16 **Abstract**

17 Iodine plays a vital role in oxidation chemistry over Antarctica, with past observations showing
18 highly elevated levels of iodine oxide (IO) leading to severe depletion of boundary layer ozone in
19 West Antarctica. Here, we present multi axis differential absorption spectroscopy (MAX-DOAS)
20 based observations of IO over three summers (2015-2017) at the Indian Antarctic bases, Bharati
21 and Maitri. IO was observed during all the campaigns, with mixing ratios below 2 pptv for the
22 three summers, which are lower than the peak levels observed in West Antarctica. This suggests
23 that sources in West Antarctica are different or stronger than sources of iodine compounds in East
24 Antarctica, **the nature of which are still uncertain**. Vertical profiles estimated using a profile
25 retrieval algorithm showed decreasing gradients, with a peak in the lower boundary layer. The
26 ground-based instrument retrieved vertical column densities (VCDs) were approximately a factor
27 of three-five higher than the VCDs reported using satellite-based instruments, which is most likely
28 related to the sensitivities of the measurement techniques. Airmass back-trajectory analysis failed
29 to highlight a source region, with most of the airmasses coming from coastal or continental regions.
30 This study highlights the variation in iodine chemistry in different regions in Antarctica and the
31 importance of a long-term dataset to validate models estimating the impacts of iodine chemistry.

34 1. Introduction

35 Reactive halogen species (RHS) have been shown to play a critical role in causing ozone depletion
36 events in the polar boundary layer (BL) (Barrie et al., 1988; Bottenheim et al., 1986; Kreher et al.,
37 1997; Oltmans and Komhyr, 1986) and could contribute to new particle formation in this remote
38 environment (Allan et al., 2015; Atkinson et al., 2012; O'Dowd et al., 2004). Observations of RHS
39 have been made in the Antarctic BL for almost two decades. Early observations focused on
40 bromine oxide (BrO), the presence of which was observed in the Antarctic using ground based
41 instruments (Kreher et al., 1997) and via satellites (Hollwedel et al., 2004). The presence of iodine
42 oxide (IO) in the Antarctic atmosphere was also confirmed through integrated column
43 measurements from the ground (Frieß et al., 2001). Later, year-long ground-based observations of
44 RHS made at Halley Bay showed the critical role that bromine and iodine compounds play in
45 regulating the oxidizing capacity, causing ozone depletion and new particle formation in the
46 Antarctic BL (Saiz-Lopez et al., 2007a). These ground-based observations showed that both IO
47 and BrO, are present at elevated concentrations (from 1 pptv to as high as 20 pptv) in certain parts
48 of the Antarctic BL, and show a significant seasonal variation peaking in the spring, with elevated
49 concentrations observed through the summer (Saiz-Lopez et al., 2008). Satellite-based
50 observations of both IO and BrO reported a similar annual cycle, although with large geographical
51 differences (Hollwedel et al., 2004; Richter et al., 2002; Saiz-Lopez et al., 2007b; Schönhardt et
52 al., 2008, 2012; Theys et al., 2011; Wagner et al., 2001). These satellite observations have been
53 validated by ground-based observations, although most of them have hitherto focused around the
54 Weddell Sea (Atkinson et al., 2012; Buys et al., 2013; Frieß et al., 2001, 2010; Saiz-Lopez et al.,
55 2007a, 2008). Previous studies show that similar levels of BrO have been observed between the
56 Arctic and Antarctic while much lower levels of atmospheric iodine have been reported in the

57 Arctic compared to the Antarctic (Hönninger et al., 2004; Raso et al., 2017; Schönhardt et al.,
58 2008; Tuckermann et al., 1997). The satellite observations also show a difference in the
59 geographical distribution of IO over Antarctica, with the Weddell sea being an iodine hotspot, the
60 reasons for which are still not completely clear (Saiz-Lopez and Blaszcak-boxe, 2016). Ground-
61 based observations have also been made at McMurdo Sound, near the Ross Sea, where lower
62 concentrations of IO were observed (Hay, 2010). Additional observations over the 2011-2012
63 summer were made at Dumont d'Urville using a cavity enhanced absorption spectroscopy based
64 instrument and showed a maximum of 0.15 pptv of IO (Grilli et al., 2013). However, observations
65 of IO have not been reported in the Indian Ocean sector of the Antarctic peninsula to date (Saiz-
66 Lopez et al., 2012; Saiz-Lopez and von Glasow, 2012).

67 Ground based observations at Halley Bay and in the Weddell Sea suggest that the main source of
68 iodine compounds is the sea ice region based on observations of iodocarbons and back trajectory
69 analysis (Atkinson et al., 2012; Saiz-Lopez et al., 2007a). Other studies have also measured
70 iodocarbons in Antarctica, although their levels are too low to explain the high levels observed in
71 the Weddell Sea region (Carpenter et al., 2007; Fogelqvist and Tanhua, 1995; Reifenhäuser and
72 Heumann, 1992). The exact process is still not known, although a mechanism for biologically-
73 induced iodine emissions from sea-ice has been suggested based on the idea that micro-algae
74 (Garrison and Buck, 1989) are the primary source of iodine emissions in this environment (Saiz-
75 Lopez et al., 2015a) with halogen compounds then moving up brine channels in the sea ice to
76 finally get released into the atmosphere. There are further questions regarding the propagation of
77 reactive iodine chemistry across the continent because satellite observations show the presence of
78 IO deep within the Antarctic continent, even as far as the South Pole (Saiz-Lopez et al., 2007b;
79 Schönhardt et al., 2008). However, although enhanced, the observed IO column densities are close

80 to the detection limit of the satellite instrument ($\sim 7 \times 10^{12}$ molecules cm^{-2} for a single
81 measurement) and are therefore subject to uncertainties. The study by Frieß et al. (2010) suggested
82 a strong source within the snowpack, which hints at active recycling and re-emission of IO aiding
83 the long transport inland. However, questions remain about why such a source would function
84 only in parts of the continent and why the primary source is different from the Arctic, where much
85 lower peak concentrations are sporadically observed (Mahajan et al., 2010; Saiz-Lopez and
86 Blaszczak-boxe, 2016). To further understand the sources of iodine in the polar environment,
87 understanding the geographical distribution is critical. Satellite observations play a useful role for
88 this, although validation of the satellite observations using ground-based instruments is necessary
89 to ascertain their accuracy to observe IO in the Antarctic troposphere.

90 Questions also remain about the vertical profiles of iodine compounds within and above the
91 Antarctic boundary layer. Modelling based studies using the one-dimensional Tropospheric
92 Halogen Chemistry MOdel (THAMO) have suggested a strong gradient in IO from the surface to
93 the edge of the boundary layer (Saiz-Lopez et al., 2008). Only once in the past have vertical profiles
94 of IO been measured in Antarctica. These measurements were made at McMurdo Sound in East
95 Antarctica (Hay, 2010). Observations over two “golden days” in 2006 and 2007 show surface
96 concentrations of about 1 pptv, decreasing to ~ 0.2 pptv at about 200 m, before reaching a second
97 maximum of 0.6 pptv at ~ 700 m. However, models did not reproduce this measured IO vertical
98 profile shape and there are also large uncertainties associated with the a priori (Hay, 2010). In most
99 models, the assumption is that the source of iodine compounds is from the snowpack, with
100 photochemistry in the atmosphere resulting in a steady decrease with altitude. However,
101 considerable challenges remain in reproducing the surface variation and vertical gradients in
102 addition to the geographical distribution (Fernandez et al., 2019). More recent modelling studies

103 combined with aircraft observations suggest that the gradient is not very sharp all the latitudes,
104 with a significant free tropospheric and stratospheric contribution to the total column of IO
105 (Koenig et al., 2020; Saiz-Lopez et al., 2015b), although such observations have still not been done
106 in the Antarctic. One of the main reasons for the uncertainties in models is the lack of consistent
107 measurements of vertical gradients across the world, especially in the Polar Regions, to validate
108 these model simulations.

109 Considering the uncertainties in the satellite observations and questions regarding the sources and
110 vertical and geographical distribution of IO, further observations are necessary. Here we present
111 observations made at two new locations in Antarctica over three summers and compare them with
112 the satellite-based retrievals and past observations.

113

114 **2. Methodology**

115 Figure 1 shows the location of the two Indian Antarctic stations, Maitri (11.73 °E , 70.77 °S) and
116 Bharati (76.19 °E, 69.41 °S). The other stations where observations of IO have been reported in
117 the past are also marked on the map. Observations of IO and the oxygen dimer (O₄) were made
118 using the Multi-Axis Differential Optical Absorption Spectroscopy technique (MAX-DOAS) over
119 three summers: February-March 2015 as a part of the 34th Indian Scientific Expedition to
120 Antarctica (ISEA-34), November 2015 – February 2016 as a part of ISEA-35 and January-
121 February 2017 as a part of ISEA-36.

122 Observations at the Maitri station were made over a short span of 9 days (9th March – 17th March
123 2015) and only during ISEA-34. The research station is in the ice-free rocky area on the
124 Schirmacher Oasis. The MAX-DOAS instrument was installed in a summer-time residential

125 container, ~150 m north the station, about 120 m above sea level during the ISEA-34. The scanner
126 unit was mounted on top of the container with the clear line of sight to the horizon. The scanner
127 pointed $\sim 60.0^\circ$ with respect to magnetic north. The spectrometer unit was kept inside the container,
128 which was temperature controlled. The open ocean is 125 km north of Maitri.

129 Observations at the Bharati station were made for 10 days (9th February-18th February 2015) during
130 ISEA-34, for 63 days (30th November 2015 – 1st February 2016) during ISEA-35 and for 35 days
131 (5th January-11th February 2017) during ISEA-36. The station is located between the Thala Fjord
132 and Quilty Bay, east of the Stornes Peninsula. The MAX-DOAS instrument was installed in a hut
133 on top of a ridge around 200 m south-west of the Bharati station and was approximately 56 m
134 above sea level. The scanner unit was mounted on the wall of the hut and had a clear line of sight
135 to the horizon, pointing -23.2° with respect to the north, overlooking the open ocean. The coastline
136 is within 500 m of the hut, but it becomes ice free from mid-January to late March. Depending on
137 the sea ice conditions, the open ocean is within 8-10 km north from the end of November.

138 The MAX-DOAS instrument (EnviMes) makes use of scattered sunlight along different elevation
139 angles and by combination of several lines of sight including the zenith. The concentration of an
140 absorber in the boundary layer can be obtained either in a first approximation by a simple
141 geometric approach or by simulating the light path with a radiative transfer model taking into
142 account also multiple scattering effects and the correct treatment of the aerosol loading in the
143 atmosphere (Hönninger et al., 2004; Platt and Stutz, 2008; Wagner et al., 2004). The instrument
144 consists of an indoor unit, housing a spectrometer with a spectral resolution of 0.7 nm (UV: 301.20-
145 463.69), which is connected to an outdoor unit, containing a scanning telescope. Discrete elevation
146 angles (1° , 2° , 3° , 5° , 7° , 10° , 20° , 40° , and 90°) were recorded for a total exposure time of 1
147 minute each during all the four campaigns. The spectra were recalibrated before analysis using

148 mercury emission lines recorded at the end of each day. For DOAS retrieval, the QDOAS 3.2
149 software was used (Fayt and Van Roozendael, 2013). For estimation of the O₄ Differential Slant
150 Column Densities (DSCDs), the cross-sections of O₄ (Thalman and Volkamer, 2013) at 293K;
151 NO₂ (Vandaele et al., 1998) at 220 K and 298 K (220 K orthogonalized to 294 K); O₃ (Bogumil et
152 al., 2003) at 223 K and 243 K (orthogonalized to O₃ at 243 K); HCHO (Meller and Moortgat,
153 2000) at 298 K; HONO (Stutz et al., 2000) at 296 K were used in the 351-390 nm window. The
154 cross-sections used for IO retrieval in the 417-440 nm spectral window were: IO (Gómez Martín
155 et al., 2005), NO₂ 220 K and 298 K (Vandaele et al., 1997), H₂O (Rothman et al., 2013), O₄
156 (Thalman and Volkamer, 2013) and O₃ (Bogumil et al., 2003). In addition to these cross-sections
157 a ring spectrum (Chance and Spurr, 1997), a second ring spectrum following Wagner et al. (2009),
158 and the 3rd order polynomial were used for both windows. The zenith spectrum from each scan
159 was used as a reference to remove contribution from possible free tropospheric or stratospheric
160 absorption. An example of a DOAS fit for O₄ and IO are given in Figure S1. Surface mixing ratios
161 and the total vertical column densities (VCDs) were retrieved from the MAX-DOAS DSCDs of
162 IO and O₄ by employing the Mainz Profile Algorithm (MAPA) (Beirle et al., 2018). Only
163 observations with solar zenith angles (SZA) less than 75° were used for the profile retrievals due
164 to the large path lengths through the stratosphere for high SZA angles. This algorithm uses a two-
165 step approach to determine the trace gas vertical profiles. In the first step, the aerosol profiles are
166 retrieved using the measured O₄ DSCDs. A Monte Carlo approach is utilized to identify the best
167 ensemble of the forward model parameters (column parameters (c) (VCD for trace gases and
168 aerosol optical depth for aerosol), height parameter (h) and shape parameter (s)), which fit the
169 measured O₄ DSCDs for the sequence of elevation angles. In the second step, the aerosol profiles
170 retrieved from the O₄ inversion are used as an input to retrieve similar model parameters (c, h, and

171 s) for IO. The state of the atmosphere was calculated using the pressure and temperature profiles
172 observed by the in-situ radiosondes, which were launched once a week at both stations. An
173 angstrom exponent of 1 was used for the difference in the retrieval wavelengths as per observations
174 made at Bharati in the past (Prakash Chaubey et al., 2011). Within MAPA, the differential air mass
175 factors (AMFs) are calculated offline with the radiative transfer model McArtim (Deutschmann et
176 al., 2011) for fixed nodes for each parameter and stored as a lookup table (LUT) for quick analysis.
177 To assess the quality of the retrievals, MAPA provides “valid”, “warning” or “error” flags for each
178 measurement sequence, which are calculated based on pre-defined thresholds for various fit
179 parameters. For further details about MAPA, please refer to the description paper by Beirle et al.
180 (2018). Additionally, MAPA provides the option to use a scaling factor for significant mismatch
181 between the modelled and measured O₄ DSCDs, which has been shown to be close to 0.8 in the
182 past (Wagner et al., 2019). Using the variable option, where the model estimates the scaling factor,
183 which ranged between 0.75 and 0.9. Therefore, a scaling factor of 0.8 was applied for all the
184 campaigns.

185 We also make use of the IO vertical column densities retrieved using the SCanning Imaging
186 Absorption spectroMeter for Atmospheric CHartography (SCIAMACHY), a UV-vis-NIR
187 spectrometer onboard the ENVISAT satellite (Burrows et al., 1995). Observations from
188 SCIAMACHY stopped due to instrumental problems in April 2012. Here we make use of the mean
189 from 2004-2011 to look at the geographical distribution and compare it with the ground-based
190 observations made during the study period. Further details about the IO retrieval algorithm and the
191 SCIAMACHY instrumental setup can be found elsewhere (Schönhardt et al., 2008, 2012).

192

193 3. Results and Discussion

194 3.1 Meteorological parameters

195 Figure 2 shows the 5-day back-trajectories arriving every hour at the two stations at a height of 10
196 m on the days that the DOAS measurements were conducted as a part of the three ISEA
197 expeditions. The back-trajectories were calculated using the HYbrid Single-Particle Lagrangian
198 Integrated Trajectory (HYSPLIT) using the using the EDAS-40 km database (Draxler and Rolph,
199 2003). The trajectories show that the airmasses sampled throughout the three expeditions were
200 from either a remote oceanic region, coastal Antarctica, or the continental shelf. In general, most
201 of the trajectories show that the airmasses had travelled over hundreds of kilometres over the last
202 five days. For the local meteorological conditions, Figure 3 (top panels) show the wind direction
203 at the Bharati station. Most of the time, the wind was from the ocean, with the winds coming from
204 the north-west sector and a few instances of northern and north eastern winds (although during
205 ISEA-34 the winds were mostly from east to north-east). This was during all the three expeditions
206 at the Bharati station. The wind speed was mostly below 20 knots ($\sim 10 \text{ m s}^{-1}$) for all the campaigns,
207 although periods of high winds were observed during ISEA-35 and ISEA-36, which were of a
208 longer duration than ISEA-34. The temperature at the station hovered between $-5 \text{ }^\circ\text{C}$ and $+5 \text{ }^\circ\text{C}$,
209 through the summer period, with higher values closer to noon (Figure 3, middle panels). The
210 humidity fluctuated from 40% to above 90%. The radiation followed a clear diurnal pattern, with
211 the highest values seen around local noon and minima at local midnight. Considering that this
212 region experiences continuous light for 24 hours, the radiation also showed a non-zero minima
213 between November to January (Figure 3, bottom panels). However, in February, a clear night-time
214 is seen in the radiation data. Finally, a measure of the cloudiness was also tracked using visual full
215 sky cloud cover observations. Any cloud cover of more than 30% was considered to be cloudy

216 (cloud flag value of 1), which helps in filtering the MAX-DOAS observations. In addition to the
217 visual inspection of the sky, which was performed once an hour, a second cloud index was
218 calculated based on the ratios of the radiances at 320 nm and 440 nm from the 3° and zenith spectra
219 (Mahajan et al., 2012; Wagner et al., 2014). Both **manual and radiance-based** indices showed a
220 close match, indicating that cloudy conditions were well discerned by the cloud index calculation.
221 Meteorological data was unfortunately not available at the Maitri station.

222 **3.2 Differential Slant Column Densities (DSCDs)**

223 Figure 4 shows the observed O₄ DSCDs at different elevation angles for all the campaigns. O₄
224 DSCDs were found to be higher at lower elevation angles, as expected, which is because the O₄
225 concentration is proportional to the square of the oxygen pressure and thus increases towards the
226 surface. This also suggests that the aerosol loading was low in the atmosphere. Photons travel
227 longer paths at lower elevation angles and interact more with tropospheric absorbing species before
228 reaching the instrument resulting in a decreasing profile with increasing elevation angles. The
229 average residual root mean square (RMS) and 2σ detection limit for the O₄ DSCDs were 4.46×10⁻
230 ⁴ (range: 1.56-10.01×10⁻⁴) and 2.11 × 10⁴² molecules² cm⁻⁵ (range: 0.72-4.66 × 10⁴² molecules²
231 cm⁻⁵), respectively (Figure 4). The O₄ DSCDs were then used to estimate the aerosol profiles and
232 hence the IO mixing ratios, as described earlier in section 2.

233 Figure 5 shows the observed IO DSCDs at different elevation angles for all the campaigns. The
234 IO DSCDs were found to be higher at lower elevation angles, which indicates a decreasing gradient
235 in the IO vertical profile. The residual RMS was in the 1.15-9.73×10⁻⁴ range (mean: 3.46×10⁻⁴),
236 resulting in 2σ IO DSCD detection limits of 6.57×10¹² to 5.71×10¹³ molecules cm⁻² (mean
237 1.88×10¹³ molecules cm⁻²) (Figure 5). For several days, only the lowermost elevation angles were

238 found to be above the two-sigma detection limit of the instrument. Higher IO DSCDs were
239 observed at high SZAs, which is related to an increase in the path length. However, only
240 observations with $SZA < 75^\circ$ were used to estimate the vertical profiles and surface mixing ratios
241 using the aerosol profiles derived using the O_4 DSCDs, as described earlier in section 2. A zoomed
242 in view of two example days for both the O_4 and IO DSCDs is shown in Figure S2, which clearly
243 shows the decreasing gradient with increasing elevation angles.

244 3.3 IO Vertical Column Densities (VCDs) and mixing ratio profiles

245 The O_4 and IO DSCDs were used to retrieve the vertical column densities and the vertical profiles
246 for aerosols and IO. A comparison of the MAX-DOAS observed O_4 DSCDs with the MAPA
247 modelled DSCDs for all the four campaigns are shown in Figure S3, and Figure S4 shows a similar
248 plot for the IO DSCDs. Figure 6 and 7 show the MAPA calculated AODs and IO VCDs,
249 respectively, for all the campaigns. Several datapoints are flagged as error or warnings, with a few
250 scans giving a 'valid' flag. In the case of aerosols, the warning or error flags are mainly for scans
251 which were during cloudy weather (Figure S5 shows the data, which were flagged as 'bad' and
252 'warning' along with the valid scans). As mentioned above, the cloud cover was regularly
253 measured throughout the campaigns as a part of the meteorological observations. In addition to
254 visual observations, we also computed the cloud index following past works based on MAX-
255 DOAS observations (Mahajan et al., 2012; Wagner et al., 2014), which confirmed that the error
256 and warning flags were during cloud cover periods. For the valid scans, the aerosol optical depth
257 (AOD) ranged between 0.002 and 0.016, with a mean value of 0.003 for ISEA-34 at Bharati;
258 between 0.001 and 0.067, with a mean value of 0.011 for ISEA-34 at Maitri; between 0.001 and
259 1.866, with a mean value of 0.037 for ISEA-35 at Bharati; and between 0.001 and 0.878, with a
260 mean value of 0.016 for ISEA-36 at Bharati (Figure 6). The low values are expected considering

261 the pristine conditions in Antarctica, although during a couple of scans elevated levels were
262 observed as demonstrated by the maximum value during ISEA-35 and ISEA-36. In the case of IO,
263 there were far fewer valid retrieved profiles as can be seen in Figure 7 (Figure S6 shows the all
264 scans, including the ‘bad’ and ‘warning’). Only 343 valid total scans were retrieved for the vertical
265 profiles of IO. One of the main reasons is that for most of the scans the IO DSCDs at higher
266 elevation angles are below the detection limit and not enough information is available for the
267 model to retrieve a valid vertical profile. In the case of IO VCDs, there were only two scans that
268 showed a valid flag over the 10-day period during the ISEA-34 campaign at Bharati due to adverse
269 weather conditions leading to mostly cloudy weather. Thus, the mean VCD value of 2.83×10^{12}
270 molecules cm^{-2} , should be treated with some caution. In Maitri during ISEA-34, the IO VCD
271 ranged between 2.37×10^{12} molecules cm^{-2} and 4.25×10^{12} molecules cm^{-2} , with a mean value of
272 $3.40 \pm 0.57 \times 10^{12}$ molecules cm^{-2} . During ISEA-35 at Bharati, which had the highest number of
273 valid scans over the four campaigns, the IO VCDs ranged between 0.01×10^{12} and 5.86×10^{12}
274 molecules cm^{-2} , with a mean value of $2.62 \pm 1.16 \times 10^{12}$ molecules cm^{-2} . During ISEA-36, the IO
275 VCDs ranged between 2.78×10^{12} molecules cm^{-2} and 4.90×10^{12} molecules cm^{-2} , with a mean value
276 of $3.92 \pm 0.79 \times 10^{12}$ molecules cm^{-2} at Bharati.

277 In addition to the VCDs, vertical profiles of aerosols (Figure S7) and IO were estimated using
278 MAPA. Figure 8 shows the typical vertical profiles of IO mixing ratios over the four expeditions.
279 The surface mixing ratios for the valid scans across all the campaigns range between 0.2 and 1.3
280 pptv. The surface (<30 m) concentrations observed at both Maitri and Bharati are lower than
281 observations in the Weddell Sea region, where summer time concentrations exceeding 6 pptv have
282 been reported in the past (Atkinson et al., 2012; Saiz-Lopez et al., 2007a), or at the Neumayer
283 station, where long-term zenith sky DOAS measurements of IO suggest mixing ratios as high as

284 ~10 pptv during the summer (Frieß et al., 2001). It should be noted that although elevated
285 concentrations were observed at Halley, the average summer concentration, measured only 4 m
286 above the snowpack using a Long-Path DOAS instrument, was about 3 pptv, approximately a
287 factor of three higher than the observations at Bharati and Maitri. Considering that the MAX-
288 DOAS retrieved profiles are not very sensitive to the lowermost few meters, this **difference** is
289 expected. This is because the source of IO is expected to be from the surface and remote sensing
290 estimates have suggested that high IO concentrations in the order of 50 ppbv are present in the
291 snow interstitial air (Frieß et al., 2010), suggesting that snowpack is indeed the source for iodine
292 compounds. If **this is the case**, a strong gradient would be observed considering the short lifetime
293 of IO in the atmosphere, and hence the MAX-DOAS observations would be lower than the LP-
294 DOAS observations. **However, this does not explain the large difference compared to Neumayer,**
295 **where the estimated value was 10 pptv. Indeed, Maitri is close to Neumayer, and the reasons for**
296 **the large difference between the two sites remains a mystery.** The observations reported in this
297 study are also similar to measurements at McMurdo Sound, near the Ross Sea, where MAX-DOAS
298 observations reported a maximum of 2.6 ± 0.1 pptv with most of the observations below 1 pptv
299 during 2006 and 2007 (Hay, 2010). **It should be noted that the surface values were not highly**
300 **weighted by the a priori.** McMurdo Sound is also located in the East Antarctic, which shows lower
301 levels of IO in the satellite estimates (Schönhardt et al., 2008) and in models (Fernandez et al.,
302 2019).

303 Vertical profiles of IO have been reported only once in the past from Antarctica. These
304 measurements were made at McMurdo Sound in East Antarctica (Hay, 2010). IO over two days in
305 2006 and 2007 show typical surface concentrations of ~1 pptv (with a maximum of 2.6 pptv),
306 decreasing to ~0.2 pptv at about 200 m. A second maximum of 0.6 pptv at ~700 m was also

307 observed, but the models do not reproduce this profile shape and the observations were subject to
308 large uncertainties with the vertical profile above 200 m dominated by the a priori (Hay, 2010).
309 During the four campaigns studied here, elevated concentrations, similar to the surface, were
310 usually observed until about 400 m. Above this height, there is a decrease, with the retrievals
311 reducing to below 0.1 pptv (Figure 8). The reducing standard deviations in the profile retrieval
312 with altitude show that all the profiles which reproduce elevated IO close to the ground approach
313 zero for higher altitudes, suggesting that most of the IO is within the lower part of the troposphere.
314 However, this gradient is much more gradual than estimates predicted using the THAMO one-
315 dimensional model at Halley Bay (Saiz-Lopez et al., 2008). In most models, the assumption is that
316 the source is from the snowpack, and hence a strong decreasing gradient with altitude has been
317 predicted (Saiz-Lopez et al., 2008). The gradient of this decrease depends on the photolysis of the
318 higher oxides, and on the recycling of iodine reservoir species on aerosols, both of which have
319 uncertainties. When the gradient was estimated in 2008 (Saiz-Lopez et al., 2008), the photolysis
320 rates for the higher iodine oxides were not available but this has recently been measured in the
321 laboratory (Lewis et al., 2020) and THAMO needs to be updated accordingly. Another important
322 point to consider is that the MAX-DOAS observation-based profile retrievals typically get only a
323 couple of points of information in the boundary layer and are hence not expected to capture this
324 strong decrease.

325 **3.4 Comparison with satellite-based estimates**

326 The satellite-based vertical column densities of IO across the Weddell Sea region, and the region
327 encompassing Bharati and Maitri are shown in Figure 9. The averaged satellite based VCD
328 observations suggest that lower levels of IO are expected at both the Indian bases as compared to
329 places where ground-based observations have been reported in the past, such as Halley Bay and

330 Neumayer. The mean and standard deviation over the eight years of observations for Bharati is 0.6
331 $\pm 0.5 \times 10^{12}$ molecules cm^{-2} , while for Maitri the amount is $0.5 \pm 0.5 \times 10^{12}$ molecules cm^{-2} , each
332 for the whole time series. For single months the values can be higher: the mean IO VCD for Bharati
333 is 0.8 or 0.4×10^{12} molecules cm^{-2} in December or February, respectively, and 0.6×10^{12} molecules
334 cm^{-2} in March for Maitri. This is lower than mean value of $2.62 \pm 1.16 \times 10^{12}$ molecules cm^{-2}
335 observed at Bharati during ISEA-35, which was the longest dataset available in this study which
336 suggests that the ground-based instruments observe larger VCDs as compared to the satellite based
337 instruments. However, it should be noted that the SCIAMACHY data is an average over all the
338 seasons, and individual daily datapoints as high as 2.1×10^{12} molecules cm^{-2} have been observed.
339 Figure 10 shows the timeseries for Bharati and Maitri with daily averages (red dots) as well as
340 monthly averages (blue triangles) for the years 2004 to 2011. Satellite measurements from within
341 500 km around the stations were included in the analysis. It should be mentioned that this spatial
342 averaging could cause introduction of larger uncertainties due to the heterogeneity in the IO
343 distribution, but are necessary to improve the signal to noise.

344 When the whole IO column is constrained to the lower 400 m, the satellite retrieved VCDs translate
345 to a range between $0.6 - 1.3$ pptv. The daily satellite VCDs tend to exceed these averaged values
346 and result in mixing ratios as high as 2 pptv. This is similar to the range observed through the four
347 campaigns reported here. However, observations during the spring time were not made over these
348 four campaigns, when emissions of iodine species have been show to peak at Halley Bay (Saiz-
349 Lopez et al., 2007a). During the spring season, values as high as 20 pptv was observed at Halley
350 Bay, a factor of ten higher than during the summer at the Indian stations. However, the satellite
351 observations do not show a large peak over the springtime over both Indian stations. Another
352 outstanding question is whether the satellites are sensitive to the lower 100-200 m, considering the

353 strong gradient in IO. Figure S8 shows the block AMFs for satellite retrievals showing a significant
354 difference between the block AMFs over Antarctica at different albedo values. Over the ice-
355 covered regions in Antarctica, the satellite is sensitive to the lower troposphere as the albedo is
356 usually 0.9 or above. Observations have shown that open water has an albedo of 0.05–0.2 (Jin et
357 al., 2004), whereas the albedo of sea ice ranges between 0.6 and 0.7 for bare ice and 0.8–0.9 for
358 snow-covered ice (Perovich et al., 2002). In the case of Bharati, the Quilty Bay is not ice covered
359 during the summer and hence along the light path in Bharati, the sensitivity of the satellite is much
360 lower. Use of a higher albedo would result in an underestimation of the VCD by the satellite, which
361 is the case when compared to the ground-based instruments. At Mairi this should not be the case
362 considering that Mairi is 125 km inland from the coast, and the ice shelf is less than 1 km from
363 the station along the light path. It should be noted that the MAPA LUTs are calculated for a low
364 surface albedo (5%) and hence, at least for some of the measurements, the surface albedo is
365 probably much higher, especially at Mairi. As far as we understand, the effect of the surface
366 albedo mainly cancels out in the MAX-DOAS analysis, but it could be one possible uncertainty
367 on the retrieval results. Another reason for the discrepancy between the ground based and satellite
368 retrieved VCDs could be the overpass time, which was approximately 09:00 am local time.
369 Although this should not be a large factor during the summer months due to long sunlit hours, and
370 that the numbers given above were averages through the entire campaign for the ground-based
371 observations, measurements at Halley Bay have shown a strong diurnal profile peaking at noon
372 (Saiz-Lopez et al., 2007a). Hence, it is possible that the ground-based observations, which are
373 filtered for $SZA > 75^\circ$, capture higher values than the satellite.

374 Finally, a point to consider is that the satellite data available from SCIAMACHY is for the period
375 of 2004-2011, whereas the MAX-DOAS observations were conducted over three summers from

2015. This temporal discrepancy, although small considering the long satellite dataset, could contribute to the difference in the retrieved VCDs. Recent observations of iodine in ice-cores in the Alpine region and over Greenland have shown an increasing trend for atmospheric iodine in the northern hemisphere (Cuevas et al., 2018; Legrand et al., 2018). In the Antarctic only seasonal and geographical variations in halogens in the ice have been studied and no long term dataset is available (Vallelonga et al., 2017). The main cause for this increase is suggested to be an increase in tropospheric ozone, which drives the emission of iodine compounds from the ocean surface through heterogenous chemistry at the ocean interstitial surface (Carpenter et al., 2013). Although questions regarding the strength of this inorganic source in affecting IO concentrations in the Southern Ocean remain (Inamdar et al., 2020; Mahajan et al., 2019), it is possible that the discrepancy between the satellite and ground based data is because of a different time period. However, no increasing trend was observed in the satellite data for the period between 2004-2011 (Figure 10), which suggests that a factor of three increase in the VCDs is most likely due to a difference in the measurement technique and sensitivities rather than a change in the emissions.

390

391 **3.5 Airmass origin dependence**

Year-long observations at Halley Bay in West Antarctica, which were made using the LP-DOAS instrument, suggested a oceanic primary source (Saiz-Lopez et al., 2007a). The authors showed through the tracking of airmass back-trajectories, which displayed that elevated levels of IO were present in airmasses that passed over the coastal and oceanic regions compared to the airmasses that had only continental exposures. However, even in airmasses that had passed only over the continent for the past five days, the IO levels were still above the detection limit, which suggested

398 that even if the primary source is oceanic, a secondary source from the snow pack contributed to
399 the atmospheric IO. Indeed, subsequent studies have tried to explain the snowpack source through
400 recycling of primary emissions from the ocean (Fernandez et al., 2019) and one study has even
401 suggested a strong snowpack source based on simulated observations (Frieß et al., 2010). Although
402 the levels of IO are much lower than the peak concentrations seen at Halley Bay, we studied the
403 back-trajectories to see if the origin of airmasses lead to a difference in the observed IO levels at
404 both Bharati and Maitri. Considering the short lifetime of reactive iodine compounds in the
405 atmosphere, we calculated the exposure of each HYSPLIT calculated back-trajectory according to
406 the region it passed over the last 12 hours. Depending on where the trajectories spend the most
407 amount of time, they were classified into coastal, continental, and oceanic airmasses. The coastal
408 region was defined as a 0.5° belt along the Antarctic coastline, with regions to the north and south
409 of this belt considered to be oceanic and continental, **even though most of them had coastal origin**
410 **when the 5 day trajectories are considered** (Figure S9). Using the profiles which were valid, no
411 clear dependence on the airmass origin was observed. Indeed, most of the data points at both
412 stations corresponded to airmasses which were either coastal or continental (Figure S10) and is
413 representative of the typical wind patterns during the summer season. Thus, using this dataset, it
414 was not possible to draw any conclusions regarding the possible sources of IO in this region, and
415 a longer study is needed in the future.

416

417 **4. Conclusions**

418 This study presents observations of iodine oxide (IO) at the Indian Antarctic bases Maitri and
419 Bharati made over three summers from 2015 through 2017. IO was observed intermittently during

420 all the campaigns, with mixing ratios below 2 pptv. Using a profile retrieval algorithm, vertical
421 gradients of IO were estimated, and these showed a decreasing profile with a peak in the boundary
422 layer. The vertical profiles confirmed past hypothesis of a source from the ground considering a
423 sharp gradient. The vertical columns observed using the ground-based instrument are
424 approximately a factor of three-five higher than the climatological mean observed by the satellite,
425 which could be due to a difference in the measurement techniques and sensitivities. Airmass origin
426 analysis using back-trajectories did not lead to a conclusive answer about the source regions.
427 Indeed, it raises new questions on comparison with past observations, which show that we still do
428 not understand iodine chemistry in the polar regions. This study suggests that a longer dataset over
429 different seasons and regions of Antarctica is necessary to answer the outstanding questions
430 regarding the sources and seasonal importance of IO in the Indian Ocean sector of Antarctica.

431

432 **5. Acknowledgements**

433 We thank the logistical and scientific teams of the ISEA-34, ISEA-35, and ISEA-36 campaigns
434 for enabling observations through the expeditions. The ISEA campaigns are organised by the
435 National Centre for Polar and Ocean Research (NCPOR), Ministry of Earth Sciences (MOES),
436 Government of India. IITM and NCPOR are funded by MOES, Government of India.

437 **6. Author contributions:**

438 ASM conceptualised the research plan and methodology, did the analysis and wrote the
439 manuscript. MSB did the field observations. SB, TW, NB and ASL helped with the interpretation
440 of the observations and AS provided the satellite observations and helped interpret them.

669 2019, 2019.

671

672

674

675 **Figure 1:** Map showing the location of the two Indian Antarctic stations, Maitri and Bharati, where
676 observations of IO were performed during this study (blue dots). Previous locations that have
677 reported observations of IO are also marked on the map (red dots).

678

679

680 **Figure 2:** 5-day back-trajectories arriving at the two stations on the days that the measurements of
 681 IO were conducted as a part of the 34th, 35th and 36th ISEA expeditions are shown. The back-
 682 trajectories were calculated using the HYbrid Single-Particle Lagrangian Integrated Trajectory
 683 (HYSPLIT) model, arriving every hour (Draxler and Rolph, 2003).

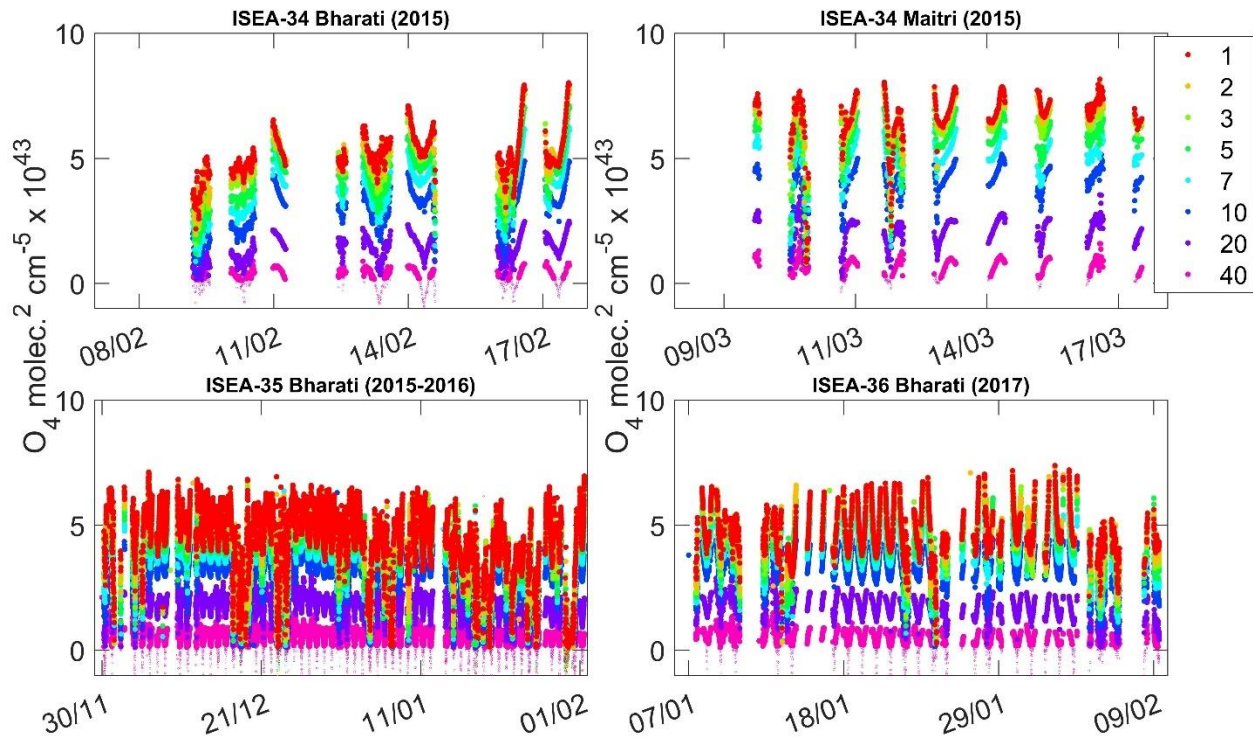

684

685

686 **Figure 3:** Observations of different meteorological parameters that were measured during the
 687 various summer campaigns are shown here. The top panels show the wind direction and speed; the
 688 middle panels show the temperature and humidity; and the bottom panels show the radiation and
 689 cloudiness (1 is defined as 30% cloudy skies and above). Observations of these parameters were
 690 not made during the 34th ISEA at Maitri and the gaps indicate instrumental or observational issues.
 691 The data had a time resolution of 5 min.

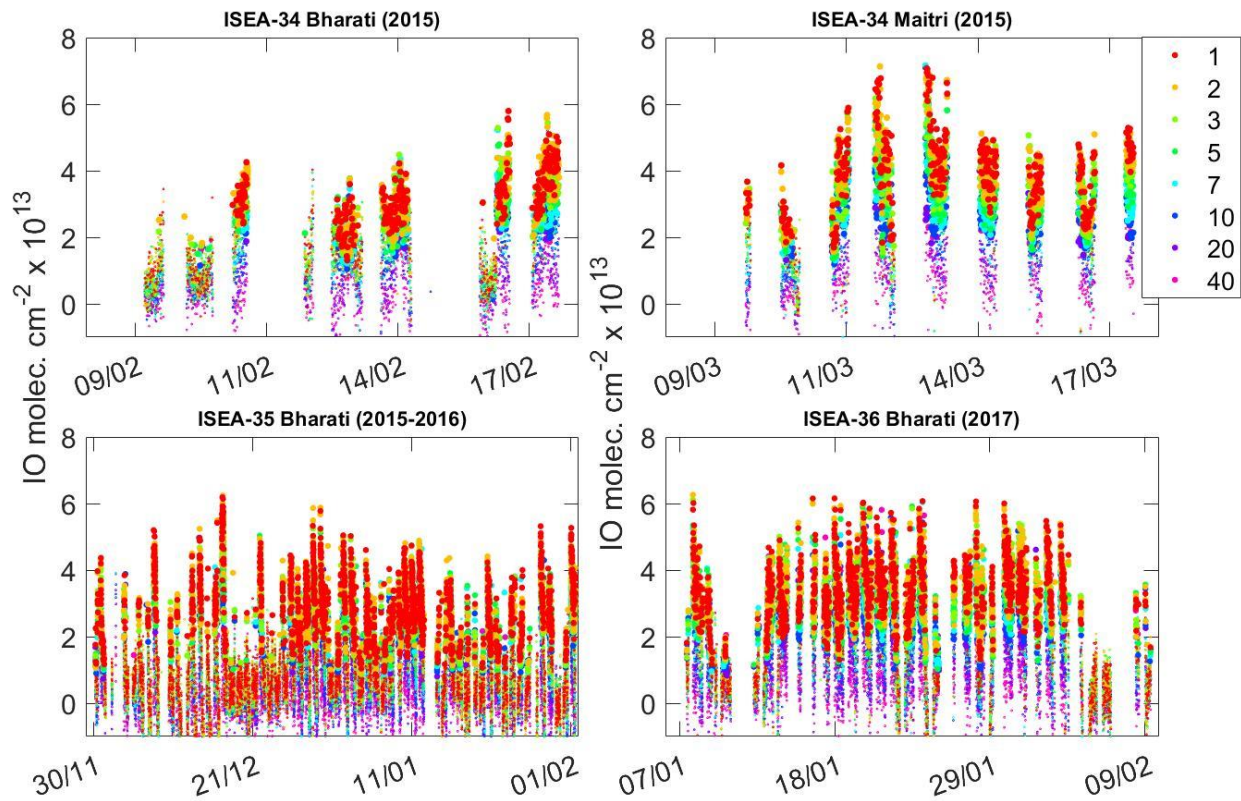

692

693

694 **Figure 4:** O₄ DSCDs observed during the four campaigns are shown. The empty circles represent
 695 values below the 2σ detection limit of the instrument, while the filled circles are values above the
 696 2σ detection limit. The data are color-coded according to elevation angles.

697

698

699 **Figure 5:** IO DSCDs observed during the four campaigns are shown. The smaller circles represent
 700 values below the 2σ detection limit of the instrument, while the bigger circles are values above the
 701 2σ detection limit. The data are color-coded according to elevation angles.

702

703

704

705 **Figure 6:** AOD timeseries retrieved using the O₄ DSCDs for all the four campaigns are shown.

706 The data show only the ‘good’ datapoints, which are reliable and were mostly during clear sky

707 conditions.

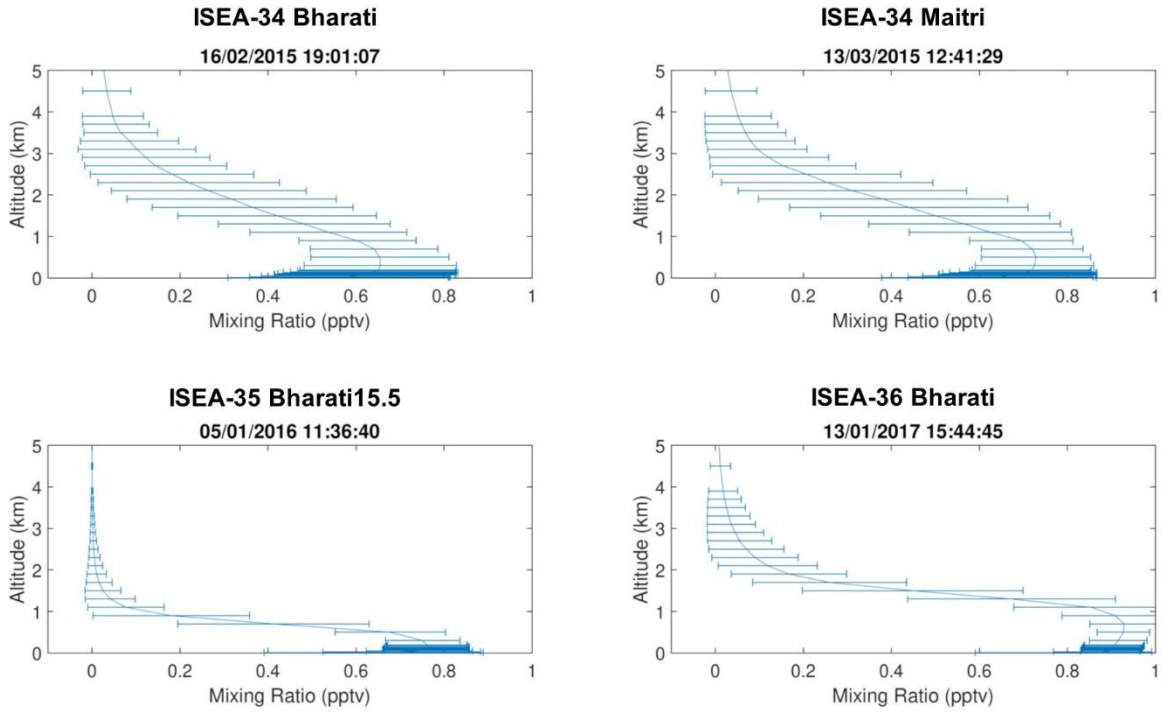

708

709

710 **Figure 7:** Observations of IO vertical column densities observed through all the four campaigns
 711 are shown. These data were mostly during periods of clear sky, and where IO was observed above
 712 the detection limit for most of the set elevation angles, enabling a reliable profile retrieval.

713

714

715 **Figure 8:** Typical examples of IO vertical profiles retrieved during all the four campaigns are
 716 shown.

717

718

719 **Figure 9:** Averaged VCDs of IO as retrieved by SCIAMACHY between 2004-2011 are shown.
 720 Observations suggest that lower levels of IO are expected at Bharati and Maitri, as compared to
 721 Halley Bay and Neumayer.

722

723

724 **Figure 10:** Timeseries of IO VCD observations at the Bharati station as retrieved by
 725 SCIAMACHY. The monthly mean values are shown in blue, and the daily datapoints are shown
 726 in red.
