ABSTRACT: The volatility of organic aerosols plays a key role in determining their gas-particle partitioning, which subsequently alters the physicochemical properties and atmospheric fates of aerosol particles. Nevertheless, an accurate estimation of the volatility of organic aerosols (OA) remains challenging. Because most standards for particulate organic
15 compounds are not available, and even for those with standards, their vapor pressures are too low to be measured by most traditional methods. Here, we deployed an iodide-adduct Long Time-of-Flight Chemical Ionization Mass Spectrometer (LToF-CIMS) coupled with a Filter Inlet for Gases and AEROSols (FIGAERO) to probe the relationship between the molecular formulae of atmospheric organic aerosol's components and their volatilities. A number of T_{max} (*i.e.*, the temperature corresponding to the first signal peak of thermogram) were abstracted and validated from the desorption thermograms of mixed
20 organic and inorganic calibrants which were atomized and then collected onto a PTFE filter. Besides, 30 filter samples of ambient air were collected in winter 2019 at Wangdu station in Beijing-Tianjin-Hebei region, and analyzed by FIGAERO-LToF-CIMS, leading to the identification of 1,448 compounds dominated by the CHO (containing carbon, hydrogen, and oxygen atoms) and CHON (containing carbon, hydrogen, oxygen, and nitrogen atoms) species. Among them, 181 organic formulae including 91 CHO and 90 CHON compounds were then selected since their thermograms can be characterized with
25 clear T_{max} values in more than 20 out of 30 filter samples and subsequently divided into two groups according to their O/C ratios and different thermal desorption behavior. The mean O/C of these two groups are 0.56 ± 0.35 (average \pm one standard deviation) and 0.18 ± 0.08 , respectively. Then the parameterizations between volatility and elemental composition for the two group compounds were obtained. Compared with previous volatility parameterizations, our functions provide a better estimation for the volatility of low-volatility organic compounds (LVOCs) in ambient organic aerosols. Furthermore, it is
30 suggested that volatility parameterizations should be specialized for organic compounds with different O/C ratios.

1 Introduction

Aerosol particles can significantly impact human health, visibility and climate (Stocker et al., 2013). Organic aerosol (OA) comprises tens of thousands of organic substances and makes up a significant mass fraction of the total submicron particles in the troposphere (Jimenez et al., 2009). Whether an organic compound will exist in the gas phase or particles under a specific
35 temperature is determined by its volatility, which depends on its molar mass and functional groups (Capouet and Müller, 2006; Pankow and Asher, 2008). The volatility of a compound is usually expressed as saturation mass concentration (C_0) or saturation vapor pressure (P_{sat}). The effective saturation mass concentration (C^*) includes the effect of non-ideal thermodynamic mixing with an activity coefficient (γ), thus $C^* = \gamma C_0$, and C^* equals C_0 under the assumption of ideal thermodynamic mixing (Donahue et al., 2011). Saturation mass concentration is regarded as one of critical physicochemical parameters for organic
40 aerosols' components. The organic compounds with $C^* < 0.1 \mu\text{g} \cdot \text{m}^{-3}$ are mostly in the condensed phase, the organic compounds with $C^* > 1000 \mu\text{g} \cdot \text{m}^{-3}$ are almost entirely in the gas phase, and the organic compounds with $1 < C^* < 100$

$\mu\text{g} \cdot \text{m}^{-3}$ will be found in both phases under typical conditions (Donahue et al., 2009).

During the past years, two major methods relevant to the Chemical Ionization Mass Spectrometer (CIMS) have been developed
45 to characterize the volatility of aerosols. The first one estimates the volatility of an organic species based on its molecular
formula. The relationship between C^* and molecular formulae of alkane, aldehyde, ketone, alcohol, acid, diol, and diacid was
proposed by Donahue et al. (2011), which clarifies the relationship between n_C (the numbers of carbon) and n_O (the numbers
of oxygen), and $\log C_0$. The relationship was derived from a group contribution method SIMPOL that actually is a structure-
50 based estimation method (Pankow and Asher, 2008). Li et al. (2016) updated this function by including 31066 compounds
from the National Cancer Institute (NCI) open database, which applies to not only CHO compounds (containing carbon,
hydrogen, and oxygen atoms) but also the nitrogen- and sulfur-containing compounds. However, Isaacman-Vanwertz and
Aumont. (2021) showed that the volatility of CHON compounds estimated by the Li et al. (2016) parameterization is
significantly biased by an increase in the number of nitrogen atoms, and thus they modified the nitrogen coefficient for CHON
55 compounds from Li et al. (2016) study by using a fixed relationship between the nitrogen coefficient and the number of the
oxygen atom (*i.e.*, $b_N = 2 * b_O$). On the other hand, Donahue et al. (2011) took only -OH, =O and -C(O)OH functionalities into
account when describing an average effect of an added oxygen, which could result in a large uncertainty when estimating the
volatility of highly oxygenated organic molecules (HOMs) that contain hydroperoxide (-OOH) functionalities. Thus,
Stolzenburg et al. (2018) and Mohr et al. (2019) updated the parameters for the volatility estimation of HOMs, based on 15
HOMs. The molecular structures of these 15 HOMs are unclear, but their saturation concentrations were estimated using the
60 SIMPOL method on the basis of supposed molecular structures (Tröstl et al., 2016). As the covalently bonded dimers are
abundant in HOMs from ozonolysis of α -pinene, Stolzenburg et al. (2018) fitted parameters using monomer and dimer HOMs
separately, allowing a parameter to include the covalent binding. Since molecular formulae of organic aerosols can be obtained
by state-of-the-art instruments such as high-resolution mass spectrometers, C^* of organic compounds in the aerosol particles
can then be calculated based on the above-mentioned empirical function (Huang et al., 2019).

65 The second one estimates the volatility of an organic species on the basis of its desorption thermogram. When analyzing
physicochemical properties of aerosol particles, one of the most popular techniques is to heat the particles and then detect the
evaporated compounds utilizing mass spectrometry techniques, such as Thermodesorption-particle Beam Mass Spectrometer
(Faulhaber et al., 2009), Thermal-Desorption Chemical Ionization Mass Spectrometer (TD-CIMS) (Smith et al., 2004), Micro-
70 Orifice Volatilization Impactor Coupled to a Chemical Ionization Mass Spectrometer (MOVI-CIMS) (Yatavelli and Thornton,
2010), Chemical Analysis of Aerosols Online -Proton Transfer Reaction Mass Spectrometer (CHARON-PTR-MS) (Eichler et
al., 2015), and the Filter Inlet for Gases and AEROSols (FIGAERO) coupled with Time-of-Flight Chemical Ionization Mass
Spectrometer (ToF-CIMS) (Lopez-Hilfiker et al., 2014). Basically, the desorption temperature is ramped up linearly, the
particulate organic compounds with different vapor pressures are thermo-desorbed and then characterized with distinct
75 thermograms (*i.e.*, desorption signal versus temperature), and the temperature corresponding to the first peak signal (T_{max})
correlates with the vaporization enthalpy of a compound (Lopez-Hilfiker et al., 2014). It is thus applicable to estimate C^* , *i.e.*,
the volatility of the chemical constituents in the particles, from the measured T_{max} , after calibration with a set of standards with
known vapor pressures (Bannan et al., 2019), which has been widely applied in many previous studies (Nah et al., 2019; Stark
et al., 2017; Wang et al., 2020a; Ye et al., 2019; Ylisirniö et al., 2019). Compared with the parameterization method from
80 organic aerosols' molecular formulae, the thermogram method is able to give a volatility distribution that is likely closer to the
real one. Since the molecular formula method likely treats the thermal decomposition products after heating as evaporated
organic molecules, and thus overestimates the overall volatility of a group of organics (Stark et al., 2017).

The FIGAERO-ToF-CIMS has been widely used in the field and laboratory studies in recent years. For example, Wang et al.
85 (2020a) explored the volatility of aromatic hydrocarbon photo-oxidation products, Ylisirniö et al. (2020) compared the
volatility of SOA (Secondary Organic Aerosol) components formed from oxidation of real tree emissions with that formed
from oxidation of single VOC-systems, and Ye et al. (2019) studied the volatility of nucleated particles from α -Pinene
oxidation between -50 °C and +25 °C using FIGAERO-ToF-CIMS. Accurately measuring the desorption thermograms of the

standards is one of the essential factors for the success of this method. For example, previous studies typically used the syringe
90 deposition method to prepare the mimic filter, which leads to wide variations in results. A new method for volatility calibration,
the atomization method, accurately captures the evaporation of chemical constituents from ambient aerosol particles (Ylisirniö
et al., 2021). In addition, the influences of mixing of organic compounds and inorganic salts that are a major component in
ambient aerosol particles on the thermograms of organics, were not considered in these previous studies.

95 On the other hand, with rapid economic growth and urbanization in the North China Plain (NCP), air pollution and extreme
haze events frequently occurred in this region, the formation of which is closely related to the volatility of aerosol components
(Li et al., 2017; Shiraiwa and Seinfeld, 2012). Therefore, it is crucial to understand the volatility of aerosol components in the
NCP.

100 In this study, we compared the effects of the methods of syringe deposition and atomization on T_{max} with a series of authentic
organic standards using FIGAERO-LToF-CIMS. Also, we investigated the influences of inorganic salts and the mixing of
organic compounds on the T_{max} of organics. In addition, we developed empirical volatility-molecular formula functions based
on selected CHO and CHON compounds with varying O/C ratios from ambient OA particles. The C^* of these selected
105 compounds were estimated by obtained T_{max} from thermograms. The ambient particles were collected at Wangdu station in the
North China Plain, China, from January 15 to 22, 2019. Besides, our empirical functions were also compared with previous
ones.

2 Experimental methods

2.1 FIGAERO-LToF-CIMS

We measured the chemical composition and thermograms of particulate compounds collected on filters via a FIGAERO-LToF-
110 CIMS with a mass resolving power of 7700-8500, and the volatility of compounds was acquired from thermograms (Bertram
et al., 2011; Lee et al., 2014; Lopez-Hilfiker et al., 2014). The design and operation of the FIGAERO have been introduced in
previous studies (Bannan et al., 2019; Lopez-Hilfiker et al., 2014; Thornton et al., 2020; Ye et al., 2020). In this study, particles
collected in the lab calibration experiments or from the field campaign were thermally desorbed utilizing an ultrahigh purity
(UHP) nitrogen flow at 2.3 Liter per minute⁻¹ (lpm), among which 1.0 lpm UHP N₂ passed the filter and entered the ion-
115 molecule reaction (IMR) chamber. In IMR, organic molecules were charged by iodide ions generated by exposure of a 1.0 lpm
mixture of CH₃I and UHP N₂ to a 0.1 mCi radioactive Am-241 source. During the thermo-desorption process, the heating
temperature ramp linearly started from room temperature (~25 °C) to 134 °C and then the filter was held at 134 °C for 40 min
to ensure that most of the organic compounds had been desorbed from the filter (Lopez-Hilfiker et al., 2016). The measured
ramping rate for heating was 2.27 °C /min in this study. A slower ramping rate allows more time to stay at any momentary
120 desorption temperature so that a larger fraction of molecules would evaporate. Also, a slower ramping rate can separate
compounds with similar volatilities better and lead to a smaller number of thermal decomposition products (Lopez-Hilfiker et
al., 2014; Yang et al., 2021; Ylisirniö et al., 2021). Most of the ambient organic compounds can be desorbed from the filter at
less than 134 °C (Huang et al., 2019). Furthermore, high molecular weight organic compounds (e.g. C₂₇H₅₂O₄) can be
evaporated from the filter below 120 °C (Wang et al., 2016). Therefore, the highest temperature of 134 °C is feasible in our
125 study. The desorption procedure for the calibration experiments and the field measurements were the same, as shown in Figure
S1. During ambient filter measurements, background measurements using a blank filter were also conducted. The blank filter
was analyzed by the same thermal desorption procedure as that of the field samples. The obtained signals are treated as the
background signals. An example of the background signal of an identified compound was shown in Figure S2.

130 A Tofware software (version 3.1.2, Tofwerk AG, Switzerland) was used to analyze the data of the mass spectrometer. To plot
thermograms, signals of evaporated compounds were normalized by the abundance of reagent ions and then subtracted with
the background signals, which were normalized similarly. The raw data was acquired at a frequency of 1 Hz and then averaged
to a 20 s time interval during the data analysis. As the desorption features of ambient aerosol particles were quite complex, we

135 applied the Levenberg–Marquardt algorithm to fit the thermograms and conducted peak deconvolution for the multimodal thermograms (Goodman and Brenna, 1994; Lopez-Hilfiker et al., 2015; Stolzenburg et al., 2018). In the case of a multimodal thermogram, the higher-temperature peak(s) (*i.e.*, the warmer peak) was assumed to come from the thermal decomposition of larger molecules or isomers with different vapor pressures (Huang et al., 2018; Wang et al., 2016). Hence, in this study, T_{max} of the cooler peak (*i.e.*, the first peak) was used to estimate the volatility of an organic compound.

2.2 Calibration experiments

140 The C^* versus T_{max} calibration curve was obtained by species with known vapor pressures. Two methods referred as the syringe deposition method and the atomization method, were used to prepare filter samples of authentic compounds. For the syringe deposition method, certain amounts of authentic species dissolved in the acetonitrile solvent were injected onto a PTFE filter by a syringe. While the acetonitrile solvent was supposed to quickly evaporate from the filter and have a minor effect on authentic species, only the authentic species were thermally desorbed during the subsequent FIGAERO-LToF-CIMS analysis.
145 For the atomization method, the authentic species dissolved in deionized water were atomized by a commercial atomizer (TSI[®] 3076). Atomized particles were diluted and dried by a zero-gas flow and silica gel, after which the relative humidity (RH) of the flow was regulated to around ~2% (Figure S3). Then, particles were collected onto a PTFE filter and subsequently analyzed by the FIGAERO-LToF-CIMS. The mass of collected particles can be calculated based on the number size distribution of particles measured by a Scanning Mobility Particle Sizer (SMPS, TSI[®] 3776), the particle density, the collection time, and the
150 flow rate through the filter (Ylisirniö et al., 2021). Among them, the particle density can be estimated according to the density of corresponding authentic standards and their mixing ratios in the solution.

During our laboratory tests, eleven sets of calibration experiments were conducted. These experiment conditions are summarized in Table 1. One set of (No.1) experiments using the syringe deposition method were performed, where
155 polyethylene glycols (PEGs) were used as authentic organic standards (Bannan et al., 2019). Besides, ten sets of atomization experiments were also conducted. The No.2 set works as an intercomparison with previous syringe deposition (No.1) experiments. The No.3-7 sets of experiments were conducted to explore the effects of ammonium sulfate and mixed organic compounds on the T_{max} of organics. Erythritol, PEG-6, PEG-7, PEG-8, and citric acid were used as authentic organic standards because they can co-dissolve with ammonium sulfate in deionized water. In No.3, ammonium sulfate was not added to the
160 standard solution, and there were only organic standards. In No.4 and No.5, ammonium sulfate was mixed with erythritol, PEG-6, PEG-7, PEG-8, and citric acid, respectively. 200 ng and 1000 ng atomized particles were collected in No.4 and No.5, respectively. It is assumed that the atomized particles were internally mixed with the same mass ratio as that in the solution (Drisdell et al., 2009), consisting of 100 ng/500 ng of ammonium sulfate and 100 ng/500 ng of the mixed organic standard. Although ammonium sulfate is much less volatile than mixed organics and the mixing ratio of ammonium sulfate to organic
165 compounds in atomized particles might be different with that in solution, this assumption likely leads to a minor effect on the matrix effect of ammonium sulfate. In the sixth (No.6) set, erythritol, PEG-6, PEG-7, PEG-8, and citric acid were mixed together and 1000 ng atomized particles were collected. In No.7, ammonium sulfate was mixed with erythritol, PEG-6, PEG-7, PEG-8, and citric acid. The No.7-11 sets of experiments were conducted to explore the effect of mass loading of filters. Four replicates were performed for each set of experiments.

170

175

180 **Table 1.** Conditions of eleven sets of calibration experiments.

No.	Method	Authentic standards	Concentration	Solvent	Deposited volume	Mass loading
1	Syringe deposition	PEG-4 (C ₈ H ₁₈ O ₅)	0.05 g L ⁻¹	Acetonitrile	2 µl	100 ng
		PEG-5 (C ₁₀ H ₂₂ O ₆)	0.05 g L ⁻¹			100 ng
		PEG-6 (C ₁₂ H ₂₆ O ₇)	0.05 g L ⁻¹			100 ng
		PEG-7 (C ₁₄ H ₃₀ O ₈)	0.05 g L ⁻¹			100 ng
		PEG-8 (C ₁₆ H ₃₄ O ₉)	0.05 g L ⁻¹			100 ng
2	Atomization	PEG-4 (C ₈ H ₁₈ O ₅)	1.0 g L ⁻¹	Deionized water	/	500 ng

2.3 Field Campaign

An ambient campaign was conducted from December 16, 2018 to January 22, 2019 at Wangdu station, Hebei Province, China (Wang et al., 2020b). The campaign site (38.66 °N, 115.19 °E) was mainly influenced by the surrounding transportation, industrial and residential sources, and farmlands and forests and can be treated as a typical suburban station.

Aerosol particles (PM_{2.5}) were collected four times every day, and each collection lasted for 15 minutes (*i.e.*, 7:00-7:15, 12:00-12:15, 17:30-17:45, and 21:00-21:15 local time, respectively). Ambient PM_{2.5} was sampled onto PTFE filters (5 μm pore size, 25 mm diameter, Millipore), and the flow rate was regulated at 1.42 L min⁻¹. After the collection, filter samples were preserved
 190 at -20 °C in a freezer until further analysis. In this study, 30 filter samples between January 15, 2019 and January 22, 2019 were analyzed with FIGAERO offline, because mass loadings of these 30 filter samples varied from 200 ng to 3500 ng with a median of 1100 ng, which is similar to those in the calibration experiments. The mass concentration of PM_{2.5} was also measured by a commercial synchronized hybrid real-time particulate monitor (TEI, Model 5030i).

2.4 Saturation mass concentration (C*)

195 2.4.1 Calculation of C*

By correlating the logarithm of P_{sat} at 298K of these authentic standards in the literature to their T_{max} values obtained from the desorption thermograms, a linear relationship can be obtained (Bannan et al., 2019):

$$\log_{10}(P_{sat}) = aT_{max} + b, \quad (1)$$

where a and b are fitted parameters, and this expression can also be expressed as:

$$200 \quad P_{sat}(pa) = 10^{aT_{max}+b}, \quad (2)$$

On the other hand, P_{sat} can be converted to C^* with the assumption of the ideal gas law (Ylisirniö et al., 2020, 2021). In this way, the relationship between C^* and T_{max} was deduced as:

$$C^* (\mu g \cdot m^{-3}) = \frac{(10^{aT_{max}+b})M_w}{RT} 10^6, \quad (3)$$

where M_w is the molecular weight of an authentic compound (g mol⁻¹), R is the gas constant (8.314 J mol⁻¹ K⁻¹), and T is the
 205 temperature when the P_{sat} is determined (K; in our study, T is 298 K).

2.4.2 Correlation between C* and molecular formulae

We substituted the measured T_{max} of selected organic compounds in the ambient aerosol particles into Eq. (3) with fitted a and b values from experiments with authentic standards, and obtained their C^* . Then we correlated C^* to molecular formulae of these selected organic compounds in a function similar to what was developed in a previous study (Donahue et al., 2011; Mohr
 210 et al., 2019) :

$$\log_{10} C_0 = (n_c^0 - n_c)b_c - (n_o - 3n_N)b_o - 2 \cdot \frac{(n_o - 3n_N)n_c}{(n_c + n_o - 3n_N)} b_{co} - n_N b_N \quad (4)$$

where n_c^0 is the reference carbon number and set to be 25 (Donahue et al., 2011); n_c , n_o and n_N is numbers of carbon, oxygen and nitrogen atoms in an organic species, respectively; b_c , b_o and b_N denotes the contribution of each kind of atoms to $\log_{10} C_0$, respectively, and b_{co} is the carbon-oxygen nonideality (Donahue et al., 2011; Li et al., 2016). Values of b_c , b_o ,
 215 b_N , and b_{co} were fitted with multi-linear least-squares analysis.

3 Results and discussion

3.1 Laboratory Calibration

Figure S4 compares the T_{max} values for the same authentic organic standards when using different calibration methods. PEG4 was not detected by CIMS with the second (No.2) set of calibration experiments, which is consistent with the result of a
 220 previous study (Ylisirniö et al., 2021). This observation is most likely due to the high volatility of PEG-4 that leads to its evaporation even before the CIMS measurement (Ylisirniö et al., 2021). The T_{max} values measured with the syringe deposition experiments have larger error bars (Figure S4). The T_{max} may increase with increased filter loadings (Wang and Hildebrandt Ruiz, 2018), if calibrated with the same method. However, despite a larger mass loading (500 ng) in the atomization (No.2) experiments than that (100 ng) in the syringe deposition (No.1) experiments, the T_{max} values measured with the atomization

225 method is about 20 °C lower than those with the syringe deposition method for the same compound. This observation can be explained by the fact that the surface area of the material deposited by the syringe is smaller than that of deposited aerosol particles, which requires more time to evaporate and correspond to higher T_{max} values (Ylisirniö et al., 2021).

230 **Figure 1.** Comparison of calibration results obtained in this study with those reported previously. These solid lines denote the calibration results obtained in this study. Error bars represent \pm one standard deviation of T_{max} from four replicate experiments. The light blue dash-dot line denotes calibration results obtained with acids and erythritol by Nah et al. (2019) using the syringe method. The black dash-dot line represents calibration results obtained with 100 ng deposited PEGs (including PEG-4, PEG-5, PEG-6, PEG-7, and PEG-8) by Ylisirniö et al. (2021) using the syringe method. The red dash-dot line denotes calibration
 235 results obtained with 100-200 ng PEGs (including PEG-5, PEG-6, PEG-7, and PEG-8) by Ylisirniö et al. (2021) using the atomization method.

In Figure 1, we further compared our calibration results with previously reported ones. Six solid calibration lines acquired in this study are located between the dash-dot calibration lines by Ylisirniö et al. (2021) using the atomization method and the
 240 syringe deposition method. The solid calibration line obtained with PEGs ($O/C > 0.25$) by the syringe deposition method in this study is quite close to the dash-dot calibration line that was also obtained by the syringe deposition method with acids ($O/C < 0.25$ and $O/C > 0.25$) and erythritol ($O/C > 0.25$) (Nah et al., 2019). Yet the slopes of two lines are a bit different, which may be attributed to different O/C ratio of organic standards. In addition, the calibration line obtained with 100 ng deposited standards in this study by the atomization method almost overlaps that obtained with the same method, standard,
 245 and mass loading (Ylisirniö et al., 2021). However, the calibration line obtained with 100 ng deposited standards in this study by the syringe deposition method is far away from the dash-dot calibration line obtained with the same method, standard, and mass loading (Ylisirniö et al., 2021). Clearly, compared with the syringe deposition method, the atomization method shows much better repeatability, even between different studies.

250 The effects of ammonium sulfate and mixed organic compounds on T_{max} of organics are also investigated, as shown in Figure 1 and Figure S5, since the majority of atmospheric aerosol particles consists of ~50% ammonium sulfate and 50% carbonaceous components (Drisdell et al., 2009). Clearly, mixing the same amount of ammonium sulfate with each of the five organic standards, as done in No.4, increased the T_{max} values of erythritol and citric acid but did not alter the T_{max} values of PEGs 6-8 significantly. Comparison of the T_{max} values of No.6 and No.7 showed that the T_{max} of five organics exhibited a slight
255 increase (1 to 4 °C), which is likely due to the addition of ammonium sulfate. Furthermore, elevated T_{max} (1 to 8 °C) between No.5 and No.7 was observed, which means the matrix effects within mixed organic compounds can also enhance the T_{max} of organics. The T_{max} of five organic compounds increased by 3 to 17 °C with the increase of mass loadings according to No.4 and No.5 (Figure S5). Furthermore, as shown in Figure S6, the T_{max} of five organic compounds generally increases with increased mass loadings, and T_{max} has increased approximately 8 °C as the mass loading increases from 200 ng to 1500 ng.
260 The 95% credible intervals of No.5, No.6 and No.7 experiments are significantly larger than the others, which may be attributed to their higher mass loading (1000 ng) than those in other experiments (100 ng, 200 ng and 500 ng) (Figure S7). Therefore, the T_{max} values of organic compounds are affected together by the addition of ammonium sulfate, the matrix effects within organic compounds, and mass loadings. However, these effects cannot be quantified separately in our study.

265 Moreover, the fraction of organic species and inorganic salts of non-refractory submicron aerosol species (NR-PM1) in Beijing in winter 2018 were about 48% and 52%, respectively (Zhou et al., 2020). The fraction of organic species and inorganic salts in total particulate matters (PM) in a rural site (Gucheng in Hebei province) in winter 2018 were about 40% and 60%, respectively (Xu et al., 2021). The mass ratios of the inorganic salt to organic species were close to 1:1 which was similar to that of our laboratory tests (*i.e.*, No.7 set of calibration experiments). In addition, Ylisirniö et al. (2021) shows that particle
270 size has a moderate impact on the measured T_{max} of organic compounds. The particle size distributions and peak diameters of polydisperse particles in our laboratory experiments (No.4, No.6 and No.7) are similar to those of the ambient samples (Figure S8). Therefore, in our study, particle size distributions have a minor effect on measured T_{max} .

To minimize the uncertainties from multiple factors (e.g., the presence of ammonium sulfate, multiple organic compounds, particle size distributions, and mass loading) on T_{max} , the calibration line obtained from No.7 was utilized to estimate T_{max}
275 values of organic compounds in ambient particles and to derive our parameterizations, because the experimental conditions of mimic particle samples in No.7 are the closest to those of the ambient samples and can represent ambient organic aerosol particles.

3.2 Volatility of OA components

280 We identified 1,448 compounds from the filter collected on 7:00-7:15, January 15, 2019, in Wangdu, whose mass defect plot is shown in Figure 2. Among them, 340 CHO and 663 CHON species account for 43.5% and 20.8% of the total signals, respectively, because the iodide-adduct chemical ionization is sensitive toward multifunctional oxygenated organic compounds with minimal fragmentation (Bertram et al., 2011; Lopez-Hilfiker et al., 2016). In addition to 326 other species (30.8% of the total signals) that have been assigned with molecular formulae but cannot be divided into either the CHO or CHON groups,
285 there are 119 species (4.9% of the total signals) without attributed molecular formulae.

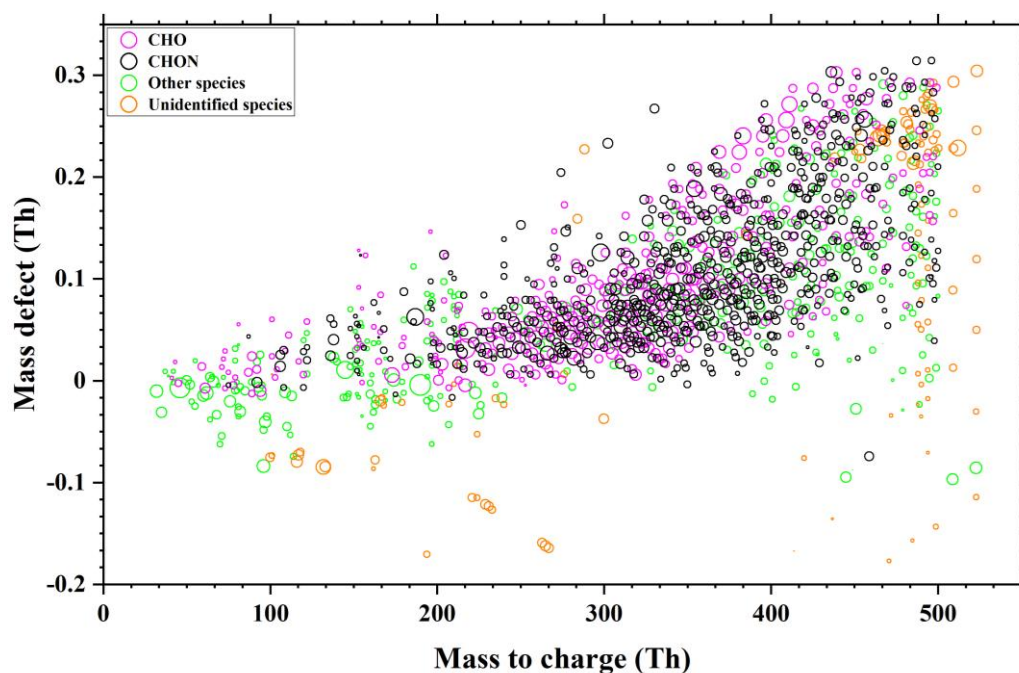

Figure 2. A typical mass defect plot for compounds desorbed from a filter collected on 7:00-7:15, January 15, 2019, in Wangdu. The symbol size is proportional to the logarithm of signal intensity. The reagent ion (I) was not removed from their formulae.

290

Among the 1,448 species, we can attribute a T_{max} to 765 species whose thermograms are characterized with a distinguishable T_{max} with one or two desorption peaks, as shown in Figure S9a and c and Figure S9b and d, and the rest whose thermograms did not show a peak and thus the position of T_{max} cannot be judged, as shown in Figure S9e and f. In Figure S10, we show the thermal desorption temperature of these 765 particulate compounds during the FIGAERO-LToF-CIMS analysis. The desorption temperatures of these organic compounds mainly concentrated in the 80~100 °C range. The thermograms of most organic compounds show a single peak, and the mass-to-charge ratio (m/z) of these compounds are mainly concentrated in the range of 250~450 Th, and the dominated compounds are $C_{13}H_{25}NO_2$, $C_{16}H_{32}O_2$, $C_{18}H_{35}NO_4$, $C_6H_{10}O_5$, $C_9H_{17}NO_2$ and $C_{18}H_{34}O_2$.

295

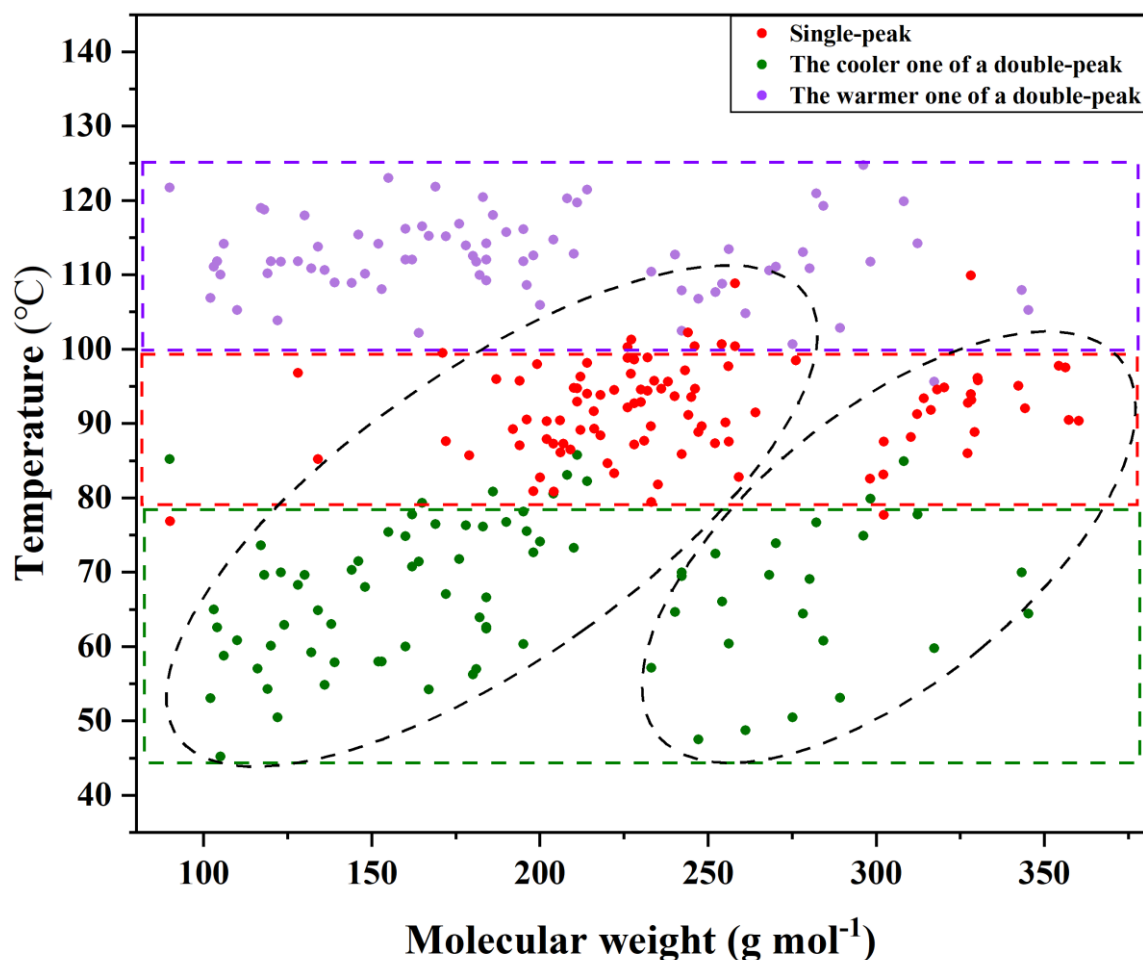

We analyzed 30 filter samples in total. For each filter, we selected species that can be assigned with a reliable molecular formula in the format of either CHO or CHNO, and species that can be designated with a T_{max} , the intersection of which correspond to species with both reliable CHO/CHNO type molecular formulae and T_{max} values. There are 181 such organic compounds including 91 CHO and 90 CHON species that were present in more than 20 out of 30 filter samples. The 181 species are dominant compounds accounting for 34.1% of the total signal of 1448 compounds. It should be noted that several compounds (e.g., $C_3H_8O_3$, CH_2O_2) with high signals in these 1448 compounds were not further analyzed, because they are very volatile at the room temperature (25 °C) and their thermograms cannot be characterized with clear T_{max} values from most filter samples. The molecular formula, molecular weight, T_{max} , and C^* calculated according to our calibration in Figure 1 for the 91 CHO and 90 CHON species are summarized in Table S1 and Table S2, respectively.

305

The thermal behaviors of these 181 organic compounds during the FIGAERO analysis are shown in Figure 3. The cooler peak temperatures in double-peak thermograms mostly appeared in the green rectangular band of 45~80 °C, whereas the higher peak temperatures in double-peaks those are mainly the result of thermal decomposition of higher molecular weight organic compounds (Huang et al., 2018), and concentrated in the purple rectangular band of 100~125 °C, which is consistent with the result of Wang et al. (2016). On the other hand, the corresponding evaporation temperature for compounds with single-peak thermograms concentrated in the red rectangular band of 80~100 °C. Clearly, the compounds in Figure 3 can be divided into two groups, as illustrated with the two dashed ellipses. For each group, the T_{max} values of the single peaks and the cooler ones

315

of double-peaks increase with their corresponding molecular weight, which is consistent with the fact that similar compounds with larger molecular weight tend to possess lower volatility.

320 **Figure 3.** Evaporation and decomposition of 91 CHO and 90 CHON compounds, of which the reagent ion (I^-) was excluded from their formulae. The signal peaks, the cooler and warmer peaks of double-peaks are denoted by red, green and purple circles, respectively. Rectangular bands depict the temperature zones in which peaks appear.

In Figure 4, the T_{max} of these 181 compounds (91 CHO and 90 CHON) are translated into C^* values according to Eq. (3). Since
 325 most of the warmer peaks of double peaks could be from thermal decomposition, the T_{max} for the higher-temperature ones in double-peak thermograms of 78 compounds are not taken into account. As shown in Figure 4, the volatilities of CHO and CHON compounds both concentrate in the range of $-4.5 < \log_{10}(C^*) < 1.5$. In addition, CHO and CHON compounds are randomly distributed in two groups according to O/C and there is no obvious distinction. The species in the red dashed ellipse are the same as those in the left dashed ellipse in Figure 3, and the compounds in the blue dashed ellipse are the same as those
 330 in the right dashed ellipse. The molecular weights of species in the two groups overlapped, although the ones in the red dashed ellipse are characterized with relatively lower molecular weights, and the ones in the blue dashed ellipse are with relatively higher molecular weights. The O/C ratios can clearly distinguish the two groups: 0.56 ± 0.35 (average \pm one standard deviation) for the red ellipse group and 0.18 ± 0.08 for the blue ellipse group, indicating that the O/C ratio of these compounds could be a key parameter.

335

Figure 4. Saturation mass concentration of CHO and CHON compounds against their molecular weights, as colour-coded by the O/C ratios. Note that compounds with an O/C ratio equal to or greater than 1.0 are marked with the same colour. The CHO and CHON compounds are denoted by squares and hexagrams, respectively. Whiskers denote 25th and 75th percentile values of measured saturation mass concentration from 30 ambient samples, and whiskers are ultimately due to variability in the measured T_{max} of CHO and CHON compounds. Dashed ellipses group compounds on the basis of O/C range.

340

Figure S11 clearly shows the O/C characteristics of compounds in the two regions, where the red triangles correspond to those in the red dashed ellipse of Figure 4, and the blue circles correspond to those in the blue dashed ellipse. The O/C ratios of organic compounds in the red dashed ellipse ranged from 0.25 to 1.0, and the O/C ratios of those in the blue dashed ellipse varied between 0-0.25 (Figure S11). $C_6H_{10}O_5$ (levoglucosan or related isomers) in the red dashed ellipse, is a well-accepted tracer of biomass burning OA (BBOA) (Gaston et al., 2016). $C_{16}H_{32}O_2$ (palmitic acid), $C_{17}H_{34}O_2$ (margaric acid), $C_{18}H_{32}O_2$ (linoleic acid), and $C_{18}H_{34}O_2$ (oleic acid) in the blue dashed ellipse, have been previously identified as markers of cooking-influenced OA (COA) (Chow et al., 2007; Pei et al., 2016). The correlation coefficients (*Pearson's r*) between $C_6H_{10}O_5$ and 92% of compounds in the red dashed ellipse are from 0.64 to 0.98, and the correlation coefficients between $C_{18}H_{34}O_2$ and 37% of compounds in the blue dashed ellipse are from 0.60 to 0.74. We show examples of the correlation of $C_6H_{10}O_5$, $C_{18}H_{32}O_2$ and other compounds in Figure S12. Indeed, there are a number of sources of COA and BBOA near the campaign site, and the campaign was carried out during the heating season. Hence, organic compounds in the red dashed ellipse may be mainly derived from BBOA, and those in the blue dashed ellipse may be partly derived from COA.

350

355 We thus separately optimized the correlation between the molecular elemental composition and the saturation mass

concentration of organic compounds in these two regions in Figure 4. As shown in Table 2, the parameterization of Eq. (4-1) is dedicated to compounds with O/C ratios of 0.25-1, whereas Eq. (4-2) is more suitable for compounds with O/C ratios of 0-0.25. Mohr et al. (2019) derived parameterization mainly based on HOMs ($-11 < \log_{10}(C^*) < 3$) produced by α -pinene oxidation, whereas our fits are mainly based on semi-volatility organic compounds (SVOCs, $10^{-0.5} < C^* \leq 10^{2.5}$) and low-volatility organic compounds (LVOCs, $10^{-4.5} < C^* \leq 10^{-0.5}$), which are predominantly in the particle phase in the atmosphere.

Table 2. The volatility parameterizations of this study and cited literature. In this study, the parameterizations of saturation mass concentration were modified by the least-square optimization from Eq. (4) at 298 K.

	n_c^0	b_c	b_o	b_{co}	b_N	Suggested O/C range	b_{add}
Eq. (4-1) in this study	25	0.0700	0.6307	-0.0615	2.3962	0.25-1	/
Eq. (4-2) in this study	25	0.2075	2.8276	-1.0744	1.8223	0-0.25	/
Donahue et al. (2011)	25	0.475	2.3	-0.3	/	/	/
Mohr et al. (2019)	25	0.475	0.2	0.9	2.5	/	/

Li et al. (2016) (CHO)	22.66	0.4481	1.656	-0.7790	/	/	/
Li et al. (2016) (CHON)	24.13	0.3667	0.7732	-0.07790	1.114	/	/

4 Atmospheric implications

For ambient studies, it is crucial to develop a more accurate empirical formula to estimate the volatility of organics in particles. Parametrization in Donahue et al. (2011) is mainly based on mono-functional compounds such as alcohol, aldehyde, acid and etc., and could cause a large uncertainty when estimating the volatility of compounds in the range $-5 < \log_{10}(C^*) < 2$ and $1:3 < O/C < 1:1$, because volatilities in this region are extrapolated with volatilities of compounds with simpler molecular formulae (Donahue et al., 2011). In addition, compounds in this region may be characterized with multiple functionalities, which are also lacking as reference standards in the Donahue et al. (2011) study. Compounds in this region can be roughly regarded as oxygenated organic aerosols (OOAs) (Donahue et al., 2011). In our study, a yellow dashed frame is used to mark this region in Figure S11, which is occupied by organic compounds that are concentrated in the red dashed ellipse of Figure 4. Furthermore, we used the 15 highly oxygenated organic molecules (HOMs) with O/C ratios of 0.25-1 and 230 CHO compounds with O/C ratios of 0.25-1 as benchmarks to compare the performance of different parameterization methods, as shown in Figure 5a. The volatilities of 15 HOMs was obtained by SIMPOL from the Tröstl et al. (2016) study. The 230 CHO (O/C: 0.25-1) compounds are from Zhao et al. (2013) and Mazzoleni et al. (2010), because predicted molecular structures of these 230 compounds are reliable. As expected, volatilities predicted by the Donahue et al. (2011) parameterization are not consistent with those by SIMPOL. Although Mohr et al. (2019) updated parametrization based on those 15 HOMs detected by Tröstl et al., (2016), the volatility predicted by the Mohr et al. (2019) parameterization does not match those by SIMPOL very well, which could be explained by not considering covalent binding, using the same parameterization for dimer and monomer may cause deviations. On the other hand, the accuracy in predication of volatility of the parameterizations of Stolzenburg et al. (2018), Li et al. (2016), and Eq. (4-1) is generally comparable (Figure 5a). Compared to the parameterizations of Stolzenburg et al. (2018) and Li et al. (2016), the consistency between the parameterization of Eq. (4-1) and SIMPOL is not as good for the more volatile compounds ($\log_{10}(C^*) > 0.5$), but the consistency is better for the LVOCs ($10^{-4.5} < C^* \leq 10^{-0.5}$), which reflects the inherent strength and deficiency of the FIGAERO method. One of reasons may be that in this study, we used the saturation mass concentration (C^*) of five organic standards concentrates in the range of $-5 < \log_{10}(C^*) < 0.5$, as shown in Figure S13. Moreover, the parameterization of Eq. (4-1) was derived based on the ambient compounds in the red dashed ellipse of Figure 4, whose volatilities predominantly concentrate in the range of $-4.5 < \log_{10}(C^*) < 1.5$.

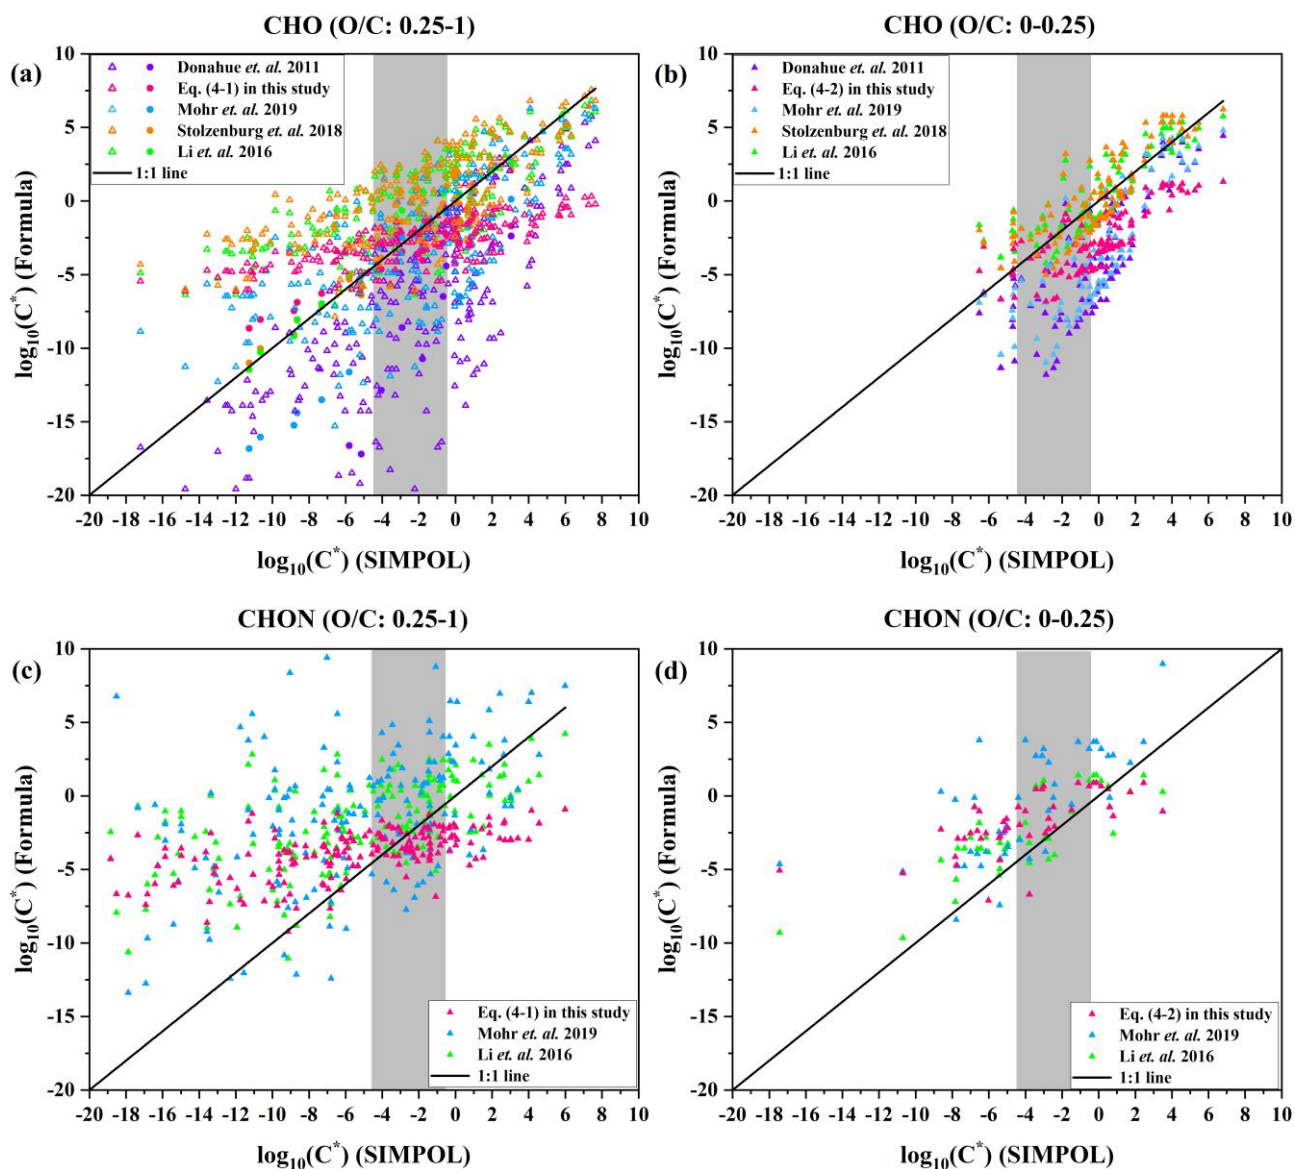

Figure 5. Saturation mass concentration (C^*) of 15 HOMs (O/C: 0.25-1) and 230 CHO compounds (O/C: 0.25-1) estimated by Eq. (4-1) (a), 106 CHO compounds (O/C: 0-0.25) estimated by Eq. (4-2) (b), 183 CHON compounds (O/C: 0.25-1) estimated by Eq. (4-1) (c), 46 CHON compounds (O/C: 0-0.25) estimated by Eq. (4-2) (d) and the parametrizations from Donahue et al. (2011), Mohr et al. (2019), Stolzenburg et al. (2018), and Li et al. (2016), against that estimated by SIMPOL. In panel a, the 15 HOMs are denoted by circles and 230 CHO compounds are denoted by triangles. The 230 CHO (O/C: 0.25-1), 106 CHO (O/C: 0-0.25), 183 CHON (O/C: 0.25-1) and 46 CHON (O/C: 0-0.25) compounds are from Zhao et al. (2013) and Mazzoleni et al. (2010) field campaigns. The grey colored band denotes low-volatility organic compounds (LVOCs).

400

Also, we selected 106 CHO compounds with O/C ratios of 0-0.25 from compounds observed by Zhao et al. (2013) and Mazzoleni et al. (2010). The saturation mass concentration (C^*) of these compounds are estimated by different parameterizations and SIMPOL. As shown in Figure 5b, volatilities predicted by the Donahue et al. (2011) parameterization is off those by SIMPOL, this is mainly because the parameterization was developed according to higher volatility of organic compounds whose volatilities concentrate in the range of $0 < \log_{10}(C^*) < 9$, but those selected 106 CHO compounds with lower volatility whose volatilities concentrate in the range of $-6 < \log_{10}(C^*) < 6$. Although Mohr et al. (2019) updated parametrization based on 15 HOMs whose volatilities concentrate in the range of $-11 < \log_{10}(C^*) < 3$, volatilities predicted by Mohr et al. (2019) parameterization still is off those by SIMPOL. This is mainly because those 106 CHO compounds with lower O/C (0-0.25), but the O/C of those 15 HOMs is 0.25-1. Compared to the parameterizations of Stolzenburg et al. (2018)

405

410 and Li et al. (2016), in general, the Eq. (4-2) parameterization does not match SIMPOL as well. However, the parameterizations of Stolzenburg et al. (2018), Li et al. (2016) and Eq. (4-2) are comparable for LVOCs. This may be again explained by the difference between the C^* of our organic standards in the literature and those calculated by SIMPOL and by the volatility distribution of organic standards (Figure S13).

415 We selected 183 CHON compounds with O/C ratios of 0.25-1 and 46 CHON compounds with O/C ratios of 0-0.25 from Zhao et al. (2013) and Mazzoleni et al. (2010). The molecular structures of selected species can be reliably predicted, and then their saturation mass concentration (C^*) are estimated by different parameterizations and SIMPOL, respectively. The parameterizations of Donahue et al. (2011) and Stolzenburg et al. (2018) relies only on carbon and oxygen number and do not explicitly mention the nitrogen coefficient (b_N), thus these two parameterizations are excluded from the comparison of the
420 volatility of CHON compounds. As shown in Figure 5c, the performance of Eq. (4-1) parameterization for CHON compounds (O/C: 0.25-1) is similar to that for CHO compounds (O/C: 0.25-1) (Figure 5a). The volatilities LVOCs predicted by the Eq. (4-1) parameterization are more consistent with SIMPOL than the parameterizations of Li et al. (2016). In Figure 5d, the volatilities of CHON compounds (O/C: 0-0.25) predicted by the parameterizations of Li et al. (2016) and our study are comparable, and most of the data points are close to the 1:1 line. The volatility of CHON compounds predicted by the Mohr
425 et al. (2019) parameterization does not match those by SIMPOL very well.

Although the applicability of the parameterizations of Li et al. (2016) and Stolzenburg et al. (2018) is more extensive and the volatilities estimated by these two parameterizations agree well with SIMPOL, Li et al. (2016) and Stolzenburg et al. (2018) modified parameterizations based on a large number of organic species from NCI open database and SIMPOL calculations,
430 respectively. However, the parameterizations of Eq. (4-1) and Eq. (4-2) were derived from organic compounds with different O/C ratios in ambient particles, whose volatilities were estimated by the calibration experiments instead of SIMPOL. Therefore, Eq. (4-1) and Eq. (4-2) can better represent the volatility of ambient organic aerosols. In addition, in Figure 5, for LVOCs, the volatility estimation by Eq. (4-1) and Eq. (4-2) is better than Li et al. (2016) and Stolzenburg et al. (2018). Compared with the ELVOCs, IVOCs and SVOCs, the LVOCs have a dominant contribution to particle growth in new particle formation events.
435 Hence, our parameterizations could be well applied to assess the condensational growth of newly formed particles.

In summary, our study developed empirical volatility-molecular formula functions (Eq. (4-1) and Eq. (4-2)), based on measured C^* of selected CHO and CHON compounds in ambient particles. The parameterizations of Eq. (4-1) and Eq. (4-2) can more accurately predict the volatility of LVOCs with higher O/C (0.25-1) and lower O/C (0-0.25) in the ambient organic aerosols,
440 respectively, owing to the nature of the FIGAERO method. The comparison with previous empirical functions suggests that it is feasible to modify empirical functions based on atmospheric organic compounds with unknown structures and functional groups using calibration experiments. When analyzing the volatility of atmospheric organic aerosols, it is suggested to create the calibration curve from experiments with the same conditions as that of ambient samples, because the addition of inorganic salts, mixing of organic compounds, mass loadings, and particle size distributions could together influence T_{max} values of
445 organic compounds. Furthermore, we suggest there should be specialized volatility parameterization for different O/C compounds.
