20 **Abstract**

We present a satellite-derived global dust climatological record over the last two decades, including the monthly mean visible dust optical depth (DAOD) and vertical distribution of dust extinction coefficient at a 2° (latitude) \times 5° (longitude) spatial resolution derived from CALIOP and MODIS. Dust is distinguished from non-dust aerosols based on particle shape information (e.g., lidar depolarization ratio) for CALIOP, and on dust size and absorption information (e.g., fine-mode fraction, Angstrom exponent, and single-scattering albedo) for MODIS, respectively. On multi-year average basis, the global (60°S - 60°N) and annual mean DAOD is 0.029 and 0.063 derived from CALIOP and MODIS retrievals, respectively. In most dust active regions, CALIOP DAOD generally correlates well with the MODIS DAOD, with CALIOP DAOD being significantly smaller. CALIOP DAOD is 18%, 34%, 54% and 31% smaller than MODIS DAOD over Sahara Deserts, the tropical Atlantic Ocean, the Caribbean Sea, and the Arabian Sea, respectively. Over East Asia and the northwestern Pacific Ocean (NWP), however, the two datasets show weak correlation. Despite these discrepancies, CALIOP and MODIS show similar seasonal and interannual variations in regional DAOD. For dust aerosol over NWP, both CALIOP and MODIS show a declining trend of DAOD at a rate of about 2% yr^{-1} . This decreasing trend is consistent with the observed declining trend of DAOD in the southern Gobi Desert at a rate of -3% yr^{-1} and -5% yr^{-1} according to CALIOP and MODIS, respectively. The decreasing trend of DAOD in the southern Gobi Desert is in turn found to be significantly correlated with an increasing trend of vegetation and a decreasing trend of surface wind speed in the area.

1 Introduction

Mineral dust, referred to as dust for short, is one of the most abundant type of atmospheric aerosol in terms of dry mass (Textor et al. 2006; Yu et al. 2012; Kok et al. 2017). Dust aerosol directly interacts with both solar and thermal infrared radiation, known as the direct radiative effect, and thereby influences the Earth's radiative energy budget (Kok et al, 2017; Song et al., 45 2018; Di Biagio et al. 2020). Dust also influences the life cycle and properties of clouds by altering the thermal structure of the atmosphere (known as semi-direct effects) (Hansen et al., 1997) and by acting as cloud condensation nuclei (CCN) and ice nuclei (IN) (known as indirect effects) (Albrecht 1989; Rosenfeld and Lensky 1998; Twomey 1977). Dust storms and plumes 50 can degrade air quality and generate adverse impacts on human health (Griffin, 2007; Querol et al., 2019). Dust also contains a variety of nutrients and the deposition of dust during transport provides essential nutrients to marine and terrestrial ecosystems (Jickells et al. 2005; Yu et al., 2015b). The deposition of dust on snow reduces the snow albedo and promotes snow melting (Painter et al., 2007). All these impacts manifest the important role of mineral dust in the Earth 55 systems (e.g. Evan et al., 2006; Lau & Kim, 2007; Miller & Tegen, 1998; Shao et al., 2011)

Dust production is sporadic in nature and it can be transported on intercontinental, hemispherical, and even global scales (Grousset et al. 2003; Uno et al. 2009; Yu et al. 2012, 2013). Thus, global and routine measurements of dust spanning over years or even decades are 60 vital for studying dust transport and deposition, estimating the dust radiative effects, and evaluating and constraining dust simulations in numerical weather and climate models. Satellite remote sensing is the only means to observe dust on regional to global scales. Satellite remote sensing techniques usually retrieve the optical depth or extinction profile for total aerosol in the

atmosphere with additional retrievals of particle size, shape, or absorption properties that are
65 sensor specific. Passive sensors, such as the Total Ozone Mapping Spectrometer (TOMS)
(Prospero et al., 2002), Ozone Monitoring Instrument (OMI) (Chimot et al. 2017), Multiangle
Imaging SpectroRadiometer (MISR) (Ge et al., 2014 and Y. Yu et al. 2019), Moderate
Resolution Imaging Spectroradiometer (MODIS) (Ginoux et al., 2010; Remer et al., 2005; Yu et
al., 2009), multi-angular and polarimetric POLDER/PARASOL measurements (Chen et al. 2018)
70 and IASI (Klüser et al., 2011; Clarisse et al. 2019) are used to detect dust sources and track dust
plumes at global scales. On one hand, these passive sensors provide global or quasi global
coverage of column integrated properties of aerosol with satisfactory temporal resolution. On the
other hand, they do not provide the vertical structure of aerosol that is critical for studying
aerosol-cloud interactions and aerosol influences on the thermal structure of the atmosphere.
75 Space-borne lidar systems, such as the Cloud-Aerosol Lidar with Orthogonal Polarization
(CALIOP) onboard the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation
(CALIPSO) spacecraft (Winker et al., 2010) and the Cloud-Aerosol Transport System (CATS)
onboard the International Space Station (Yorks et al. 2015) are able to provide the vertical
structure of aerosol and clouds, albeit with limited spatial coverage. All these passive and active
80 remote sensing observations have been used extensively in studies of the spatial and temporal
evolution of aerosol over the past decade (e.g., Proestakis et al. 2018).

A significant hurdle of applying satellite remote sensing measurements for dust studies is
how to distinguish dust from other aerosol types in a quantitative way. While many studies have
85 used total aerosol retrievals by focusing on regions and seasons where dust dominates, some
studies have developed sensor-specific methods of partitioning total aerosol into dust and non-

dust components with varying assumptions (Kaufman et al., 2005; Kalashnikova et al. 2005; Dubovik et al. 2006; Ginoux et al., 2010; Yu et al., 2009, 2013, 2015a, 2019). In general, the dust separation methods are based on dust physical and optical properties such as their large size, 90 their irregular or nonspherical shape, and absorption characteristics. For example, CALIOP dust classification is mainly based on the fact that dust aerosols are nonspherical in shape and their lidar depolarization ratio is significantly larger than those spherical aerosols. In contrast, the wide spectral coverage of MODIS measurements enables the retrieval of aerosol particle size information, such as effective radius, fine-mode fraction (FMF), and aerosol extinction 95 Angstrom exponent, as well as spectral gradient of absorption (decreasing of absorption from UV to red) (Remer et al., 2005). The combinations of these retrievals provide the basis for dust separation and DAOD retrievals from MODIS. Some recent studies have also characterized dust distribution through integrating satellite measurements with other data sources and model simulations. For example, Voss and Evan (2020) developed a dust optical depth record from 100 MODIS retrievals, similar to Kaufman et al. (2005) over ocean and Ginoux et al. (2012) over land. Unlike Kaufman et al. (2005) and Yu et al. (2020) that derived characteristic FMF values for combustion, dust, and marine aerosol from MODIS retrievals, Voss and Evan (2020) determined these characteristic FMFs from AERONET measurements. Voss and Evan (2020) also extended the MODIS-based method to AVHRR over-ocean retrievals with some 105 assumptions and produced the long-term (1981-2018) record of dust optical depth. Gkikas et al. (2020) developed a global fine resolution ($0.1^\circ \times 0.1^\circ$) DAOD dataset for the period 2006-2017 by scaling MODIS retrieved AOD with the DAOD-to-AOD ratios provided by MERRA-2 (Modern-Era Retrospective analysis for Research and Applications, Version 2) reanalysis (Gelaro et al., 2017). Given that MODIS and other remote sensing measurements (e.g., MISR

110 and AERONET) have been assimilated in the MERRA-2 reanalysis to constrain the aerosol optical depth, the DAOD-to-AOD ratio reported by MERRA-2 is the same as that from the underlying GOCART aerosol transport model in the MERRA-2 reanalysis system.

In this study, we focus on the dust optical depth derived from CALIOP and MODIS with two
115 major objectives. First, we produce a decadal (2007-2019) record of global DAOD and dust vertical extinction coefficient profile climatology from the CALIOP observations, which represents an extension of the trans-Atlantic dust transport and deposition studies by Yu et al. (2015a, 2015b, 2019), both in terms of spatial and temporal coverages. Second, we compare the CALIOP DAOD climatology with the MODIS DAOD over both land and ocean (Yu et al. 2020;
120 Pu and Ginoux, 2018) to identify and understand their differences in terms of global dust distribution and interannual variabilities including decadal trend in key dust regions. Our analysis goes beyond broad dust-laden regions by zooming into potential dust source areas, which provides important insights into local dust activities. A systematic comparison and better understanding of DAOD from the two sensors based on distinct retrieval algorithms is critical for
125 applying satellite measurements to evaluate global dust modeling (Kim et al. 2019). In comparison to some most recent studies (Voss and Evan, 2020; Gkikas et al. , 2020), our dust climatology is derived by using the satellite observations in a self-consistent way without blending in other measurements (e.g., AERONET) or models (e.g., MERRA-2) (see section 2 for details). As discussed in Yu et al. (2009), the self-consistent use of MODIS data could minimize
130 the introduction of additional biases due to discrepancies in FMF between MODIS and AERONET. Furthermore, we use the latest version 4.2 CALIOP products and version 6.1 MODIS products in this study to characterize the three-dimensional distributions of dust. The

rest of the paper is organized as follows. Section 2 provides a description of the methodology of deriving dust climatology from CALIOP and an overview of MODIS dust retrieval algorithm.

135 Section 3 provides the main results including analysis of CALIOP dust climatology data and its comparison against MODIS dust data. Section 4 discusses the uncertainties in CALIOP as well as MODIS DAOD retrievals. Section 5 provides a summary of the study along with the main conclusions.

2 Dust Detection and AOD Partition Schemes

140

2.1 CALIOP Dust Detection and AOD Partition

CALIPSO is in a sun-synchronous polar orbit with an equator crossing time of around 13:30 local time and 98° orbit inclination. CALIOP is a two-wavelength (532nm and 1064nm) polarization-sensitive lidar onboard CALIPSO. CALIPSO orbit track repeats every 16 days,

145 CALIOP sensor never provides global coverage due to its small footprint. At Earth's surface, the diameter of CALIOP footprint is around 70m, with spacing distance of 333m between two adjacent footprints along the orbit track. CALIOP utilizes three receiver channels (one measuring the 1064nm backscatter intensity and two measuring orthogonally polarized components of the 532nm backscatter) to provide high vertical resolution 30-60m of aerosol and cloud structure

150 profiles (Winker et al., 2009).

Aerosol subtype classification and a priori assumption of lidar ratio for specific aerosol type are critical for CALIOP aerosol retrievals. CALIOP Level 2 product has been validated by comparing with ground-based measurements. The comparison between aerosol subtypes in CALIOP level 2 V2.01 and NASA Aerosol Robotic Network (AERONET) aerosol types shows

155 that 70% of the CALIOP and AERONET aerosol types are in agreement. Best agreement is

achieved for dust and polluted dust (Mielonen et al. 2009). Schuster et al. (2012) compared CALIOP AOD to the collocated AERONET AOD measurements and found a CALIPSO bias of -13% , corresponding to an absolute bias of -0.029 relative to AERONET AOD on global average. Further comparison between CALIPSO AOD measurements and the collocated
160 AERONET AOD measurements for the columns that contain the dust subtype exclusively showed a larger bias (i.e., -29% and corresponding absolute bias of -0.1), although they show a relatively high correlation of $R=0.58$; this indicates that the assumed lidar ratio (40 sr) for the CALIPSO dust retrievals is too low. Omar et al. 2013 showed that CALIOP AOD are lower than AERONET AOD especially for low AOD. Furthermore, they found that the median of relative
165 AOD difference between CALIOP and AERONET (500nm) is 25% of AERONET AOD for $\text{AOD} > 0.1$.

CALIOP observations have been used widely in previous studies of the spatial and temporal evolution of dust aerosols over the past decade (Huang et al. 2007, 2008; Yang et al. 2012; Xu et al. 2016; Kim et al., 2019). It is important to note that these studies are regional in scope and
170 they use the standard CALIPSO product and aerosol subtype classification algorithm (Omar et al. 2009). In the standard CALIPSO product, each detected aerosol layer is classified as one of the six subtypes: dust, polluted dust, polluted continental, smoke, clean marine and clean continental. In the latest CALIOP version, another sub-type “marine-dust” is introduced (Kim et al. 2018). In these studies, the “dust” subtype or a combination of “dust” and “polluted dust” subtypes is
175 categorized as dust. While the former assumption leads to an underestimate of dust due to neglecting dust component in the “polluted-dust” subtype, the latter assumption results in an overestimate of dust because of accounting for non-dust component in the “polluted-dust” subtype. In order to better distinguish dust component from each CALIOP detected aerosol

layers, Yu et al. (2015a) developed an algorithm independent of the standard aerosol subtype
180 classification to distinguish dust from non-dust aerosol by using their respective thresholds of
particulate depolarization ratio. They further used the derived three-dimensional distribution of
dust extinction to quantify the trans-Atlantic dust transport and deposition and its implications
for Amazon rainforest (Yu et al., 2015b, 2019).

185 In this study, we use the methodology in Yu et al. (2015a) to derive the monthly mean dust
extinction profile under clear-sky conditions from the latest V4.20 CALIOP products on a global
scale from 2007 to 2019. First, we select the clear-sky profiles based on the operational CALIOP
vertical feature mask and cloud layer product. In order to increase the sampling, we define clear-
sky cases in this study either as columns that are completely cloud-free or with the presence of
190 optically thin (cloud optical depth < 0.2) and high-level (cloud base $> 7\text{km}$) clouds. This is
justified that the presence of high-level optically thin clouds does not significantly affect the
retrieval of aerosol layers below the clouds (Yu et al. 2015a). After clear-sky screening, we use
the operational 5 km level 2 CALIOP aerosol profile product that contains aerosol
depolarization, backscatter and extinction profiles over a global scale (Young et al. 2018) to
195 derive the dust extinction profile. The depolarization ratio from CALIOP is a key variable for
detecting and distinguishing dust from non-dust aerosol. Backscatter by spherical particle largely
retains the polarization of the incident light, resulting in a depolarization ratio of nearly zero. In
contrast, dust particles are generally non-spherical in shape and large in size, which gives them
non-zero depolarization ratio that is significantly larger than other types of aerosol. The cloud-
200 aerosol discrimination (CAD) score in the products gauges the level of confidence for a feature
being classified as aerosol or cloud. In this study, in order to screen out low-confidence aerosol

and cloud discrimination, we select layers with CAD scores between -90 and -100 (high level of confidence for aerosol feature) by following Yu et al. (2019). Aerosol profile product also provides extinction quality control flag (Ext_QC) to indicate problematic retrievals. This study
205 only uses layers with Ext_QC values of 0, 1, 18, and 16 (Winker et al., 2013). Only nighttime data are used to avoid sunlight interference in aerosol signals.

For each backscatter coefficient profile, we derive the fraction of dust backscatter to total backscatter (f_d) at each altitude from the following equation

$$f_d = \frac{(\delta - \delta_{nd})(1 + \delta_d)}{(\delta_d - \delta_{nd})(1 + \delta)}, \quad (1)$$

where δ is CALIOP observed particulate depolarization ratio, δ_d and δ_{nd} is a priori knowledge
210 of depolarization ratios of dust and non-dust aerosols respectively. Clearly, the calculations of f_d in Eq. (1) rely on the a priori depolarization ratios of dust and non-dust aerosols (i.e., δ_d and δ_{nd}). To account for various types of non-dust aerosols with different depolarization ratio, we follow Yu et al. 2015a and assume 0.02 and 0.07 as lower and upper bounds for δ_{nd} (Burton et al., 2012; Fiebig et al., 2002; Sakai et al., 2010). Dust aerosols have significantly larger
215 depolarization ratio compared to non-dust aerosols. In order to account for the variability of dust shape and size, we use 0.2 and 0.3 as lower and upper bounds for δ_d (Ansmann et al., 2012; Esselborn et al., 2009; Sakai et al., 2010). Given an observed dust depolarization ratio δ , the f_d based on Eq. (1) has the minimum value when $\delta_d = 0.30$ and $\delta_{nd} = 0.07$ and the maximum value when $\delta_d = 0.20$ and $\delta_{nd} = 0.02$. In order to account for this variability, the final f_d is
220 based on the mean of the lowest (i.e., $\delta_d = 0.30$ and $\delta_{nd} = 0.07$) and the highest (i.e., $\delta_d = 0.20$ and $\delta_{nd} = 0.02$) dust scenario. The DAOD is also calculated for low dust and high dust scenarios for uncertainty study in section 4.

Dust backscatter coefficient profiles are derived by multiplying CALIOP total backscatter
225 coefficient with the calculated f_d from Eq. 1. In order to derive dust extinction coefficient from
dust backscatter coefficient, we assume dust lidar ratio (LR), i.e., extinction to backscatter ratio,
of 44 sr at 532nm, consistent with CALIOP Version 4.20 operational retrieval (Kim et al., 2018).
The use of globally uniform LR could also induce uncertainty to the derived regional DAOD,
which is discussed in section 4.

230

2.2 MODIS Dust Detection and AOD Partition

As described above, the CALIOP-based DAOD derivation mainly makes use of dust non-
sphericity in shape to separate dust aerosol from others. Another important difference of dust
aerosol from other types of aerosols is their relatively large size. This difference provides the
235 basis for the dust separation and DAOD derivation scheme based on the Moderate Resolution
Imaging Spectroradiometer (MODIS) retrievals that is introduced in this section.

MODIS sensors onboard of the Aqua and Terra satellites measure radiances at 36 spectral
bands ranging from 0.41 to 14 μm , with a 2330 km swath that provides near-global coverage
240 every day. As aforementioned, we use CALIOP nighttime observations to avoid solar
contamination. However, MODIS AOD retrievals rely on the solar reflective bands and therefore
are only available during daytime. Kittaka et al., 2011 shows that daytime and nighttime global
seasonal-mean AOD distributions for JJA 2006 from CALIOP are generally similar in both
outflow and source regions (see their Figure 1). It is difficult to tell what caused the minor
245 differences because it could be a combination of different calibration procedures and algorithms
for day and for night, different spatial sampling, and diurnal changes in the aerosol. Based on

this consideration, we choose to use the nighttime CALIOP product that is free of solar noise, in hoping that the better data quality would outweigh the diurnal difference between nighttime CALIOP product and daytime MODIS retrievals.

250

MODIS aerosol retrievals employ two complementary algorithms to achieve the global coverage. The Dark Target (DT) algorithm is applicable for the retrieval of aerosol loading and properties over dark surfaces, including ocean-water and vegetated land. The MODIS aerosol AOD retrievals over ocean are found within the retrieval errors of $\Delta\tau_a = \pm 0.03 \pm 0.05\tau_a$ relative to AERONET AOD measurements (Remer et al. 2005). An approach was developed in previous studies to separate DAOD from other types of aerosol by using aerosol optical depth τ and fine mode fraction retrieved from MODIS DT retrieval over ocean (details can be found in Kaufman et al., 2005; Yu et al., 2009, 2020). Over land, MODIS aerosol properties including AOD, Angstrom exponent, SSA are retrieved from the Deep Blue (DB) algorithm (Hsu et al. 2004, 2013). The MODIS aerosol AOD retrievals over land are found within the retrieval errors of $\Delta\tau_a = \pm 0.05 \pm 0.15\tau_a$ relative to AERONET AOD measurements (Remer et al. 2005). To separate dust from scattering aerosols, it is required that the single-scattering albedo at 470nm to be less than 0.99. Then a continuous function relating the Angstrom exponent to fine-mode AOD is used to separate dust from fine particles (more details can be found in Pu and Ginoux, 2018).

265 Overall, multi-wavelength observations from MODIS contains aerosol size information such as fine-mode fraction and Angstrom exponent in the observed reflectance spectral pattern, which was used to separate dust aerosol from others in MODIS dust retrieval over ocean and land. In this study, the latest retrieved aerosol properties from MODIS Collection 6.1 are used. We use data from Aqua MODIS only, because Terra MODIS retrievals may generate spurious dust trend

270 (Yu et al. 2020). In order to minimize cloud contamination and avoid the infrequent sampling to
bias DAOD in MODIS dust retrieval over ocean, we screen the data by requiring a minimum of
10 DAOD retrievals in a month.

3 Global Dust Climatology

Based on the dust detection and separation schemes of two sensors described above, we derived
275 the following two datasets:

1. The monthly mean CALIOP-based total aerosol optical depth (TAOD) and DAOD, as well
as the vertical extinction profile on a 2° (latitude) \times 5° (longitude) spatial resolution grids for
the period of 2007 – 2019. This relatively coarse resolution is limited by CALIOP's sampling.
2. We combine the monthly mean Aqua MODIS over-ocean (Yu et al., 2020) and over-land (Pu
280 and Ginoux, 2018) TAOD and DAOD on a $1^\circ \times 1^\circ$ spatial resolution grids to get the monthly
mean MODIS-based TAOD and DAOD from 2003 to 2019. In order to compare with
CALIOP-based dust climatology data, we aggregate the $1^\circ \times 1^\circ$ MODIS-based data to $2^\circ \times 5^\circ$
resolution grids.
3. For evaluation and comparison purpose (see section 3.1), we also produce a seasonal global
285 distribution of conditionally sampled DAOD from CALIOP. Different from the
climatological DAOD introduced above, where we include all cloud-free cases in the average
of dust extinction and DAOD regardless of the presence of dust or not. In other words,
DAOD and dust extinction are assumed to be zero when no dust is detected. In the
conditionally sampled DAOD calculation, we only average those cases where dust is
290 detected (i.e., DAOD and dust extinction are non-zero). Therefore, the conditionally sampled
DAOD is directly related to the intensity of the detected dust events, whereas the
climatological DAOD is determined by a number of factors including not only the intensity

of the detected dust events but also the frequency of the dust events as well as the capability of the instrument to sample the dust events.

295

In this section, we compare shape-based CALIOP global dust retrieval against size-based MODIS dust retrieval, more specifically MODIS ocean dust retrieval from Yu et al. (2009, 2020) and land dust retrieval from Pu and Ginoux (2018), we analyze the similarities and differences between two dust climatology data and furthermore study seasonal cycle and decadal trend of dust aerosols based on these datasets.

300

3.1 Comparison between CALIOP and MODIS dust Climatology

The DAOD climatology datasets derived from the CALIOP and MODIS observations, as described in the last section, have two major sources of uncertainty:

1) The uncertainty associated with the AOD retrieval. The primary uncertainty sources in MODIS AOD retrieval include instrument calibration errors, cloud-masking errors, inappropriate assumption of surface reflectance and aerosol model selection (Remer et al. 2005; Levy et al. 2013, 2018). Uncertainty sources in CALIOP aerosol retrieval include instrument calibration errors, errors in discriminating cloud from aerosol, uncertainties associated with the a priori assumption of lidar ratios, and the under detection of tenuous aerosol layers, and overestimation of the elevation height of heavy aerosol plume base (Winker et al. 2009; Yu et al., 2010; Schuster et al., 2012; Thorsen and Fu, 2015; Rajapakshe et al. 2017).

310

2) The uncertainty associated with dust detection and separation. As explained in section 2, CALIOP- and MODIS-based dust detection and separation methods are based on different characteristics of dust aerosols in comparison with other types of aerosols, as summarized in Table 1. CALIOP-based method makes use of the fact that depolarization ratio of dust aerosols is

315

much higher than other types of aerosols, primarily because of irregular non-spherical shape and also to a lesser extent because of coarse size of dust particles. MODIS-based method is largely based on the characteristics of coarse particle size. Over ocean, DAOD is derived from total aerosol AOD (TAOD) and fine mode fraction (FMF) with a priori characteristic FMF for individual aerosol types. Over land, DAOD is derived using spectral dependence of aerosol extinction (i.e., Angstrom exponent) and single scattering albedo. In other words, MODIS retrieves DAOD based on dust size supplemented by absorption characteristics.

Given these retrieval uncertainties and methodological differences, some discrepancies between the two DAOD climatology datasets are expected. In this section, we will compare the two datasets to identify and understand their similarities and differences. Since the mechanisms of dust generation, dust transport and dust removal processes all have a seasonal cycle (Mbourou et al. 1997; Parrington et al. 1983), we first present and discuss dust spatial distributions for each season in this section. Table 2 summarizes the seasonal and annual mean DAOD and TAOD values averaged over ocean, land and the globe (all limited to 60° S-60° N), respectively, based on MODIS and CALIOP dust retrievals from 2007 to 2019. On multi-year average basis, the global, annual mean DAOD (TAOD) is 0.029 (0.112) and 0.063 (0.167) according to CALIOP and MODIS retrieval, respectively. Generally, DAOD from two retrievals differ by a factor of about 3 over ocean and less than 2 over land, while TAOD differ by a factor of less than 2 over both ocean and land. The ratio of DAOD over land to that over ocean is about 2 and 3 for MODIS and CALIOP, respectively. For TAOD, the land to ocean ratio is about 2 for both products. Overall, the difference in TAOD between two retrievals is less than their difference in DAOD. On a global average, both MODIS and CALIOP-based DAOD peaks in boreal summer (June-July-August). DAOD reaches minimum in boreal Fall (September-October-November) for

MODIS but in boreal Winter (December-January-February) for CALIOP. The MODIS and
340 CALIOP differences are region dependent, which is discussed as follows.

Figure 1 shows the spatial distribution of seasonal mean DAOD and the percentage of
DAOD to the TAOD based on 13-year (2007-2019) CALIOP and MODIS observations. Note
that this period is chosen because both datasets are available. Generally, MODIS-based DAOD is
larger than CALIOP-based DAOD. As expected, high values are seen from both CALIOP-based
345 and MODIS-based DAOD over the ‘dust belt’ regions extending from the west coast of North
Africa to the Middle East, Central Asia, and China, where large-scale dust activities occur
persistently throughout the year. However, the CALIOP-based DAOD is rather low in some
other regions that are known to be dusty in certain seasons, such as the southwestern United
States, South America (Patagonian Desert), Australia, and South Africa (i.e., Kalahari Desert).
350 These regions do stand out in MODIS DAOD maps (i.e., the second column in Figure 1).
Interestingly, these regions indeed show up in the DAOD to TAOD ratio plot based on both two
sensors (i.e., the last two columns in Figure 1). One of possible reasons for this is that dust
activities in those regions are more intermittent and CALIOP’s narrow swath results in more
frequent miss of detection than MODIS does. To test this hypothesis, we compare the seasonal
355 climatological DAOD and conditional DAOD product. The second column of Figure 2 shows the
seasonal climatological DAOD which is the average dust load over a geographical domain and
time interval. It contains information of both the intensity and frequency of dust activities. On
the other hand, the seasonal conditionally sampled DAOD shown in the first column of Figure 2
eliminates the impacts from dust frequency by excluding dust-free cases in the average. It is
360 mainly related to the intensity of observed dust events. Therefore, the comparison between
climatological and conditionally sampled DAOD sheds a light on the frequency and intensity of

dust events. For example, the third column in Figure 2 shows the relative difference between conditionally sampled DAOD and climatological DAOD with respect to the climatological DAOD. In ‘dust belt’ regions, especially in Sahara Desert and Middle East where dust activities
365 are persistent, climatological DAOD is very close to conditional DAOD. In Australia, Southwest United State, South America and South Africa, however, the conditional DAOD (column 1 in Figure 2) and the difference (column 3 in Figure 2) are relatively high. This suggests that dust activities in those regions are highly episodic and/or occur in relatively small scales. As a result, the dust events in those regions are prone to be missed by CALIOP due to its once-a-day
370 sampling over limited spatial coverage. Even if the episodic dust events are sampled by CALIOP, the monthly averaging would diminish the sparse daily DAOD retrievals in those regions. Indeed, Prospero (1999) reported that dust signals were shown in the daily TOMS aerosol index (AI) product in those regions but were not captured in TOMS monthly-mean AI product. The difference also is very large in open oceans, suggesting that dust aerosols are present at a very
375 low frequency.

Having analyzed the conditionally sampled DAOD from CALIOP, we now return to climatological DAOD and comparison between CALIOP and MODIS. Hereafter, all AOD values are climatological without otherwise explicit statement. Figure 3 shows the difference in
380 seasonal mean TAOD, DAOD and the percentage of DAOD in TAOD between MODIS retrievals and CALIOP retrievals. We note in Figure 3 that CALIOP-based DAOD is generally smaller than MODIS-based DAOD over Northeast Asia and Asian dust outflow region (Northwest Pacific-NWP). There could be several reasons for this. First, this region is a major outflow region of Asian pollution (Yu et al., 2020). It is possible that the internal mixing of dust

385 aerosols with industrial pollution in this region changes the dust morphology making it less non-
spherical (Li and Shao 2009) but larger in size, which leads to smaller depolarization ratio and
smaller fine-mode fraction. As a result, CALIOP shape-based DAOD derivation method could
not capture the dust particles contained in the mixture, while those dust particles can be captured
by MODIS size-based method. Another potential reason could be associated with that dust
390 plumes in this region are vertically dispersed (Yu et al., 2010; Su and Toon, 2011). These
tenuous dust layers are likely to go undetected by CALIOP because of its relatively low
sensitivity. However, MODIS retrieves aerosol from the columnal integrated reflectance which is
not dependent on the vertical distribution of aerosol.

The difference may also be caused by uncertainties in MODIS aerosol retrievals. The
395 West Pacific Ocean is cloudy almost all year long (see the last column in Figure 3), which makes
MODIS aerosol retrievals being susceptible to cloud contamination. The cloud contamination
can lead to an overestimation of TAOD but underestimation of FMF. Although the MODIS
retrieval algorithm neither assume coarse particles are exclusively from dust aerosols nor assume
dust particles are all coarse particles (Yu et al., 2020), coarse mode aerosols are primarily dust.
400 Thus, the overestimation of TAOD and underestimation of FMF will lead to an overestimation in
DAOD. An exception occurs during winter when cloud fraction is large in NWP. The MODIS-
based DAOD is smaller than CALIOP-based DAOD, even though MODIS TAOD is larger than
CALIOP TAOD. Similarly, over the southeastern Atlantic Ocean, CALIOP-based DAOD is also
generally smaller than MODIS-based DAOD. On one hand, cloud contamination may have
405 biased the MODIS dust retrieval high. On the other hand, CALIOP clear-sky sampling is not
large enough to capture some dust events in this region. In southern part of Sahel and India,
MODIS-based DAOD is generally smaller than CALIOP-based DAOD.

We further compare DAOD (Figure 5) and TAOD (Figure S1 in the supplementary) retrievals from CALIOP and MODIS over major dust laden regions (as shown in Figure 4), including three source regions on land (i.e., Sahara Desert, Middle East and Eastern Asia) and six oceanic outflow regions (i.e., the tropical Atlantic Ocean - TAT, the Caribbean Basin - CRB, the Mediterranean Sea - MED, the northwest Pacific Ocean - NWP, the Arabian Sea - ARB as well as the tropical Indian Ocean and the Bay of Bengal - IND). Each data point in the scatter plot represents a monthly mean DAOD (or TAOD) in a $2^\circ \times 5^\circ$ grid. The density of data is represented by different color. To avoid our analysis being biased by some extreme and rare cases, we exclude those data points within the lowest 5% of data density (grey points in Figure 5). Overall, the DAOD from the two instruments correlate well ($R^2 > 0.5$) and on average CALIOP-based DAOD is 18%, 34%, 54% and 31% lower than MODIS-based DAOD over the Sahara (Figure 5a), TAT (Figure 5d), CRB(Figure 5e) and ARB(Figure 5h) regions, respectively. Over the Sahara Desert, the good agreement in DAOD between the two sensors (bias of 18% and $R^2 = 0.61$) suggests that over the Sahara Desert dust particles can be adequately characterized by both irregular non-spherical shape and coarse size. As a result, both CALIOP- and MODIS-based methods are able to detect and separate the dust from other types of aerosols. In TAT and ARB regions, two instruments correlate well ($R^2 > 0.7$) in both DAOD and TAOD. For TAOD, CALIOP is smaller than MODIS by 2% in TAT and larger than MODIS by 15% in ARB. By comparison differences in DAOD are larger, with CALIOP DAOD lower than the MODIS DAOD by 34% and 31% in TAT and ARB, respectively. This suggests that the differences in DAOD from the two instruments are mainly resulted from differences in the dust separation method. In East Asia and NWP, on contrast, both TAOD and DAOD show poor correlation between the two methods (Figure 5c, 5g, S1(c) and S1(g)). As discussed earlier, the poor

correlation between the two methods may be contributed by many factors. For example, the total TAOD retrievals from MODIS are subject to larger uncertainties due to cloud contamination, or the DAOD retrieval from CALIOP may miss spherical dust particles that are coated by large combustion emissions from East Asia.

435 Figure 6 compares annual cycle of MODIS and CALIOP DAOD based on the 13-year (2007-2019) average over the nine dust laden regions. Each data point represents domain-averaged 13-year mean DAOD for a month, while the error bar indicates $\pm 1\sigma$ (one standard deviation of DAOD). The seasonal cycles of dust activities and dust transport are consistent with results in literature (Prospero et al. 2002; Yu et al., 2012, 2015a). Generally, CALIOP and
440 MODIS show very similar seasonality over those dust laden regions. DAOD peaks in summer (JJA) over Sahara Desert, Middle East, TAT, CRB, ARB and IND, but in spring (MAM) over Eastern Asia, MED and NWP. Over NWP, the seasonal cycle of MODIS DAOD is somewhat different from that of CALIOP DAOD. While CALIOP DAOD peaks in spring, MODIS DAOD shows a peak in late spring or even summer months for some years. This could have resulted
445 from cloud contamination in MODIS retrievals due to the large cloud fraction in summer [Yu et al., 2020]. In addition, a secondary maximum of dust activity with high elevation plume in summer over the Taklamakan desert (Ginoux et al., 2001) may also contribute to the seasonality trend captured by MODIS over NWP.

 Compared to the MODIS dust retrieval, CALIOP has a unique capability of detecting
450 dust aerosol vertical distribution. Figure 7 shows seasonal mean dust extinction vertical profile from CALIOP for the nine dust-laden regions. The values on each plot represent the seasonal mean DAOD. Both DAOD and dust vertical structure have a seasonal dependence. In Sahara (a), Middle East (b) and their dust outflow regions the Tropical Atlantic (d) and the Arabian Sea (h),

summertime dust aerosol has the highest DAOD and reaches to the highest altitude extending
455 from surface up to 6km in altitude.

The analysis above has been performed over the broad dust-laden regions. Here we focus
on MODIS and CALIOP comparison in major potential source areas (PSAs) for dust in North
Africa, namely NAF-1 to NAF-6 as illustrated in Figure 8 (adapted from Fig. 1 in Formenti et al.,
2011). Among all dust source regions around the globe, the Sahara Desert and its margins in
460 North Africa are the largest dust emitter. Within this region, prominent dust sources are often
associated with topographical lows and foothills of mountains (Prospero et al. 2002). Figure 9
shows scatterplots of CALIOP DAOD against MODIS DAOD over the six PSAs (corresponding
scatterplots for TAOD are shown in Figure S2 in the supplementary), with each data point
representing a monthly average over $2^{\circ} \times 5^{\circ}$ grid. Seasonal variations of DAOD in the six PSAs
465 are shown in Figure 10. Striking CALIOP and MODIS differences in both DAOD and TAOD
exist in NAF-5 where the correlation is very weak. NAF-5 (14N-20N, 15E-20E) is located in
Bodélé Depression, Western Chad. This region is reported as the most intense dust source in the
world (Prospero et al. 2002), and dust activity in the region occurs with a high frequency during
all seasons except fall (Mbourou et al., 1997). However, CALIOP TAOD and DAOD are much
470 smaller than MODIS retrievals in this region. In terms of dust seasonality (Figure 10), the
MODIS DAOD indicates intense dust aerosol loading all year long with a lower DAOD in Fall,
while CALIOP shows a more distinct seasonality with the highest DAOD of about 0.3 in May-
July and the lowest DAOD of <0.1 in winter. Over other PSAs in North Africa, MODIS and
CALIOP DAOD are correlated well with $R^2 \geq 0.5$ in NAF-2, 3, 6 and agree well with the slope
475 close to 1 and average bias of 0.6 – 0.7 in NAF-2, 3, 4, 6 (Figure 9), and both dust retrievals
show similar seasonality (Figure 10).

In summary, MODIS and CALIOP DAOD show largest differences under the following conditions: (1) highly cloudy oceanic regions and (2) dust-pollution internal mixtures with high relative humidity. Their differences can be explained as follows.

- 480
1. Over cloudy ocean, cloud screening is critical to the quality of aerosol retrievals. As an active sensor, CALIOP is more reliable in discriminating clouds and aerosols than passive imager MODIS. In addition, active sensor is able to avoid impact from cloud side scattering. Therefore, MODIS is subject to more cloud contamination than CALIOP. Large cloud contamination in MODIS results in overestimation in TAOD and
485 underestimation in FMF, introducing a high bias in DAOD over ocean cloudy regions (e.g., NWP).
 2. Pure dust particles are hydrophobic and will not absorb water vapor. However, for dust aerosols coated by other types of aerosols (such as the deliquescent dust-nitrate $\text{Ca}(\text{NO}_3)_2$ and saline mineral dust particles emitted from saline topsoil in arid and semiarid areas (Tang et al. 2019), those types of dust particles will take up water vapor and grow to be larger in size and more spherical in shape (Wu et al. 2020). This
490 phenomenon is most prominent for dust aerosols in polluted region (e.g., EAS) as well as with relatively high relative humidity. While such coarse spherical dust particles will not be accounted as dust in CALIOP shape-based method, they are categorized as dust in the
495 MODIS size-based method.

3.2 DAOD Inter-annual variation from CALIOP and MODIS observations

In this section we examine the inter-annual variation of DAOD captured by two sensors over some major dust source and outflow regions. Figure 11 shows a global map of DAOD

500 interannual trend derived based on the 13-year (2007-2019) time series of annual mean DAOD from CALIOP and MODIS. DAOD trend are calculated for each $2^{\circ} \times 5^{\circ}$ grid. Red color indicates positive trend and blue negative trend. Regions where the trend is statistically significant ($p < 0.05$) are marked with symbol '+'. The similar trend map for total aerosol optical depth is shown in Figure S3 in the supplementary. Overall, DAOD global pattern of interannual trend is similar to TAOD in major dust-laden regions. For example, Over Sahara Desert and tropical Atlantic Ocean region, both CALIOP and MODIS do not show statistically significant trend in DAOD and TAOD. In East Asia and the northwest Pacific Ocean, both sensors show negative trend in DAOD and TAOD.

Figure 12 displays interannual variability of annual-mean DAOD for the major dust-laden regions as defined in Figure 4. Seasonal and annual DAOD trends in the nine regions are listed in Table 3. Both MODIS and CALIOP show a clear DAOD trend in certain seasons over the Eastern Asia, ARB and NWP regions. In Eastern Asia, MODIS and CALIOP show a consistent DAOD decreasing trend at a rate of $-1.7\% \text{ yr}^{-1}$ annually. The two sensors show a DAOD decreasing trend of $-3.5\% \text{ yr}^{-1}$ and $-2.5\% \text{ yr}^{-1}$ respectively in Eastern Asia during spring and 515 show a consistent trend of DAOD in ARB during the fall, though with a factor of 2 difference in magnitude. In NWP, both MODIS- and CALIOP-based DAOD shows a decreasing trend of $-1.7\% \text{ yr}^{-1}$ and $-1.6\% \text{ yr}^{-1}$, respectively. The annual DAOD decreasing trend in NWP is mainly attributed to the DAOD decline in spring at a rate of $-2.3\% \text{ yr}^{-1}$ and $-3.0\% \text{ yr}^{-1}$ for MODIS and CALIOP, respectively. For comparison, Shimizu et al. (2017) detect the decreasing 520 DAOD trends of $-4.3\% \text{ yr}^{-1}$ in spring and $-2.5\% \text{ yr}^{-1}$ on annual mean basis from the Asian Dust Network (AD-Net) lidar observations over Japan (2007-2016). These trends are greater than our results based on MODIS and CALIOP data records.

Dust over NWP comes mainly from East Asian dust sources. The broad East Asian region (ESA defined in Figure 4) show statistically significant DAOD decreasing trends (Figure 12c) which is consistent with the DAOD decreasing trend in NWP. It is also imperative to further examine which of six major PSAs in East Asia (ESA-1 to ESA-6 in Figure 7) contribute to the decreasing trend of DAOD. As shown in Figure 13, among the six PSAs, the satellite data show consistent interannual declining trend of DAOD in EAS-5 (Southern Gobi Desert) at a rate of $-4.8\% \text{ yr}^{-1}$ and $-2.8\% \text{ yr}^{-1}$ for MODIS and CALIOP, respectively. In spring, DAOD in EAS-5 shows a significantly declining trend at a rate of $-5.6\% \text{ yr}^{-1}$ and $-3.3\% \text{ yr}^{-1}$ for MODIS and CALIOP (Figure S4). Figure 14 assesses the correlation between DAOD in EAS-5 and DOAD in NWP based on MODIS and CALIOP, respectively. For annual mean DAOD from 2007 to 2019, both sensors show a good correlation between EAS-5 and NWP with $R^2 \approx 0.4$ ($p = 0.02$). In spring, the correlation of DAOD from two regions is slightly reduced based on CALIOP ($R^2 = 0.36$, $p = 0.03$), while a much weaker correlation ($R^2 = 0.28$, $p = 0.07$) was found based on MODIS. We further examine potential factors contribute to the declining trend of DAOD in ESA-5. The first row in Figure 15 shows the springtime trend of MODIS enhance vegetation index (EVI), MERRA2 near-surface (at 10 m) wind speed and precipitation in EAS-5 region. While EVI shows a significantly increasing trend with $R^2 = 0.71$ ($p < 0.05$), the surface wind speed shows a decreasing trend with $R^2 = 0.36$ ($p < 0.05$). There is no significant trend for precipitation. The second and third row in Figure 15 shows the correlations of the three factors with MODIS DAOD and CALIOP DAOD, respectively. Clearly, EVI is anti-correlated with both MODIS and CALIOP DAOD with $R^2 > 0.42$ and $p < 0.05$. While the surface wind speed is correlated with MODIS DAOD with $R^2 = 0.53$ and $p < 0.05$, its correlation with CALIOP DAOD is weaker ($R^2 = 0.29$ and $p = 0.06$). Note that EVI and surface wind speed are not independent

variables that affect dust emissions. An increase of EVI or vegetation cover could reduce the surface wind speed. However, given the relatively coarse resolution of MERRA2, the surface wind speed trend may largely reflect the change in atmospheric circulations other than local wind decrease induced by more vegetation. The precipitation shows no statistically significant
550 correlation with MODIS and CALIOP DAOD.

As discussed earlier, our results suggest that the decrease of NWP DAOD is likely a result of the decreasing dust events in Asian deserts (i.e., EAS-5 Gobi) in turn likely due to change of vegetation. This is also reported in several recent studies. Sternberg et al. (2015) found that Gobi
555 Desert contracted from 2000 to 2012 due to increased moisture availability. Song et al. (2016) used an Integrated Wind Erosion Modeling System to simulate the spring dust emissions in northern China over the period of 1982 to 2011. They found a significant decrease of the magnitude of spring dust event in China which is attributed to both climate change and local mitigation strategies. Similarly, An et al., (2018) also noted a significant decrease of dust storm
560 event in East Asian after analyzing observational data from ground stations, numerical modeling, and vegetation indices obtained from both satellite and reanalysis data. Over the last few decades, Chinese government has been taking actions to restore overgrazed land in Inner Mongolia, the enlarged vegetation coverage and the expected earlier vegetation green-up due to global warming could have mitigated dust activity in this region (Fan et al. 2014). Together the results from our
565 analysis, along with the aforementioned recent studies, suggest that the decreasing springtime DAOD trend in the NWP region is a result of the decline of dust activities in the Inner Mongolia (i.e., EAS-5) which is likely linked to vegetation coverage changes in recent years as a result of China's mitigation projects to hold back desertification.

Some caveats must be mentioned, however, when interpreting the trend analysis here. First
570 of all, due to the limitation of satellite data record, we have only 13 years' CALIOP data and 17
years' MODIS data available. Other climate variabilities, such as the El Nino-Southern
Oscillation (ENSO), could confound the trend analysis. For example, Abish and Mohanakumar
(2013) shows that La Nina (El Nino) weakens (strengthens) the zonal circulation over the Indian
subcontinent, which result in low (high) aerosol concentration over Indian subcontinent
575 transported from Arabian Desert over the period. Gong et al. (2005) also shows the impact of
ENSO on the interannual variability of Asian dust loading and deposition. According to the
NOAA Oceanic Nino Index (ONI), the climate switched from a strong La Niña phase in 2010-
2011 to a strong El Niño phase in 2015-2016. However, the potential impact of ENSO on the
dust inter-annual variability is beyond the scope of this study and will be left for the future
580 research.

4 Uncertainty Analysis

The uncertainty of CALIOP DAOD retrieval come from several sources: One is some
technical uncertainty such as instrument calibration errors, errors in discriminating cloud from
585 aerosol and failure to detect aerosol layers (including tenuous aerosol layer and the lower part of
heavy dust layer. For example, Thorsen and Fu (2015) estimated that CALIOP may have
underestimated 30%-50% in the magnitude of aerosol direct radiative effect due to its low
sensitivity to tenuous layer), which is likely to translate into low bias in DAOD. In heavy aerosol
conditions (e.g., strong dust storms in source regions and outflow regions), CALIOP laser cannot
590 penetrate to the bottom of aerosol layer due to the laser attenuation (Chamara et al., 2017). As a
result, CALIOP AOD is biased low. DAOD is also subject to uncertainty due to the assumption

of dust lidar ratio (extinction to backscatter ratio). Different deserts produce dust with different
minerology, thus different lidar ratio. Voss et al., (2001) measures LR for African dust as 41 ± 8
sr using a micropulse lidar and Liu et al. (2002) measures LR for Asian dust as 42-55 sr.
595 Globally observed lidar ratios are summarized in Müller et al., (2007) and Baars et al., (2016).
Typical lidar ratio values for desert dust aerosols range from 35sr to 55sr. This study assumes
dust lidar ratio to be 44 sr at 532nm, which is the value used in the CALIOP V4 product (M.-H.
Kim et al. 2018) and is comparable to previous studies and nevertheless induce potential
uncertainties to DAOD. When separating dust from non-dust aerosol, the choice of
600 depolarization ratio for dust aerosols and non-dust aerosols also introduces uncertainty in DAOD.
To quantify the uncertainty caused by DPR selection, we also calculated DAOD in the lowest
($\delta_d = 0.30$ and $\delta_{nd} = 0.07$) and the highest ($\delta_d = 0.20$ and $\delta_{nd} = 0.02$) dust fraction scenarios.
We estimated that the uncertainty in monthly DAOD is 35%-47% in regions with DAOD larger
than 0.06 and up to 80% in regions with very low DAOD.

605

MODIS dust detection is also subject to some uncertainties for both over ocean and over land
retrievals. Over ocean, the persistent presence of clouds in some regions (e.g., North Pacific
Ocean, southeastern Atlantic Ocean) pose a challenge to MODIS aerosol retrievals, probably
causing a high AOD bias, and low FMF bias, and thereby a high DAOD bias. In addition,
610 DAOD was calculated from the MODIS-retrieved AOD (τ) and FMF (f) with appropriate
parameterizations of marine aerosol AOD (τ_m), FMF of dust (f_{dust}), combustion (f_c) and marine
(f_m) aerosols. All the parameterizations could also introduce uncertainty in the derived DAOD,
in particular on a regional basis (see details in Yu et al. 2020). Over land, the derived MODIS
DAOD represents the coarse-mode fraction of dust only. The exclusion of fine mode of dust

615 aerosol at emission could induce a less than 10% underestimation of the emitted mass (Kok et al.
2017). The comparison of Aqua MODIS DAOD retrievals against AERONET coarse-mode
AOD shows that Aqua MODIS DAOD values are underestimated with an error of
 $0.08+0.52\text{DAOD}$ (Pu and Ginoux, 2018).

A rigorous way to evaluate these uncertainties and validate the two dust detection
620 methods is to compare with an independent measurement of DAOD. AERONET measurements
have been considered as ground truth and often used to evaluate satellite aerosol optical depth
retrievals. However, so far there is not a valid method to derive DAOD from AERONET AOD
measurements to compare our results with. Some studies use coarse-mode AOD from
AERONET measurements as a proxy for DAOD (Pu and Ginoux, 2018), while CALIOP-based
625 DAOD retrieval and MODIS-based oceanic DAOD retrieval do not assume dust aerosols are
exclusively coarse particles. Therefore, AERONET measurements could not be used to validate
DAOD retrievals in this study.

5 Summary and Conclusion

630 Following the methodology in Yu et al. (2015a), we extend the study in both temporal
and spatial scale to present monthly mean climatology data for dust aerosol horizontal and
vertical distributions on a global scale for the period from 2007 to 2019 based on MODIS and
CALIOP observations. Our product captures very well as much hot spots along the ‘dust belt’
region well, as weaker signals in other dust active regions such as Southwestern United States,
635 Patagonian Desert in South America, Central Australia, and South Africa (Figure 1). Since
DAOD climatology product contains and mixes the information of the intensity and frequency of
dust activities, we introduce the conditional DAOD product, which diminishes impacts from dust

frequency by excluding dust-free cases in the average. The comparison between DAOD climatology data and conditional DAOD data suggests that dust activities in those regions are highly episodic. As a result, the dust events in those regions may be missed by CALIOP which has a very limited spatial sampling coverage.

CALIOP distinguishes dust aerosols based on its non-spherical shape, whereas MODIS separates dust aerosols from others based on its large size characteristics. The discrepancy in dust retrieval based on two instruments are expected due to the uncertainty associated with their TAOD retrieval and the uncertainty associated with their different mechanism in dust detection and separation. The comparison between CALIOP dust retrieval and MODIS dust retrieval facilitate a better understanding of advantages and limitations of each dust product and also provide some insights on dust morphology and dust size. Through the comparison, we found generally CALIOP-based DAOD correlates well with MODIS-based DAOD over dust-laden regions such as Sahara, TAT, CRB and ARB, but with CALIOP-based DAOD 18%, 34%, 54% and 31% lower than MODIS-based DAOD over those regions respectively. This result is consistent with the different treatment of the dust-pollution mixtures in the dust separation approaches of two instruments. The better agreement ($k=0.82$) and correlation ($R^2=0.61$) in Sahara Desert suggest that dust aerosols are irregular non-spherical and at the same time large in size in this region. In some regions such as NWP, the DAOD correlation between two sensors is quite low. There could be many reasons for this, for example, the total TAOD retrievals from MODIS have larger uncertainty due to cloud contamination, or the DAOD retrieval from CALIOP may miss coarse spherical dust-pollution mixtures.

The interannual variability of DAOD over dust-laden regions show no clear trend except the NWP region at a rate of $-1.6\% \text{ yr}^{-1}$ and $-1.7\% \text{ yr}^{-1}$ based on CALIOP and MODIS

respectively, this trend is mainly attributed to the decreasing trend in spring with a rate of $-3.0\% \text{ yr}^{-1}$ based on CALIOP and $-2.3\% \text{ yr}^{-1}$ based on MODIS. Further investigation of DAOD trend in six dust source areas in Eastern Asian where NWP dust aerosols come from shows that there is an obvious decreasing trend in DAOD over Southern Gobi Desert based on both CALIOP and MODIS dust retrievals. The decreasing trend of DAOD is correlated significantly with the vegetation index and surface wind speed in the area, whereas there is almost no correlation with the precipitation.

665

Data availability. The global DAOD and dust vertical extinction coefficient climatology data
670 derived from CALIOP in this study and the MODIS DAOD retrieval data over ocean are
available at
[‘https://drive.google.com/drive/folders/1aQVupe7govPwR6qmsqUbr4fJQsp1DBCX?usp=shari
ng’](https://drive.google.com/drive/folders/1aQVupe7govPwR6qmsqUbr4fJQsp1DBCX?usp=sharing). The MODIS DAOD retrieval data over land can be requested from Dr. Paul Ginoux. The
MODIS Enhanced Vegetation Index (EVI) data could be downloaded from
675 [‘https://lpdaac.usgs.gov/products/myd13c2v006/#tools’](https://lpdaac.usgs.gov/products/myd13c2v006/#tools). The MERRA2 surface wind speed and
precipitation data are available at
[‘https://disc.sci.gsfc.nasa.gov/datasets/M2T1NXFLX_5.12.4/summary?keywords=%22MERRA-
2%22’](https://disc.sci.gsfc.nasa.gov/datasets/M2T1NXFLX_5.12.4/summary?keywords=%22MERRA-2%22).

705

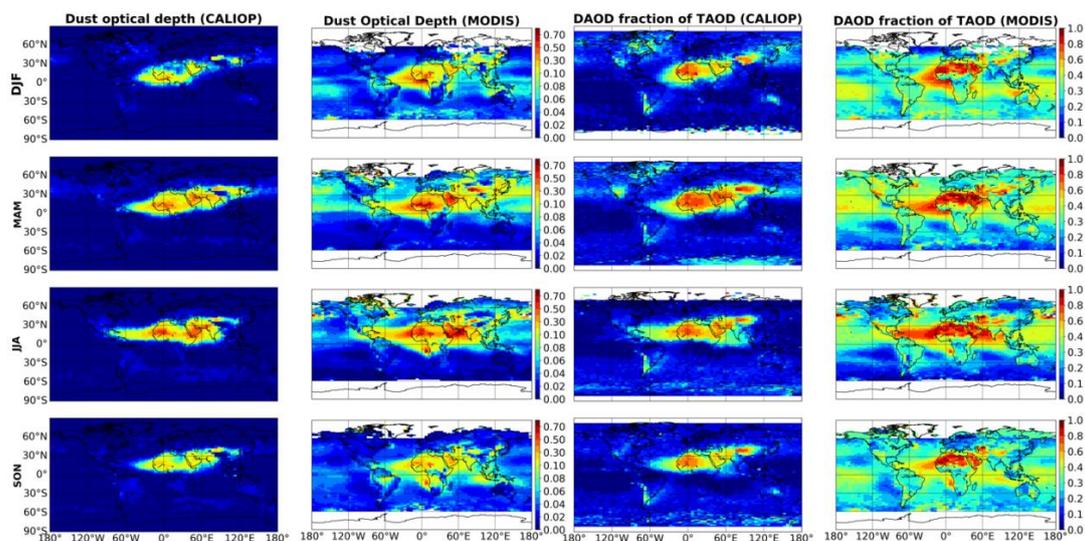

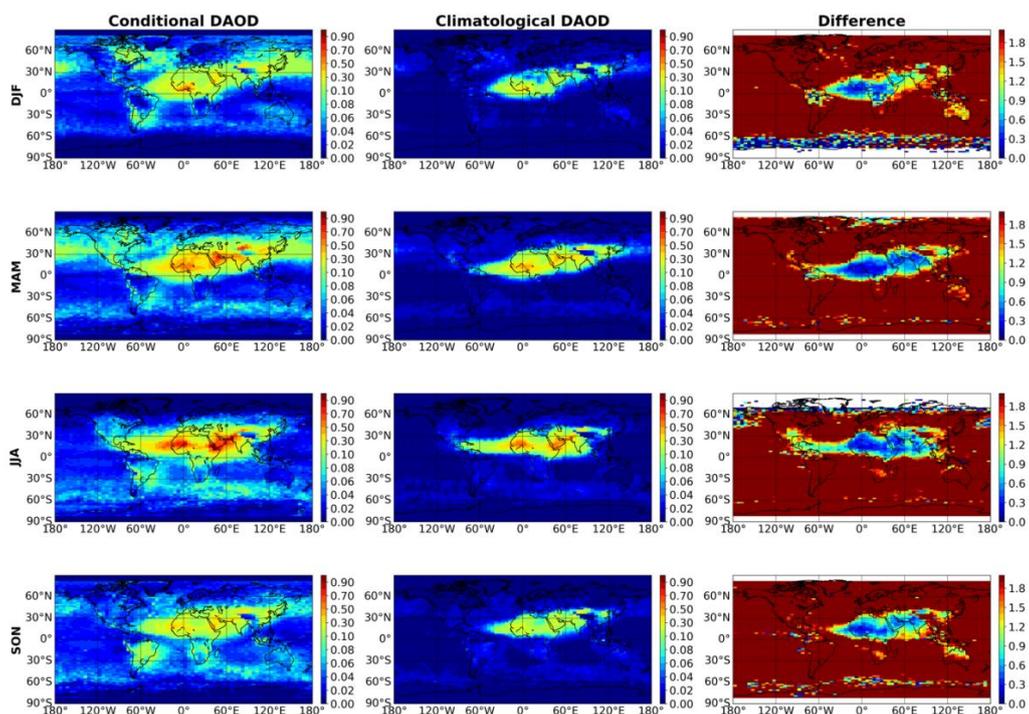

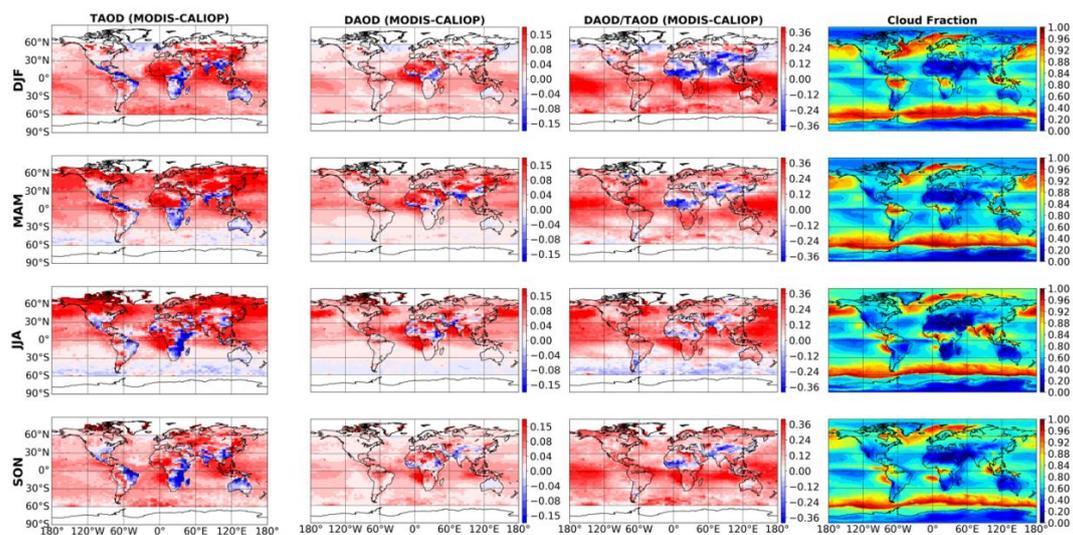

Figure 1. Spatial distribution of the seasonal mean CALIOP-based DAOD, MODIS-based DAOD and the fraction of DAOD with respect to the TAOD based on CALIOP and MODIS respectively for the globe at a 5° longitude \times 2° latitude resolution based on 13-year (2007-2019) CALIOP measurements. **DJF**: December from previous year-January-February; **MAM**: March-April-May; **JJA**: June-July-August; **SON**: September-October-November.

710

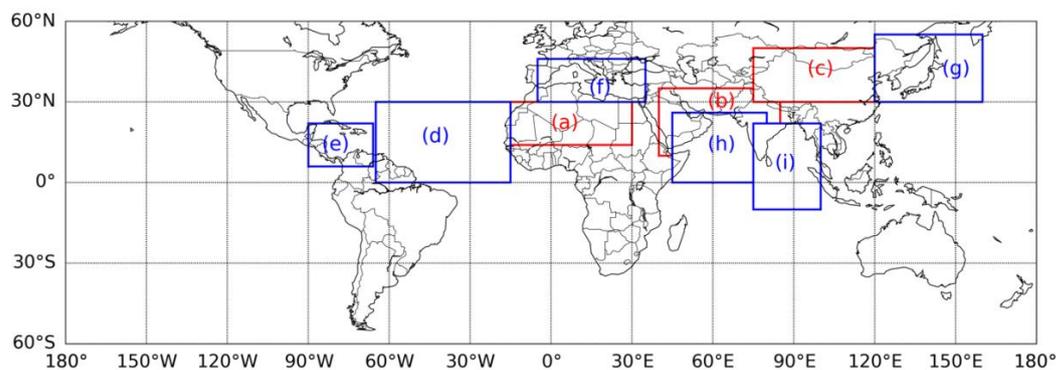

715 Figure 2. Conditional DAOD (the first column), climatological DAOD (the second column) based on CALIOP dust retrieval from 2007 to 2019. The third column shows the relative difference between conditionally sampled DAOD and climatological DAOD with respect to the climatological DAOD expressed in fraction.

720

Figure 3. The difference between MODIS and CALIOP for seasonal mean TAOD (the first column), DAOD (the second column), and the fraction of DAOD in TAOD (the third column) on a basis of 13-year (2007-2019) average. The fourth column is the seasonal mean cloud fraction from MODIS L3 product.

725

Figure 4. Major dust-laden regions including three dust source regions on land (a ~ c) and six outflow regions over ocean (e ~ i). (a) Sahara Desert (14°N-30°N, 15°W-30°E), (b) Middle East (10°N-35°N, 40°E-85°E) and (c) Eastern Asia (30°N-50°N, 75°E-130°E) (d) the tropical Atlantic Ocean–TAT (0°-30°N, 15°W-60°W), (e) the Caribbean Sea–CRB (6°N-22°N, 60°W-90°W), (f) the Mediterranean Sea–MED (30°N-46°N, 5°W-35°E), (g) the northwest Pacific Ocean–NWP (30°N-55°N, 120°E-160°E), (h) the Arabian Sea–ARB (0°-26°N, 45°E-80°E) and (i) the tropical Indian Ocean and the Bay of Bengal–IND (10°S-22°N, 75°E-100°E). Note we only consider grids over land for the three dust source regions and grids over ocean for the six dust outflow regions.

735

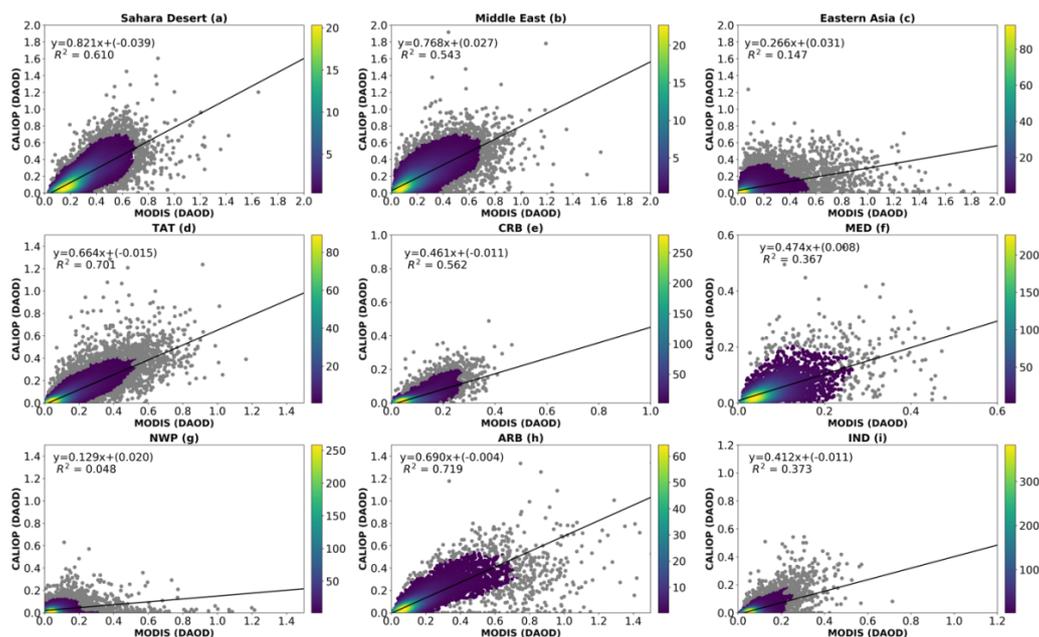

Figure 5. Comparison of CALIOP DAOD against MODIS DAOD over dust-laden regions indicated in Figure 4. Color represents the probability density using gaussian kernel density estimation. Grey points represent data points within the lowest 5% of data density. Those grey points are excluded in the linear regression analysis.

740

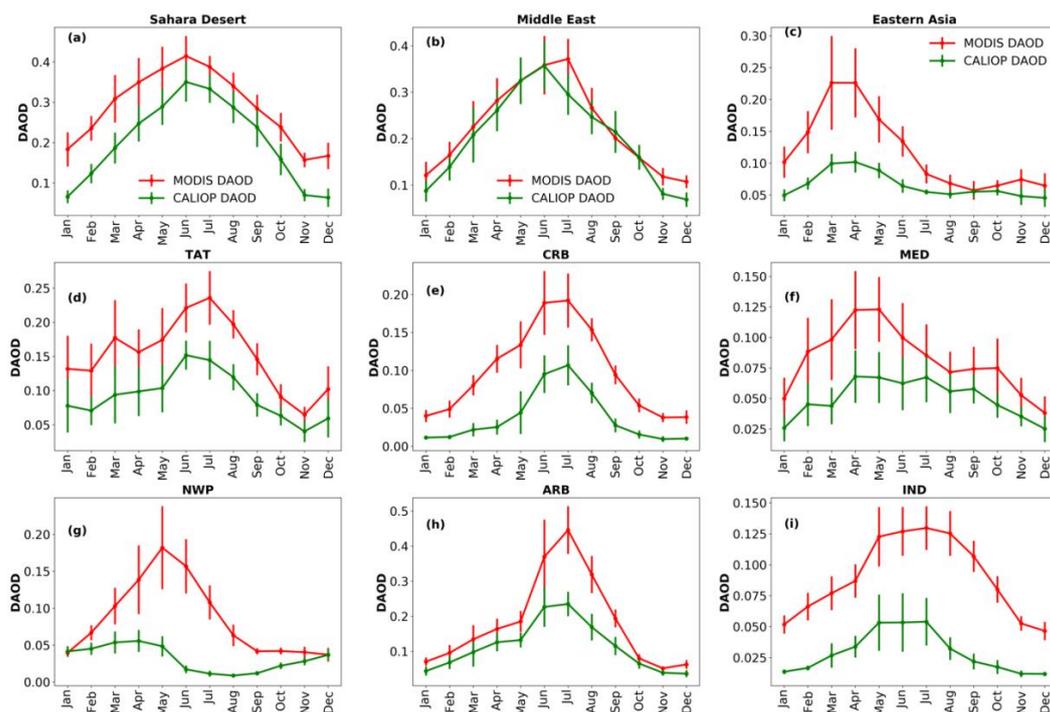

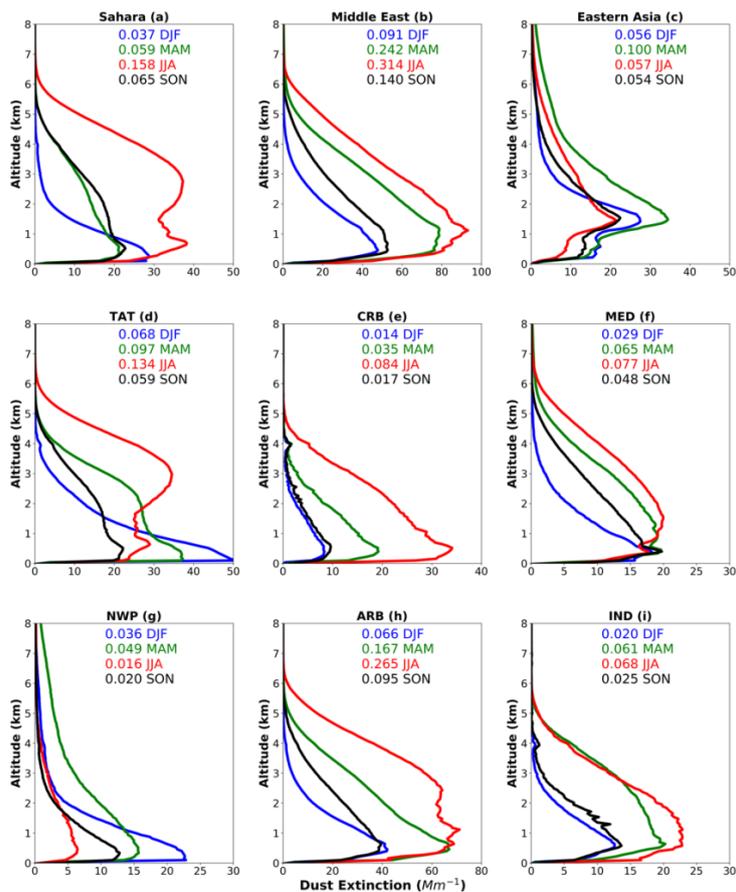

Figure 6. Monthly variation of DAOD from CALIOP (green) and MODIS (red) for major dust-laden regions indicated in Figure 4. Vertical line represents ± 1 sigma (standard deviation) over the 13-year period.

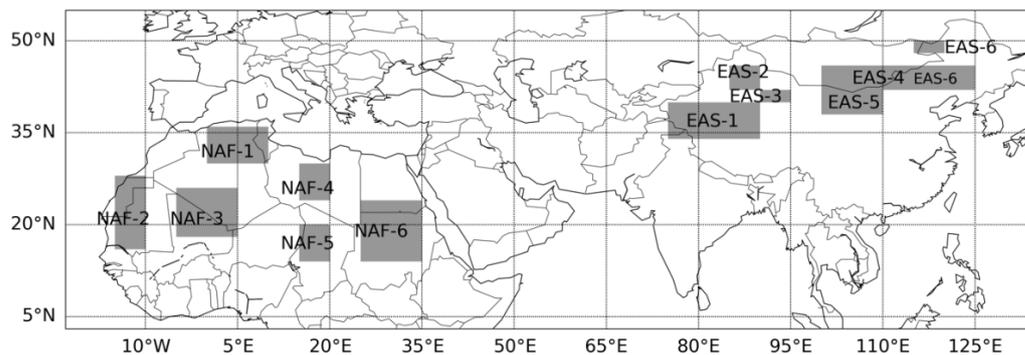

745

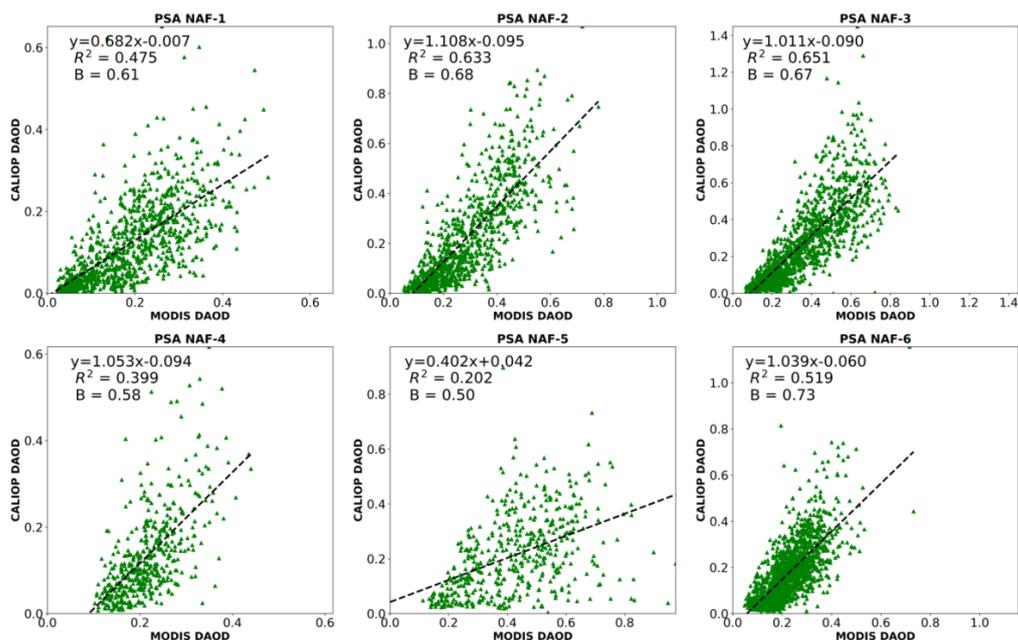

750

Figure 7. Vertical profiles of seasonal mean dust extinction coefficient (Mm^{-1}) in 9 dust-laden regions indicated in Figure 4. Different colors represent different seasons. The numbers on each plot are the seasonal mean DAOD for the region.

755

760 Figure 8. Six dust potential source subregions in Northern Africa (NAF) and Eastern Asia (EAS) based
on Fig.1. and Fig. 2. in Formenti, et al., 2011. PSA NAF-1(30N-36N, 0-9E), PSA NAF-2 (16N-28N,
10W-15W), PSA NAF-3 (18N-26N, 5W-5E), PSA NAF-4 (24N-30N, 15E-20E), PSA NAF-5 (14N-20N,
15E-20E), PSA NAF-6 (14N-24N, 25E-35E); EAS-1: (34N-40N, 75E-90E) ; EAS-2: (44N-46N, 85E-
90E); EAS-3: (40N-42N,90E-95E and 42N-44N, 85E-90E); EAS-4: (42N-46N, 100E-115E); EAS-5:
765 (38N-42N, 100E-110E); EAS-6: (42N-46N, 115E-125E and 48N-50N, 115E-120E)

770 Figure 9. Comparison of CALIOP DAOD against MODIS DAOD over six dust aerosol source regions in North Africa from NAF-1 to NAF-6 as indicated in Figure 8. The mean bias (B) is computed as the average of CALIOP DAOD / MODIS DAOD ratios of all data pairs. B = 1, >1, <1 indicates no bias, high bias and low bias.

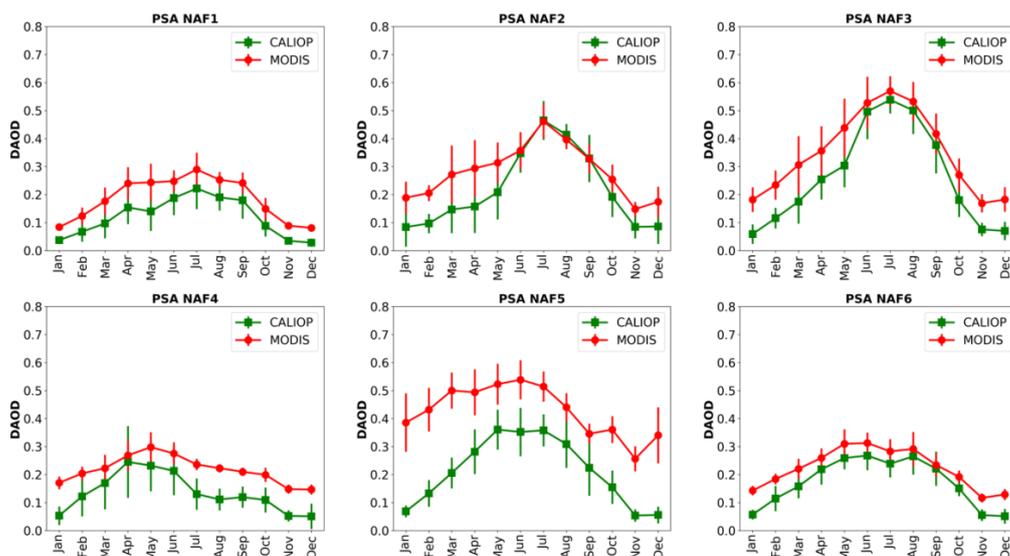

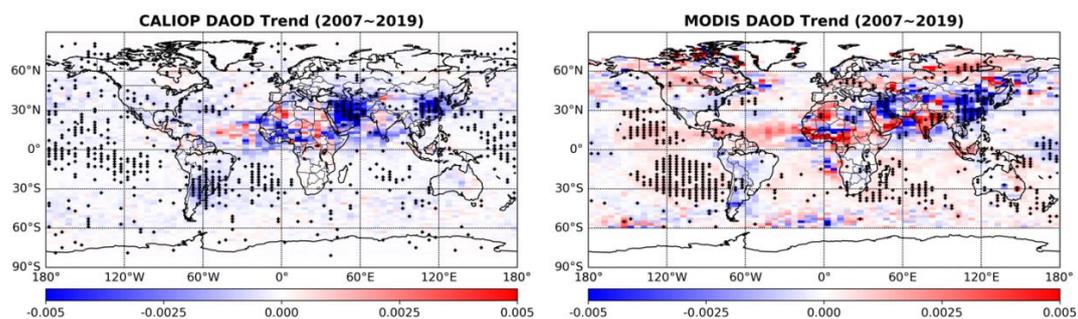

Figure 10. Annual cycle of 13-year (2007-2019) monthly mean DAOD over the six PSAs of North African dust.

775

780 Figure 11. Global map of DAOD decadal trend based on CALIOP (left) and MODIS (right) dust
climatology data over 2007-2019 period. Red and blue represents increasing and decreasing trend,
respectively. Symbol '+' denotes trends with p-value < 0.05, which are considered as statistically
meaningful trend.

785

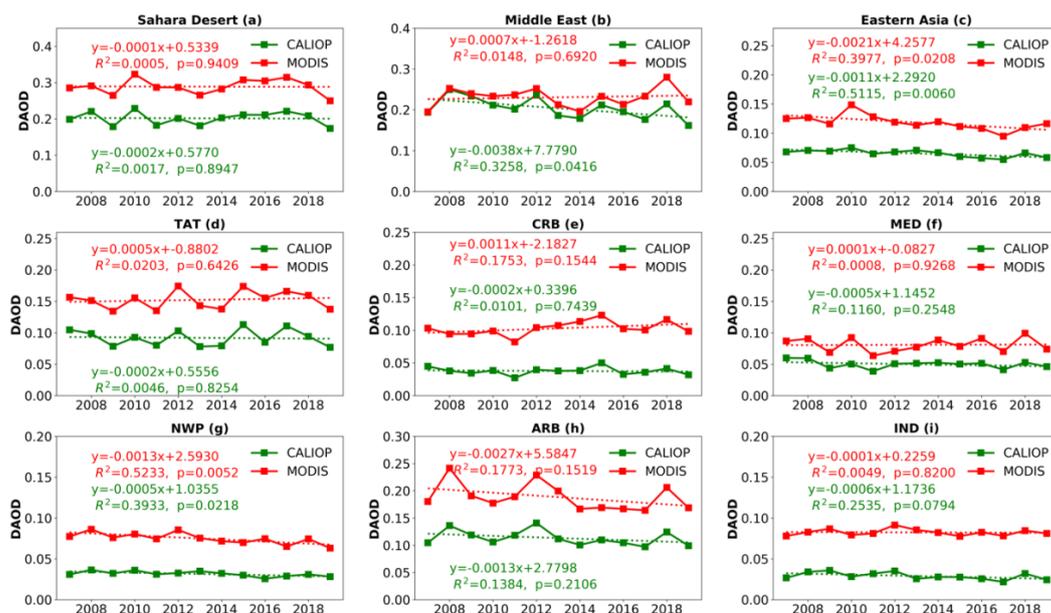

Figure 12. DAOD interannual variability over main dust source regions (a-c) and dust outflow regions (d-i) revealed by CALIOP (green curve) and MODIS (red curve) observations.

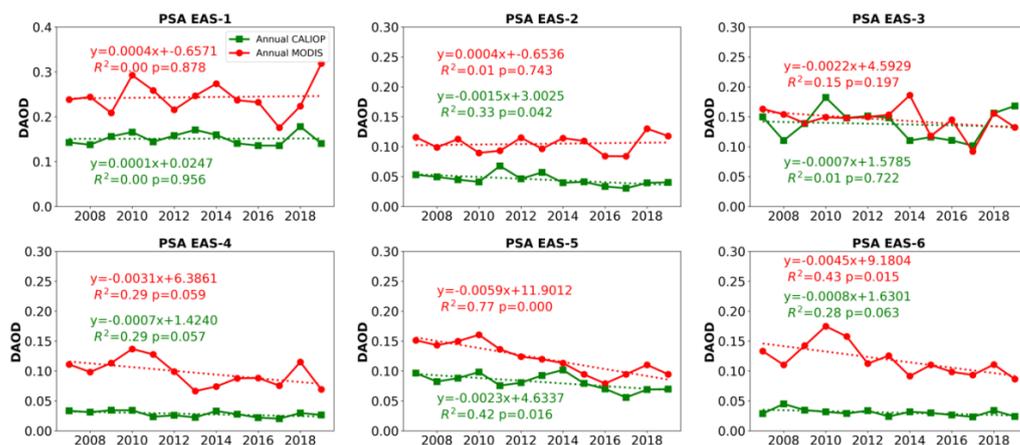

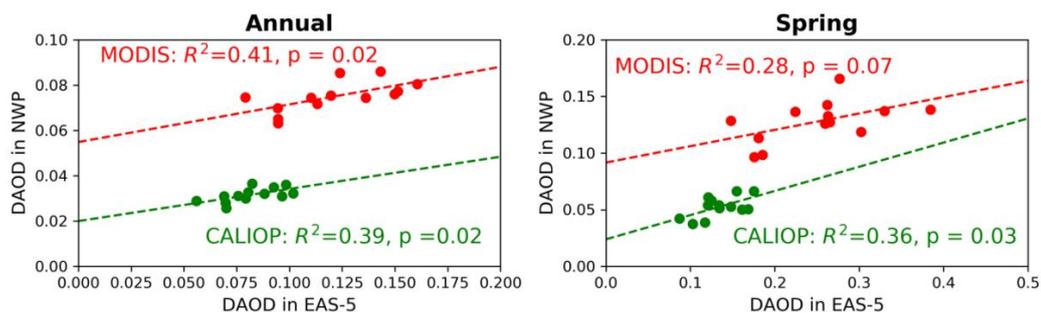

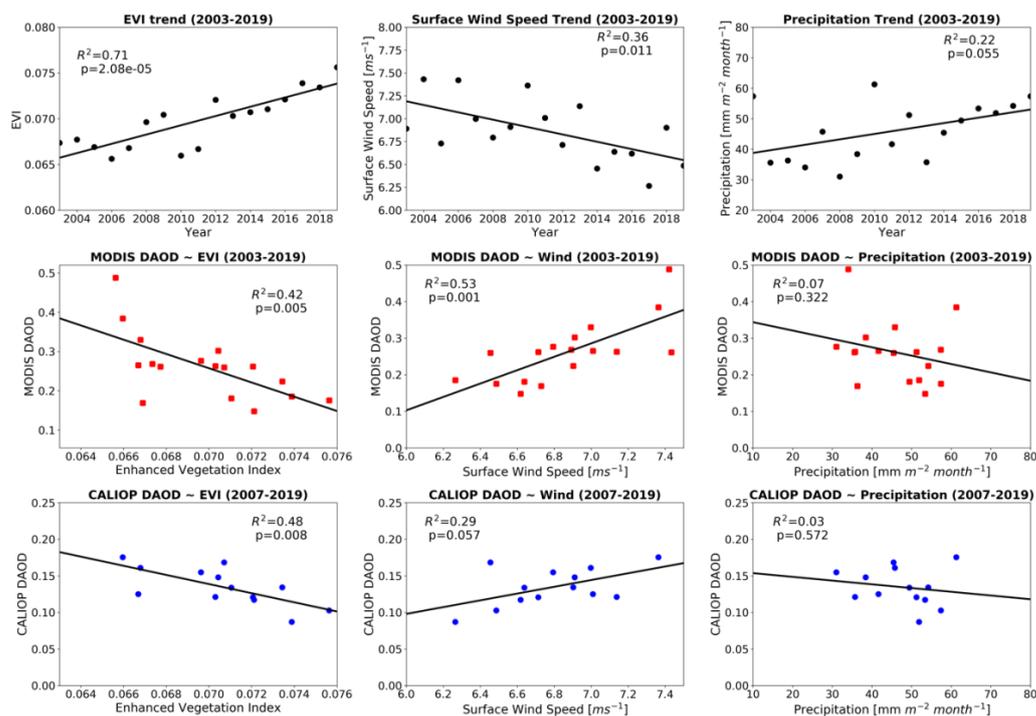

Figure 13. Interannual variability of CALIOP (green) and MODIS (red) DAOD in the six potential dust source areas in Eastern Asia (refer to Figure 8).

795

800 Figure 14. Correlation between DAOD in EAS-5 (Southern Gobi Desert) and DAOD in NWP for annual mean (left) and springtime average (right).

805 Figure 15. The inter-annual trend of Enhance Vegetation Index (EVI), surface wind speed and precipitation and their correlation with DAOD in spring, EAS5 region. The 1st row shows inter-annual trend of EVI, surface wind speed and precipitation. The 2nd and 3rd rows show the correlation of EVI, surface wind speed and precipitation with MODIS-based DAOD and CALIOP-based DAOD respectively.
