\text{Hg}$  amplitudes

434  $(\delta^{202}\text{Hg}_{\text{summer}} - \delta^{202}\text{Hg}_{\text{winter}})$  were significantly negatively correlated with latitude (ANOVA,  $R^2 = 0.46$ ,  $p < 0.01$ , Figure 5B). This indicates the seasonality in TGM concentrations and isotopic compositions were likely related to weather- and climate-dependent (e.g., solar radiation and air temperature) sources and/or atmospheric processes.

438 GEM emission fluxes from soil, building surface and pavement in urban areas are highly related to solar radiation and temperature and frequently peak in summer in the Northern Hemisphere (Gabriel et al., 2006; Eckley and Branfireun, 2008). Studies on the seasonal variations in GEM emissions from building surface and pavement are not available in Chinese urban areas, but are expected to be similar to that of soil GEM emission (Gabriel et al., 2006). Therefore, using simulated seasonal soil GEM emission data is generally adequate to interpret the effect of surface GEM emission on the seasonal variations in TGM concentrations and isotopic compositions. As shown in Figure 6A, a significant positive correlation was observed between the seasonal amplitudes of TGM concentration and simulated soil GEM emission flux  $((\text{flux}_{\text{July}} - \text{flux}_{\text{January}})/\text{flux}_{\text{July}})$ , indicating enhanced surface GEM emission is responsible for the summertime increase of TGM concentrations at most urban sites. Negative seasonal TGM magnitudes were observed in Guiyang and Guangzhou in the low latitudes where there is a small summertime increase of soil GEM emission fluxes (Figure 6A). We postulate that the effect of surface emission on the seasonal variations in TGM concentrations in Guiyang and Guangzhou was likely outbalanced by other factors, e.g., seasonal variations in atmospheric oxidization chemistry, vegetation activity, and residential coal combustion.

454 Site-specific mean TGM  $\delta^{202}\text{Hg}$  and  $\Delta^{199}\text{Hg}$  values were calculated for summer and winter sampling campaigns separately, and then values at all the sampling sites were correlated with their respective simulated soil GEM emission fluxes. A significant negative correlation was obtained between TGM  $\delta^{202}\text{Hg}$  and simulated soil emission (ANOVA,  $R^2 = 0.43$ ,  $p < 0.01$ , Figure 6B). As mentioned above, the isotopic compositions of GEM emitted from urban surfaces were characterized by highly negative  $\delta^{202}\text{Hg}$  values (mean =  $-1.57\text{\textperthousand}$ ). Thus, high surface GEM emissions should shift TGM  $\delta^{202}\text{Hg}$  towards negative values. A weak positive correlation was observed between mean TGM  $\Delta^{199}\text{Hg}$  and simulated soil GEM emission fluxes (ANOVA,  $R^2 = 0.21$ ,  $p < 0.05$ , Figure 6B), suggesting that high surface GEM emissions led to a slightly positive shift of TGM  $\Delta^{199}\text{Hg}$ . Seasonal amplitudes of  $\delta^{202}\text{Hg}$  (or  $\Delta^{199}\text{Hg}$ ) in the ten cities were significantly negatively (or positively) correlated with seasonal amplitudes of simulated soil GEM emission flux (ANOVA,  $R^2$  of 0.54 or 0.63,  $p < 0.01$  for both, Figure S7), suggesting the dominant role of surface GEM emissions on the seasonal variations in TGM isotopic compositions.

467 It should be noted that indoor TGM also have highly negative  $\delta^{202}\text{Hg}$  ( $-1.56\text{\textperthousand}$ ,  $n = 1$ ) and positive  $\Delta^{199}\text{Hg}$  ( $0.17\text{\textperthousand}$ ,  $n = 1$ ) values (Jiskra et al., 2019a), but this source is not likely a dominant

469 one contributing to the seasonal variations in TGM isotopic compositions. Indoor TGM  
470 concentrations in urban areas can be highly elevated mainly due to evaporation of GEM from Hg-  
471 containing products (e.g., spills of liquid mercury in thermometers, fluorescent light and Hg  
472 switches) in the absence of sunlight (Carpi and Chen, 2001; Baughman, 2006). This source is  
473 expected to yield  $\Delta^{199}\text{Hg}/\Delta^{201}\text{Hg}$  slopes of  $\sim 1.6$  in TGM isotopic compositions due to nuclear  
474 volume effect (NVE) (Zheng and Hintelmann, 2010; Ghosh et al., 2013). As shown in Figure S8, a  
475 York bivariate linear regression between TGM  $\Delta^{199}\text{Hg}$  and  $\Delta^{201}\text{Hg}$  in the studied cites showed a  
476 slope of  $1.01 \pm 0.10$  ( $1\sigma$ ), which is consistent with that of soil GEM emissions ( $1.09 \pm 0.06$ ,  $1\sigma$ , Figure  
477 S7) and that of photoreduction of Hg(II) to GEM ( $\sim 1.0$ ) (Blum et al., 2014), but much lower than  
478 that predicted for indoor GEM sources, suggesting that seasonal variations in TGM isotopic  
479 compositions were unlikely dominated by indoor emission sources.

480 Hence, we can conclude that the seasonal variations in TGM concentrations and isotopic  
481 compositions in the ten cities were likely controlled by surface emission sources. However, it is  
482 currently difficult to determine which of surface emission sources (e.g., soil, pavement, or building  
483 surface) was more important. As discussed earlier, GEM emitted from these sources were  
484 characterized by similar isotopic signatures and are difficult to be distinguished. GEM emissions  
485 flux data from pavement and building surface in Chinese urban areas are very limited. A previous  
486 study in Toronto, Canada and Austin, USA reported that GEM emission fluxes from soils were on  
487 average 8 times higher than those from pavement and building surface (Eckley and Branfireun,  
488 2008). This, together with the large fraction of cropland and sparsely vegetated soils area in the total  
489 urban land area (mean = 57%, Table S1), indicates soil emissions were likely more important than  
490 building surface and pavement emissions at a regional scale (e.g., the size of  $1^\circ \times 1^\circ$  surrounding the  
491 sampling sites). However, given that building surface and pavement emissions sources were in close  
492 proximity to the sampling sites (Figure S2), their contributions to atmospheric TGM budget may  
493 exceed those of soil emission sources locally. Therefore, further studies and approaches are needed  
494 to better constrain the contributions of local and regional land surface emissions to TGM variations  
495 at specific sites.

### 496 **3.5 Conclusions and implications**

497 TGM concentrations in Chinese urban areas were generally highly elevated, which was  
498 traditionally thought to be mainly attributed to primary anthropogenic emissions (Lin et al., 2010;  
499 Fu et al., 2015). Due to the implementation of aggressive air pollution control measures in China  
500 since 2014, primary anthropogenic Hg emissions within or surrounding many Chinese cities are  
501 expected to have been reduced noticeably in recent years (Liu et al., 2019b). Land surface Hg  
502 emissions are also an important source of atmospheric Hg (Selin et al., 2007; Holmes et al., 2010;  
503 Pirrone et al., 2010; Agnan et al., 2016). Therefore, questions have emerged as to whether land

504 surface emissions become important in the variations in TGM concentrations and isotopic  
505 compositions in Chinese urban areas. The present study suggests that surface GEM emissions likely  
506 dominated the seasonal variations in TGM concentrations and isotopic compositions in most cities.  
507 GEM emissions from land surface are generally higher in summer and characterized by significantly  
508 negative  $\delta^{202}\text{Hg}$  signatures, and therefore are able to cause increasing TGM concentrations and a  
509 negative shift of TGM  $\delta^{202}\text{Hg}$  in summer in Chinese cities. Therefore, we suggest that land surface  
510 emissions should be incorporated in future studies to interpret the cycling (or fractionation) of TGM  
511 (or TGM isotopes) in urban areas and/or other regions with strong land surface GEM emissions.

512 China has been regarded as the world's strongest source region of anthropogenic Hg emissions.  
513 Since the Chinese Economic Reform in 1978, more than 13000 Mg of Hg have been released into  
514 the atmosphere from anthropogenic sources (Wu et al., 2016). Large fractions (35 to 49%) of these  
515 emitted Hg were in the form of short-lived particulate bound and oxidized Hg, and would have  
516 deposited quickly to areas close to sources such as urbanized and industrial areas, which should  
517 have increased Hg contents in land surface substrates. The combining effects of global warming and  
518 increased substrate Hg contents would induce increasing surface emissions, blunting the benefits of  
519 anthropogenic Hg emission control in China. Therefore, future studies should be conducted in  
520 systematically assessing the negative effects of increasing soil Hg emissions in a changing  
521 environment (anthropogenic emission, climate, and land use change) during the implementation of  
522 the Minamata Convention. Possible strategies should also be considered to mitigate surface Hg  
523 emissions, and together with the effective controls of anthropogenic emissions, to eventually reduce  
524 the threats of Hg to human health and the environment.
