10 Abstract

11

12 Smoke from western North American wildfires reached the stratosphere in large amounts in
13 August 2017. Limb-oriented satellite-based sensors are commonly used for studies of wildfire
14 aerosol injected into the stratosphere (OMPS-LP (Ozone Mapping and Profiler Suite Limb
15 Profiler) and SAGE III/ISS (Stratospheric Aerosol and Gas Experiment III on the International
16 Space Station)). We find that these methods are inadequate for studies the first 1 – 2 months after
17 such a strong fire event due to event termination (“saturation”). The nadir-viewing lidar CALIOP
18 (Cloud-Aerosol Lidar with Orthogonal Polarization) is less affected due to shorter path in the
19 smoke, and, further, provides means that we could use to develop a method to correct for strong
20 attenuation of the signal. After the initial phase, the aerosol optical depth (AOD) from OMPS-LP
21 and CALOP show very good agreement above the 380 K isentrope, whereas the OMPS-LP tends
22 to produce higher AOD than CALIOP in the lowermost stratosphere (LMS), probably due to
23 reduced sensitivity at altitudes below 17 km. Time series from CALIOP of attenuation-corrected
24 stratospheric AOD of wildfire smoke show an exponential decline during the first month after the
25 fire, which coincides with highly significant changes in the wildfire aerosol optical properties.
26 The AOD decline is verified by the evolution of the smoke layer composition, comparing the
27 aerosol scattering ratio (CALIOP) to the water vapor concentration from MLS (Microwave Limb
28 Sounder). Initially the stratospheric wildfire smoke AOD is comparable with the most important
29 volcanic eruptions during the last 25 years. Wildfire aerosol declines much faster, 80 – 90% of
30 the AOD is removed with a half-life of approximately 10 days. We hypothesize that this dramatic
31 decline is caused by photolytic loss. This process is rarely observed in the atmosphere. However,
32 in the stratosphere this process can be studied with practically no influence from wet deposition,
33 in contrast to the troposphere where this is the main removal path of sub-micron aerosol particles.
34 Despite the loss, the aerosol particles from wildfire smoke in the stratosphere are relevant for the
35 climate.

36

37 1. Introduction

38

39 Background stratospheric aerosol is composed of sulfuric acid, water, carbonaceous components,
40 and minor extraterrestrial and tropospheric components (Murphy et al., 2007; Kremser et al.,
41 2016; Martinsson et al., 2019). Volcanism is a strong source of the stratospheric sulfurous,
42 carbonaceous and ash aerosol (Martinsson et al., 2009; Andersson et al., 2013; Friberg et al.,
43 2014). Large eruptions, like that of Mt Pinatubo in 1991, affect the stratosphere for several years,
44 causing global cooling of several tenths of degrees Kelvin (Kremser et al., 2016). These eruptions
45 are scarce, only a few per century (Ammann et al., 2003; Stothers, 2007). Moderate eruptions are
46 more frequent contributors to the stratospheric aerosol (Vernier et al., 2011; Andersson et al.,
47 2015; Friberg et al., 2018), forming the persistently variable stratospheric background aerosol
48 (Solomon et al., 2011).

49

50 The stratospheric aerosol is also influenced by pyrocumulonimbus clouds (pyroCb) that form
51 during extreme weather conditions in connection with intense wildfires (Fromm et al., 2010). The

52 ongoing climate change is projected to increase the frequency of large wildfires (Kasischke et al.,
53 2006; Dennison et al., 2014). Interestingly, the two largest events have, in terms of stratospheric
54 impact, occurred during the last few years, in North America 2017 (Peterson et al., 2018) and
55 Australia 2019-2020 (Kablick et al., 2020). Here we investigate the great pyroCbs formed in
56 southern British Columbia, Canada and northern Washington State, USA on August 12 – 13,
57 2017 (Fromm et al., 2021). Figure 1a shows an example of the strong impact on the stratospheric
58 aerosol of the 2019 Raikoke volcanic eruption, one of the strongest eruptions post Mt Pinatubo in
59 1991. In comparison, Figure 1b demonstrates the formidable early impact of wildfire aerosol. The
60 stratospheric impact of that fire has been described in terms of light-backscatter reaching
61 unprecedentedly high values for a non-volcanic aerosol layer (Khaykin et al., 2018), light
62 extinction about 20 times higher than after the Pinatubo volcanic eruption in 1991 (Ansmann et
63 al., 2018), and mass of smoke comparable to that of a moderate sized volcanic eruption (Peterson
64 et al., 2018). The pyroCbs lifted smoke from the fire to the extratropical tropopause region, where
65 absorption of radiation by black carbon (BC) in the smoke induced additional lift to 23 km
66 altitude in 2 months (Yu et al., 2019; Lestrelin et al., 2021).

67
68 Smoke particles from wildfires contain a dominating fraction of organic matter by mass
69 (Garofalo et al., 2019). Organic aerosol is susceptible to photochemical loss (Jimenez et al.,
70 2009), and laboratory studies have demonstrated that this phenomenon could be an important
71 sink of secondary organic aerosol mass (Molina et al., 2004; Sareen et al., 2013). The residence
72 time of stratospheric air spans months to years depending on its path in the Brewer-Dobson
73 circulation (Engel et al., 2009; Bönisch et al., 2009). Due to very low probability of clouds, fine
74 aerosol particles have considerably longer residence times in the stratosphere than in the
75 troposphere, which further emphasizes the importance of investigating photochemical loss in the
76 stratosphere (Martinsson et al., 2019).

77
78 The aim of this study is to further understand the stratospheric aerosol sources and its climate
79 impact. We develop methodology to correct for attenuation in dense smoke layers from wildfires
80 to properly deal with intense smoke injections into the stratosphere, with two main questions: 1)
81 does photochemical loss of wildfire smoke occur in the stratosphere, and 2) how does the AOD
82 of smoke from the wildfire studied here compare with volcanic aerosol?

83
84 The first decade of the 21st century was characterized by slower temperature evolution than
85 anticipated from CMIP5 models (Fyfe et al., 2016). The discrepancy was attributed to inter-
86 decadal Pacific oscillation (Medhaug et al., 2017), variations in solar forcing (Myhre et al., 2013)
87 and aerosol in the stratosphere from moderate volcanic eruptions (Santer et al., 2014). Should
88 wildfire smoke in the stratosphere be added to this list of phenomena that require more attention
89 in climate models?

90
91 Our investigation deals with the evolution of the wildfire AOD, and aerosol optical properties
92 obtained from the lidar CALIOP aboard the CALIPSO (Cloud-Aerosol Lidar and Infrared
93 Pathfinder Satellite Observation) satellite, OMPS-LP/Suomi and SAGE III/ISS in comparison
94 with volcanic injections to the stratosphere. Additionally, the water vapor concentrations of

95 individual smoke layers are investigated by the MLS, the spatial evolution of smoke layers is
96 investigated using OMPS-NM (Ozone Mapping and Profiler Suite Nadir Mapper), and the AODs
97 and extinction coefficients obtained from CALIOP are compared with that of OMPS-LP and
98 SAGE III/ISS.

99

100 **2. Methods**

101

102 This study of the dense stratospheric smoke layers from pyro-cumulonimbus formed over
103 Western North America in August 12 – 13, 2017 is based on five satellite sensors. For four of
104 them, OMPS-LP, SAGE III/ISS, MLS and OMPS-NM, high level products (Level 2) are used.
105 The CALIOP data evaluation is based on a Level 1 product. A method to correct for attenuation
106 of the CALIOP laser beam in the smoke layers is presented. For these reasons CALIOP requires
107 more space in this section compared to the other methods.

108

109 **2.1 CALIOP**

110

111 The evaluation of the CALIOP instrument carried by the CALIPSO satellite is based on version
112 4-10, level 1B data. CALIOP measures backscattering of laser light at two wavelengths, 532 and
113 1064 nm. For the shorter wavelength, scattered laser light is detected in parallel and
114 perpendicular polarizations relative to the outgoing beam. These almost nadir-viewing aerosol
115 and cloud measurements result in high resolution vertical profiles. For the altitude ranges <8.2,
116 8.2 – 20.2, 20.2 – 30.1 and 30.1 – 40 km the vertical resolutions are 30, 60, 180, and 300 m,
117 respectively. CALIPSO orbits between 82° S and 82° N, completing 14 – 15 orbits per day
118 (Winker et al., 2007; Winker et al., 2010).

119

120 **2.1.1 AOD**

121

122 Stratospheric AOD was obtained by integrating the backscattering intensity corrected for
123 attenuation (described below) from the tropopause to 35 km altitude. Figure 1b illustrates how
124 attenuation of the laser signal strongly reduced the signal below the dense smoke layer between
125 11 to 16 km altitude. We use the tropopause height according to MERRA-2 supplied with the
126 version 4.10 CALIOP data, which is a mixture of a dynamic and a thermal tropopause. The AOD
127 was averaged in the 20 - 80° N latitude range, where all nighttime swaths available from
128 CALIOP were included. The data were averaged over all longitudes in one-degree latitude bands,
129 and these latitude bands were averaged for the 20 - 80° N latitude range using area-weighting.
130 For dense layers, the lidar ratios estimated for the individual smoke layers were applied
131 (explained below). Apart from the first few days the lidar ratio shows no temporal evolution, it is
132 found to have geometrical mean of 48.9 sr with double-sided 95% confidence interval of 47.6 –
133 50.3 sr (Figure 2a), which is close to the typical background lidar ratio of 50 sr (Jäger and
134 Deshler, 2003). For layers that were not dense, the lidar ratio was held at this typical background
135 level. The volume depolarization ratio (δ_v) contains information that can be used to classify
136 aerosol layers. When δ_v is less than 0.05 the data is considered background and the lidar ratio is
137 set to 50 sr (Vernier et al., 2009). Ice-clouds were removed in the lowest 3 km of the stratosphere
138 by identifying them in stratospheric layers where the backscattering was high (attenuated

139 backscattering larger than $0.0025 \text{ km}^{-1} \text{ sr}^{-1}$). This limitation is introduced to avoid statistically
140 induced detection of ice clouds from weak signals. Data in these layers were classified as
141 probable ice clouds if their δ_v exceed 0.20, which classifies all the smoke layers in Figure 2c as
142 aerosol since the volume depolarization ratio always is smaller or equal to that of particles for a
143 depolarizing aerosol. The data within each swath were then clustered depending on their location.
144 Noise in the data led to some lone pixels within layers. These were reclassified depending on the
145 surrounding pixels, making sure that no single pixel marked as aerosol occurred within the ice-
146 cloud layers. Layers of ice-clouds were then expanded upwards and horizontally to capture faint
147 edges of the clouds (Friberg et al., 2018). Aerosol with δ_v in the range 0.05 to 0.2 were
148 considered to be smoke, and $\delta_v < 0.05$ as background aerosol. In the present work the latter
149 discrimination had little effect because smoke was found to have the same lidar ratio as typical
150 background aerosol. The classification was carried out on data at 8 km resolution along each
151 swath with their highest vertical resolution (30, 60, or 180 m, depending on altitude), after which
152 the tropospheric data were removed. Possible polar stratospheric cloud (PSC) signals north of
153 45°N were excluded by classifying pixels with temperature below 195 K as possible PSC
154 occasions. Underlying pixels were also excluded, to prevent bias from attenuation of the lidar
155 signals or from settling ice-crystals (Friberg et al., 2018).

156

157 ***2.1.2 Attenuation correction and radiative properties of individual smoke layers***

158

159 The evolution of the lidar, color and depolarization ratios were investigated using 32 separate
160 smoke layer measurements over the period 3 – 59 days after the fire. CALIOP has a statistical
161 disadvantage compared with lidars at the ground (Baars et al., 2019), because of small solid angle
162 due to long distance to the stratosphere ($\sim 700 \text{ km}$) and short measurement time. Optical
163 properties of old and faint individual smoke layers therefore could not be quantified with high
164 precision using CALIOP. The faint layers though still affect the AOD determinations described
165 above, where AOD elevation after the fire remains approximately one year. Out of the 32 smoke
166 layers studied, 29 were night-time measurements, whereas the remaining three are defined as
167 day-time measurements. These latter ones increased the number of early observations (day 3 – 5)
168 and were taken when the disturbance from solar radiation is small, i.e., shortly before the night.

169

170 During the first weeks after the fire the smoke layers could be very dense with layer AODs
171 exceeding 1, causing strong attenuation of the CALIOP signals with two-way transmissions down
172 to below 0.01. Such high AOD values were also observed for this fire by the Deep Space Climate
173 Observatory/Earth Polychromatic Imaging Camera (DSCOVR-EPIC) mapper and the Aerosol
174 Robotic Network (AERONET) (Torres et al., 2020). For the 532 nm wavelength the particle lidar
175 ratio was estimated by aiming the scattering ratio (R; total-to-molecular backscattering ratio)
176 below a smoke layer to a target value. The target value was obtained from the background
177 scattering ratio beside each smoke layer investigated, which on average is $R = 1.08$, with standard
178 deviation ± 0.05 . To reduce influence from noise, the CALIOP data were averaged along the
179 swath. The averaging range varied between the smoke layers, due to its extension along the
180 swath, the homogeneity of the layer, and avoidance of sub-layer features.

181

182 The particle lidar ratio of an individual smoke layer was iterated until reaching the target value (R
 183 = 1.08) described above from the combined effect of all altitude pixels. Pixels at altitudes outside
 184 the smoke layer were set to the background lidar ratio of 50 sr (Jäger and Deshler, 2003). The
 185 altitude resolution provided in the CALIOP data was used, where each altitude pixel (j) is
 186 corrected for attenuation. The calculation starts at the highest altitude (40 km) and continues
 187 downwards in two rounds. In the first round the star-marked quantities of equations 1-3 were
 188 computed, correcting for attenuation from overlaying pixels. Before moving to the next altitude,
 189 we account for self-attenuation from the pixel itself (equations to the right, without a star):
 190

$$191 \quad \beta_j^* = \frac{\beta_j'}{\prod_{k=1}^{j-1} T_k^2}; \quad \beta_j = \frac{\beta_j^*}{\sqrt{T_j^{*2}}} \quad (1)$$

192
 193 where β' is the attenuated backscattering and T^2 the two-way transmissions from both particles
 194 and molecules. The two-way particle transmission is obtained by first computing the AOD:
 195

$$196 \quad AOD_j^* = (\beta_j^* - \beta_{m,j})S_p\Delta z_j; \quad AOD_j = (\beta_j - \beta_{m,j})S_p\Delta z_j \quad (2)$$

197
 198 where Δz_j is the height of the altitude pixel, $\beta_{m,j}$ is backscattering from air molecules, and S_p the
 199 lidar ratio of the aerosol particles. The molecular lidar ratio, for computation of the molecular
 200 extinction, was set to 8.70477 sr (Prata et al., 2017). The two-way transmission of altitude pixel j
 201 due to the particles present is obtained from:
 202

$$203 \quad T_{p,j}^{*2} = \exp(-2AOD_j^*); \quad T_{p,j}^2 = \exp(-2AOD_j) \quad (3)$$

204
 205 These calculations in equations 1 – 3 are carried out until the background layer between altitudes
 206 a and b below the smoke layer reaches the target scattering ratio of 1.08 (Figure 3a):
 207

$$208 \quad R = \frac{\sum_a^b \beta_j}{\sum_a^b \beta_{m,j}} \quad (4)$$

209
 210 CALIOP measurements are affected by multiple scattering (Wandinger et al., 2010), causing
 211 overestimation of the backscattering described by the multiple scattering factor (η). This factor is
 212 not known, previous estimates for fine aerosol are in the range 0.085 – 0.95 for layers thicker
 213 than 500 m (Prata et al., 2017). In equation 2 the backscattering inflated by multiple scattering
 214 (β) is multiplied by a lidar ratio. The latter is obtained by iterating equations 1 – 3 until reaching
 215 the target scattering ratio, that of the surrounding air, below the cloud. Since the backscattering is
 216 inflated by multiple scattering, the lidar ratio obtained will become the product of the actual lidar
 217 ratio and the multiple scattering factor, i.e., the effective lidar ratio. Thus, while overestimating
 218 the backscattering and underestimating the lidar ratio to equal multiplicative degree, the method
 219 applied here corrects the AOD for multiple scattering.
 220

221 Error estimates of the effective lidar ratio were obtained by varying the target scattering ratio
 222 from its average value ($R = 1.08$) mentioned above, to its ± 0.05 standard deviation range. The
 223 fitting uncertainty in these estimates is strongly dependent on the light extinction in the smoke
 224 layer. Dense layers result in very small uncertainties in the effective lidar ratio because of the
 225 strong impact on R from a slight change in the extinction. Layers with lower extinction
 226 progressively increase the uncertainties of the estimate. When the error estimate of the effective
 227 lidar ratio fit exceeds 25% the result is excluded from the data analysis, which terminates
 228 estimates of lidar ratios from day 22 after the fire.

230 The color ratio, the ratio between the backscattering at 1064 nm to 532 nm wavelength, is
 231 affected by a difference in attenuation of the two wavelengths. This is clearly visible for dense
 232 smoke layers in the CALIOP browse images by a gradual increase of the color ratio through the
 233 layer because of the weaker attenuation for 1064 nm wavelength than for 532 nm (Figure 1d).
 234 Therefore, estimations of the attenuation were undertaken also for the long wavelength. The
 235 molecular backscattering is assumed to be 1/16 of that at 532 nm ($1/\lambda^4$ dependence of Rayleigh
 236 scattering). Weak molecular scattering at 1064 nm prohibits lidar ratio estimation at that
 237 wavelength by CALIOP. Instead, the lidar ratio was assumed to be 60 sr, inducing uncertainties
 238 in the color ratio. The volume color ratio is obtained from:

$$240 \quad \chi = \sum_{k=\text{top}}^{\text{base}} \beta_{1064,k} / \sum_{k=\text{top}}^{\text{base}} \beta_{532,k} \quad (5)$$

241
 242 To limit influence from attenuation in the color ratio computations, the estimates were based on
 243 the upper part of a smoke layer. Starting from the top of the smoke layer, the computations were
 244 truncated when the two-way transmission of the 532 nm wavelength fell below 0.7. Varying the
 245 1064 nm wavelength lidar ratio in the wide range of 60 ± 20 sr the uncertainty in the color ratio
 246 becomes less than $\pm 5\%$ with this constraint applied. From the color ratio we define the particle
 247 color ratio:

$$249 \quad \chi_p = \sum_{k=\text{top}}^{\text{base}} (\beta_{1064,k} - \beta_{m,1064,k}) / \sum_{k=\text{top}}^{\text{base}} (\beta_{532,k} - \beta_{m,532,k}) = \frac{\chi R}{R-1} - \frac{1}{16(R-1)} \quad (6)$$

250
 251 where we made use of the wavelength dependence of Rayleigh scattering for molecular
 252 scattering, and the scattering ratio for the 532 nm wavelength was obtained from eqn. 4.

253
 254 We also investigated the depolarization of the scattered laser beam at 532 nm by first forming the
 255 volume depolarization ratio:

$$257 \quad \delta_v = \sum_{k=\text{top}}^{\text{base}} \beta'_{532+,k} / \sum_{k=\text{top}}^{\text{base}} \beta'_{532,k} \quad (7)$$

258
 259 where symbol \perp indicates scattered light polarized perpendicularly to the incident beam. Having
 260 access to the volume depolarization and an estimate of the molecular depolarization ratio $\delta_m \approx$
 261 0.003656 (Prata et al., 2017; Hostetler et al., 2006) the particle depolarization ratio is obtained
 262 from:

263

$$\delta_p = \frac{\delta_v - \delta_m + \delta_v(1 + \delta_m)(R - 1)}{\delta_m - \delta_v + (1 + \delta_m)(R - 1)} \quad (8)$$

265

266 where R is obtained from eqn. 4.

267

268 **2.2 Extinction coefficients and AOD from OMPS-LP**

269

270 The aerosol data from OMPS-LP (Chen et al., 2018; Jaross et al., 2014; Loughman et al., 2018)
271 have lately been used extensively in the literature on volcanic and wildfire impact on the
272 stratospheric aerosol. Several data products are available, here we use the recently released Level
273 2 product: Suomi-NPP OMPS LP L2 AER Daily Product, version 2.0 (Taha et al., 2020). The
274 polar-orbiting Suomi satellite completes between 14 and 15 orbits per day. OMPS-LP is a limb-
275 scattering method that collects data looking backwards along the satellite orbit, and along two
276 other directions separated by 4.25° from the orbit, giving a cross-track separation of
277 approximately 250 km at the tangent point. Measurements are undertaken in the wavelength and
278 altitude ranges of 290 – 1000 nm and 10 – 80 km, respectively. The vertical resolution of OMPS-
279 LP is 1.5 – 2 km (Rault and Loughman, 2013). The measurements are evaluated by the Gauss-
280 Seidel limb scattering (GSLs) radiative transfer model. By improving calculations of the multiple
281 scattering source function, the total radiance error has become 1 – 3% (Loughman et al., 2015).
282 The aerosol product used here comprises 6 wavelengths (510, 500, 675, 745, 869 and 997 nm).
283 The group responsible for the OMPS-LP version 2.0 data (Taha et al., 2020) recommends caution
284 when using data from altitudes below 17 km altitude due to loss of sensitivity. This problem can
285 be reduced by use of the 745 nm and longer wavelengths. Here we will make use of two of
286 wavelengths: 745 nm because of the reduced problem with sensitivity, and 510 nm because it is
287 the wavelength closest to that of CALIOP (532 nm).

288

289 The OMPS-LP aerosol extinction coefficients are provided on a grid with a vertical resolution of
290 1 km. To study the smoke from the August 2017 fire we compute the average AOD over all
291 longitudes in the latitude interval $20 - 80^\circ$ N for three layers, the LMS (tropopause to 380 K
292 isentrope), lower Brewer-Dobson branch (380 – 470 K) and the upper Brewer-Dobson branch
293 (470 K to 35 km altitude). The OMPS-LP version 2 dataset use a cloud detection algorithm (Chen
294 et al., 2016), and comes in two forms: one without filtering out signals from clouds, and the other
295 where signals affected by clouds and polar stratospheric clouds are removed. In Figure 4 we
296 show both these varieties for 745 nm wavelength, and, with and without flags regarding data
297 quality including profile retrieval errors (named RetrievalFlags in the OMPS-LP files), high root-
298 mean squares (ResidualFlags), and further errors from the South Atlantic anomaly, disturbances
299 from the Moon, solar eclipses, planets, and satellite maneuvers (SwathLevelQualityFlags). In the
300 two upper layers (Figures 4a and b) the differences are usually small between the varieties except
301 for some spikes, whereas the LMS data (Figure 4c) show large stochastic variability as well as
302 periods of clear differences between the varieties. Since this data is taken well below 17 km
303 altitude, sensitivity issues can be expected (Taha et al., 2020), see above. Days 130 – 190 (during
304 December 2017 to February 2018) several spikes appear in the two higher layers which probably

305 are caused by polar stratospheric clouds. The data set filtered for clouds and flagged stands out by
306 comparably small peaks, whereas the differences between the varieties usually are small
307 elsewhere. We therefore select the cloud-filtered and flagged data for further analysis in the
308 coming sections.

309

310 *2.3 Extinction coefficients from SAGE III/ISS*

311

312 SAGE III/ISS is a limb-viewing instrument based on solar occultation. Here we make use of
313 Level 2 aerosol extinction coefficients (SAGE III/ISS User's Guide, 2018), version 5.10,
314 supplied with a vertical resolution of 0.5 km. The upper limit of the slant path optical depth is
315 about 8, translating to a vertical optical depth of approximately 0.02 (SAGE III/ISS User's Guide,
316 2018). The orbiting of ISS differs markedly from the polar orbiting satellites CALIPSO
317 (CALIOP) and Soumi (OMPS-LP). This causes sporadic coverage by ISS of the latitudes of
318 interest here, resulting in that no average AODs over the 20 – 80° N latitude range could be
319 formed with adequate time resolution. However, daily maximum extinction coefficients from
320 SAGE III/ISS could, when available, be included in a comparison with CALIOP and OMPS-LP.

321

322 *2.4 Water vapor measurements from MLS*

323

324 Water vapor concentrations (mixing ratio) in individual smoke layers was obtained from the MLS
325 instrument aboard the Aura satellite (Waters et al., 2006) in 12 vertical steps per decade of
326 pressure (version 5.0-1.0a, level 2). In nighttime measurements from days 6 – 59 after the fire,
327 the smoke layers studied by CALIOP were also investigated with MLS in almost simultaneous
328 measurements, both instruments being on satellites that are members of the A-train (L'Ecuyer
329 and Jiang, 2010). Data in the 10 – 316 hPa atmospheric pressure range were used, with vertical
330 resolution 1.3 – 3.2 km (Lambert et al., 2020; Livesey et al., 2020). Limited vertical resolution
331 induces problems to obtain well defined observation of H₂O concentration of smoke layers close
332 to the strong H₂O concentration gradient across the tropopause. H₂O from MLS for this fire have
333 previously been reported by Pumphrey et al. (2021). Close to the tropopause, but in the
334 stratosphere, no H₂O peak from a smoke layer can be detected. As the distance to the tropopause
335 increases, an H₂O peak from the smoke layer becomes discernible. Further up from the
336 tropopause, when the peak H₂O concentration is well above the extratropical tropopause at
337 atmospheric pressure of less than 110 hPa, a deep minimum appears between the tropopause
338 gradient and the peak from the smoke layer. All H₂O peaks were fitted with a Gaussian
339 distribution operating on logarithmic pressure and H₂O concentration to obtain estimates of the
340 peak concentration and the corresponding atmospheric pressure. To investigate a time
341 dependence in the smoke layer composition the peak H₂O concentration (C_{H₂O}) was compared
342 with the attenuation-corrected aerosol scattering ratio (R) from CALIOP, the optical equivalent of
343 the mixing ratio, where the latter was obtained by forming the geometrical mean over 900 m
344 around the peak scattering ratio. The ratio of the of the two quantities (R/C_{H₂O}) was formed, and
345 its dependence on time from the fire was studied. Out of the 13 smoke layers available with peak
346 water vapor concentrations above the altitude of 110 hPa atmospheric pressure, one was flagged
347 as low quality in the MLS data set, leaving 12 observations for the study of the R/C_{H₂O} evolution.

348
349 **2.5 UV aerosol index from OMPS-NM**
350
351 The UV aerosol index of OMPS-NM based on measurements at two wavelengths, 340 and 378.5
352 nm, is the official NASA aerosol index product according to OMPS-NM (NMMIEAI-L2 V2.1.1)
353 release notes (Torres, 2019). For strongly UV absorbing aerosols, like black carbon from
354 wildfires, the UV aerosol indexes strongly increases with altitude (Herman et al., 1997). UV
355 aerosol index can be used to quantify AOD when layer altitude is available (Torres et al., 2020).
356 However, here the OMPS-NM UV aerosol index was used to map the geographical evolution of
357 the smoke layers, that according to CALIOP measurements were distributed in both the
358 troposphere and the stratosphere.

360 **3. Results**

361
362 Here we use an approach based on five satellite sensors to study the influence on the stratosphere
363 of the great North American fire in August 2017. We start by briefly describing results from the
364 method to correct CALIOP data for attenuation of the backscattered laser light. Then follows a
365 comparison of AODs obtained from OMPS-LP and CALIOP. Absorption aerosol index from
366 OMPS-NM is used to describe the dispersion of the wildfire aerosol in the stratosphere. To
367 explain differences in AOD between OMPS-LP and CALIOP, a comparison of extinction
368 coefficients follows, where results from SAGE III/ISS also are included in the comparison. The
369 evolution of the optical properties of the wildfire aerosol is then described, before the North
370 American wildfire aerosol is compared with volcanic influence on the stratospheric AOD.
371 Finally, the fifth data set, water vapor from the MLS, is introduced in the discussion section,
372 where the evolution of the wildfire aerosol in the stratosphere is analyzed.

374 **3.1 Correction for attenuation**

375
376 The smoke layers usually were 1 – 3 km thick and could extend several degrees in longitude and
377 latitude. Measurements with the CALIOP lidar provide, in addition to short, nadir-viewing
378 measurement path in dense layers, the advantage that the signal is retrieved as a function of
379 position along the laser path with high resolution, which can be used to correct for attenuation of
380 the signal. Figure 3a shows the attenuated scattering ratio (R' ; the measured backscattering
381 divided by the calculated molecular backscattering) from an example-smoke-layer measured on
382 August 16, 2017. The scattering ratio should be close to 1 in air layers with low aerosol
383 concentration, whereas values below 1 is caused by attenuation from particles. As can be seen in
384 Figure 3a, the attenuated scattering ratio first increases (starting from above the layer). Then the
385 signal decreases and reaches well below unity from 11 km altitude and downwards, i.e., well
386 below the scattering ratio of particle-free air. By techniques described in the Methods section we
387 correct for attenuation and fit the lidar ratio (the ratio of extinction to backscattering) (Figure 2a)
388 to obtain an estimate of the backscattering without attenuation, as illustrated by the scattering
389 ratio (R) in Figure 3a.

390

391 The evolution of wildfire aerosol from day 3 to 59 after the North American PyroCbs on August
392 12, 2017, is first investigated by comparing 32 smoke layers from individual CALIOP swaths.
393 The influence from attenuation is shown in Figure 3b. Clear deviation from the 1:1 line appears
394 already at layer attenuated (uncorrected) AODs (AOD_{att}) of 0.12, and 50% reduction of the signal
395 appears at layer AOD_{att} of approximately 0.25. Reduction by more than 50% appears until day 10
396 after the fire, whereas those measurements close to the 1:1 line were taken after day 30. The
397 AOD, i.e., the AOD corrected for attenuation, exceeds the AOD_{att} by more than a factor of 5 in
398 the densest layers of this study (Figure 3b).

399

400 ***3.2 Comparison of CALIOP and OMPS-LP***

401

402 To study the evolution of the stratospheric AOD, we form a 3-dimensional box in the
403 stratosphere extending over all longitudes in the 20 – 80° N latitude range. In this box we use all
404 daily profiles, 14 – 15 CALIOP and 42 – 45 OMPS-LP, to form the average AOD. We apply the
405 method to correct CALIOP data for attenuation, as described in the Methods section. AODs are
406 computed for three layers, the LMS, the lower Brewer-Dobson branch, and the upper Brewer-
407 Dobson branch, as shown in Figure 5.

408

409 When comparing AODs, the measurement wavelengths should be as close as possible, due to the
410 wavelength dependence of scattering. CALIOP AODs are shown for 532 nm wavelength, and the
411 OMPS-LP data are shown for the close wavelength of 510 nm. In addition, the 745 nm AODs
412 from OMPS-LP is shown. The response to the 2017 North American fire is weak in the upper
413 Brewer-Dobson branch (Figure 5a), whereas the two lower layers (Figures 5b-c) show clear
414 increase of the AOD. Comparing the two methods, they agree well in the upper Brewer-Dobson
415 branch. In the lower Brewer-Dobson branch we see good agreement between the two methods,
416 except for the first 1 – 2 months after the fire where much higher AODs are recorded by CALIOP
417 (Figure 5b). The latter is also true for the LMS, whereas the general agreement between the two
418 methods is poor (Figure 5c). The OMPS-LP documentation advise against using data from below
419 approximately 17 km altitude, approximately the upper limit of the LMS, due to loss of
420 sensitivity (Taha et al., 2020). We therefore do not perform any further comparisons in the LMS.
421 The stratosphere above the LMS (above the 380 K isentrope) shows good agreement between the
422 two methods, except for the first 1 – 2 months after the fire (Figure 5d).

423

424 ***3.3 Early evolution of the smoke layers***

425

426 The daily AOD averages from CALIOP show large variability during the first days after the fire
427 because the lidar measures narrow curtains through the atmosphere, Figure 5e. The variability
428 remains until the smoke layers become sufficiently dispersed, allowing several daily
429 measurements of the smoke layers. The nadir-viewing OMPS-NM provides UV (ultraviolet)
430 absorbing aerosol index, where strong signal for strongly UV light absorbing aerosol is obtained
431 in the upper troposphere and the stratosphere. Figure 6 shows the geographic evolution of the
432 smoke layers from August 14 to 22, 2017 together with the orbits followed by the CALIOP
433 measurements. Up to August 16 the smoke is found in a rather confined area. From August 17 the

434 smoke layers are stretched in eastward direction, and after that the smoke spreads rapidly to the
435 east. The dispersion gradually increases the number of daily CALIOP observations of the smoke.
436 This can also be seen in Figure 5e, where the variability in the daily AOD data becomes
437 successively smaller. From day 10 (August 22) we see a clear pattern of decline of the AOD.

438
439 Figure 5e shows the total stratospheric AOD according to CALIOP from the tropopause to 35 km
440 altitude. We see a strong decline of the stratospheric AOD the first 1.5 months after the fire, and a
441 fitted exponential function has a half-life of 6.5 ± 0.9 days. Such a decline cannot be found in the
442 OMPS-LP AODs, which instead are increasing during the first month.

443
444 To further investigate this clear difference between the two methods, individual smoke layers are
445 investigated with respect to extinction coefficients. Figure 7a-d show the extinction coefficient of
446 strong smoke layers from four days in August and September 2017. From CALIOP we show the
447 attenuated extinction coefficients as well as the profiles corrected for attenuation. Together with
448 the CALIOP data the OMPS-LP data closest by are shown. It is obvious that OMPS-LP shows
449 very much smaller reaction to the smoke layers than CALIOP. However, we cannot be sure that
450 the two instruments viewed the same airmasses in these four examples, because the two
451 instruments do not belong to the same satellite constellation. To remove that obstacle, the daily
452 maximum stratospheric extinction coefficient from OMPS-LP was extracted and compared with
453 32 selected profiles' peak extinction coefficients from CALIOP. SAGE III/ISS was also included
454 in the comparison from day 19 after the fire. Unfortunately, the orbiting of ISS did not permit
455 measurements of the fire studied here before that day. The very strong signals from CALIOP are
456 not reflected in the OMPS-LP or SAGE III/ISS measurements, see Figure 7e. In part, this can be
457 explained by difference in vertical resolution, but as shown in Figures 7a-d, these high extinction
458 coefficients extend to broad vertical ranges that should allow detection of strong signals also by
459 OMPS-LP and SAGE III/ISS.

460
461 There is one principal difference between CALIOP on one hand and OMPS-LP and SAGE
462 III/ISS on the other hand: whereas the former is nadir-viewing (vertical) the latter two methods
463 operate in limb orientation (horizontal). This is important, because the horizontal extension of
464 smoke layers is much larger, e.g., the smoke layer in Figure 1b has a vertical extension of
465 approximately 2 km, whereas the horizontal extension is approximately 700 km. The vertical,
466 two-way transmission to the CALIOP sensor through this layer is approximately 0.01, which we
467 correct for. The horizontal path through this layer is 350 times longer, implying that the one-way
468 limb transmission becomes 10^{-350} for the same wavelength. Even if the horizontal extension
469 would be just one tenth the transmission is still as low as 10^{-35} . Obviously, the radiation used for
470 detection in OMPS-LP and SAGE III/ISS is rapidly eliminated in such smoke layers. Therefore,
471 these two methods are inadequate for studies of dense aerosol layers. The upper limit in terms of
472 vertical AOD is estimated to 0.02 (SAGE III/ISS Users Guide, 2018), corresponding to the
473 extinction coefficient of 0.02 km^{-1} for a 1 km thick layer. This problem is also acknowledged for
474 OMPS-LP (Chen et al., 2018; DeLand, 2019), and has been pointed out for other limb-oriented
475 satellite-based instruments (Fromm et al., 2014). Failure to properly handle this methodological
476 shortcoming could seriously affect attempts to verify results by modeling (Lurton et al., 2018).

477 Despite the clear limitation of OMPS-LP and SAGE III/ISS in this respect, the large body of
478 information on wildfires is based on these methods, e.g., Bourassa et al., (2019), Das et al.,
479 (2021), Khaykin et al., (2020), Kloss et al., (2019), Torres et al., (2020) and Yu et al., (2019). By
480 comparing with CALIOP we here show that the limb-oriented techniques miss the dramatic
481 events during the first 1 – 2 months after the fire. The rapid decline of the wildfire smoke will be
482 further analyzed below.

483

484 *3.4 Aerosol optical properties*

485

486 To further investigate the unusual evolution of the AOD, we turn to the optical properties of the
487 wildfire aerosol. The particle color and depolarization ratios are shown in Figure 2b and c. The
488 former is the ratio of backscattering at 1064 nm wavelength to that at 532 nm, where a smaller
489 color ratio indicates smaller particles, and the latter is the ratio of perpendicularly polarized to
490 total scattering at 532 nm, where a low ratio indicates particle shape close to spherical. To test the
491 significance in the evolution the data were temporally divided into two equal halves by number of
492 data points, and geometric averages were formed (black lines in Figure 2). The particle color ratio
493 shows a highly significant decrease comparing the first to the last half of the data points, whereas
494 the particle depolarization ratio increases with high significance. The change in the optical
495 properties takes place up to 15 – 30 days after the fire. This coincides with the decline of the
496 AOD, thus connecting a change of the aerosol properties to the AOD decline.

497

498 *3.5 Stratospheric AOD variability caused by volcanism and wildfires*

499

500 The stratospheric AOD varies considerably over time mainly due to influence from explosive
501 volcanic eruptions as demonstrated in Figure 8, showing the period 2008 – 2018. In this time
502 span, nine volcanic eruptions clearly, but to varying degree, affected the stratospheric AOD. We
503 also identify two cases of influence from wildfires, the Victoria fire (Australia, 2009) and the fire
504 studied here (Western North America, 2017). The residence time in the stratosphere varies from
505 several years for tropical injections into the upper layer representing the upper branch in the
506 Brewer-Dobson circulation (BD) (Figure 8a), the order of a year in the shallow branch of the BD
507 circulation (Figure 8b), to months in the LMS (Figure 8c) (Friberg et al., 2018). The sum of the
508 three layers is shown in Figure 8d. The volcanic eruptions in these 11 years mainly affected the
509 two lower stratospheric layers, only the Kelut eruption (2014) clearly reached to the deep BD
510 branch. Fire aerosol contains black carbon, which absorbs radiation, heats surrounding air and
511 induces lifting, as observed after the fire studied here (Khaykin et al., 2018; Yu et al., 2019).
512 After both fires, we see weak AOD elevation in the deep BD branch (Figure 8a), but for the fire
513 studied here the two lower layers dominate the AOD, like most of the volcanic eruptions in the
514 eleven-year period.

515

516 Comparing the evolution of the AOD of the North American wildfire with the evolution of the
517 aerosol from two of the most important volcanic eruptions during the last 25 years (Figure 9), we
518 find that the maximum stratospheric AOD after the fire is similar to that after the 2011 Nabro and
519 2009 Sarychev eruptions. During the first couple of months after volcanic events the AOD grows

520 due to formation of condensable sulfuric acid from the emitted volcanic gas sulfur dioxide. In
521 contrast, the wildfire aerosol displays a rapid decline during the first few weeks, before the AOD
522 stabilizes (Figure 9). This is followed by a period of rather stable AOD of more than 6 months,
523 before the AOD evolution turns to a slower decline towards background conditions, with similar
524 seasonality as the aerosol from the volcanic eruptions discussed (Figure 9). This latter decline is
525 mainly caused by springtime transport out from the stratosphere at mid and high latitudes
526 (Bönisch et al., 2009; Martinsson et al., 2017).

527

528 **4. Discussion**

529

530 The smoke aerosol is distributed both in the LMS and in the lower BD branch like aerosol from
531 several volcanic eruptions (Figure 8). The rapid decline of the smoke aerosol during the first
532 month after the fire thus cannot be explained by transport out of the stratosphere. Measurements
533 with Raman lidars at three wavelengths indicate that the smoke from this North American fire
534 contain an accumulation mode but no coarse mode (Haarig et al., 2018; Hu et al., 2019). To leave
535 the extratropical stratosphere particles must pass through the LMS. The influence from
536 sedimentation on submicron diameter particles is small at that level of the stratosphere, e.g., for
537 0.6 μm diameter sulfuric acid/water particles the sedimentation velocity is 0.15 km/month, which
538 is slow compared to the large-scale transport down to the troposphere from the LMS (Martinsson
539 et al., 2005). Moreover, the change in the particle depolarization ratio (Figure 2c) indicates
540 change of the aerosol particle properties, and the particle color ratio decrease after the fire (Figure
541 2b) is the expected outcome for reduced particle sizes. Based on these arguments we turn the
542 attention to loss of material from the aerosol particles to the gas phase to explain the rapid
543 decrease in AOD seen in Figure 5e.

544

545 Smoke layers contain water vapor that could induce hygroscopic growth/shrinkage. Water vapor
546 profiles for individual smoke layers from days 6 – 60 after the fire were obtained from the MLS.
547 Measurements close to the tropopause (Figure 10a) are affected by a steep gradient in H_2O
548 concentration. The profiles well above the gradient peaking at atmospheric pressure of less than
549 110 hPa are shown in Figure 10b. For the latter category the peak H_2O concentration is in the
550 range 7 – 14 ppmv, implying a maximum H_2O vapor pressure of 0.16 Pa. For typical conditions
551 in the extratropics that vapor pressure corresponds to a relative humidity of a few percent or less
552 (Murphy and Koop, 2005).

553

554 To further investigate the smoke layers, the temporal evolution of the composition is studied by
555 forming the ratio of the mixing ratios of two components: aerosol backscattering and H_2O at the
556 peak of respective vertical distribution. As pointed out above, the strong H_2O gradient around the
557 tropopause affects the MLS measurements. But for the smoke layers higher up, peaking above
558 110 hPa, we find a rapid decrease in the aerosol scattering ratio compared with the H_2O
559 concentration (Figure 10c). Fitting an exponential function ($\frac{R}{C_{\text{H}_2\text{O}}} = a + be^{-t/\tau}$), the half-life
560 becomes 9.7 ± 3.2 days, which is somewhat longer than that computed from the AOD (half-life
561 6.5 ± 0.9 days). The rapid AOD decline (Figure 5e) is thus verified by relative concentrations of

562 aerosol and H₂O under well-controlled humidity conditions, whereas the low relative humidity
563 rules out hygroscopic growth and influence from clouds as the explanation of the AOD decline.

564
565 The near-field wildfire aerosol contains, besides black carbon (Bond et al., 2013; Ditas et al.,
566 2018), approximately 90% organic material (Garofalo et al., 2019). After emission, secondary
567 organic aerosol (SOA) is formed by oxidation of gas phase compounds (Shrivastava et al., 2017).
568 Knowledge of processes controlling formation and removal in the atmosphere is limited (Hodzic
569 et al., 2016). Global aerosol models usually remove SOA mainly by wet (90%) and, to a smaller
570 extent, by dry deposition (Tsigaridis et al., 2014). In contrast to the species dominating the
571 stratospheric aerosol and its precursor compounds during background conditions and volcanic
572 influence (sulfuric acid and sulfur dioxide), organic species are not the ultimate
573 thermodynamically stable compounds (Hallquist et al., 2009). Organic aerosol is an intermediate
574 state on routes, with little known rates, from emitted compositions to the highly oxidized gaseous
575 products CO and CO₂ (Jimenez et al., 2009). Modeling and numerous laboratory studies find
576 evidence for photolytic removal rates of organic aerosol similar to that of wet deposition in the
577 troposphere (Hodzic et al., 2016; Zawadowics et al., 2020). Recently, photolytic removal of
578 particulate SOA was included in the Whole Atmosphere Community Climate Model (WACCM6)
579 (Gettelman et al., 2019). Hodzic et al. (2015) estimate the photolytic loss over a 10-day period to
580 50% for most organic species at mid tropospheric conditions.

581
582 These high rates are disputed by Yu et al. (2019), claiming a lifetime of 150 days (half-life 104
583 days) of organic aerosol from the fire studied here, whereas Das et al. (2021) explain a similar
584 half-life of the same fire by large-scale circulation and particle sedimentation using OMPS-LP
585 and modeling. The experimental data used here cannot differentiate these two explanations,
586 although the slow part of the smoke decline is similar in seasonality to that of volcanic aerosol
587 (Figure 9) where photochemical loss is less important. The modeling study by Yu et al. (2019)
588 was based on mimicking the extinction according to SAGE III/ISS at 1020 nm wavelength at 18
589 km altitude. For three reasons their study misses the strong decline of the AOD during the first
590 month. Firstly, because the orbiting of ISS prohibits studies of the wildfire smoke the first 19
591 days after the fire, secondly because of the time required to transport the wildfire aerosol to 18
592 km altitude is approximately one month (Yu et al., 2019) and thirdly because problems with
593 event termination (“saturation”), see Figure 7e. We therefore conclude that Yu et al. (2019) could
594 not observe the main decline of the aerosol taking place during the first 1 – 2 months after the
595 fire, see section 3.3 for further details.

596
597 Submicron aerosol particles have much longer residence time in the stratosphere than in the
598 troposphere due to sparsity of clouds, thus inhibiting the sink that traditionally is considered the
599 most important in the troposphere, i.e., wet deposition. This provides unique possibilities to study
600 photolytic loss without competition from other aerosol sinks. Interpreting the body of evidence
601 on the strong and rapid decline of the stratospheric AOD during the first month after the fire, we
602 find that photolytic loss of organic aerosol is a highly likely explanation. The rate of photolytic
603 loss is likely better described by the evolution of R/C_{H₂O} than by the AOD, because the latter
604 could to some degree be affected by transport across the tropopause. Our strong experimental

605 evidence leads us to the hypothesis that the rapid decline of the wildfire aerosol in the
606 stratosphere with a half-life of 10 days is caused by photochemical loss of organic material. This
607 should be further investigated by modeling, but that is outside the scope of the present study.

608
609 To further put the strong early decline of wildfire aerosol into context, we compare the AOD
610 during background conditions (years 2013 and 2014) with the year of the fire. When the
611 contribution of the exponential term is very small of the wildfire aerosol (after 7 half-lives), the
612 background is approximately 2/3 of the wildfire AOD (Figure 9). Taking the background into
613 account, the excess stratospheric aerosol due to the wildfire declines by 83% from the R/C_{H_2O}
614 value day 10 after the fire. The process starts before day 10, indicating that almost all the organic
615 aerosol constituting approximately 90% of the near-field wildfire aerosol mass (Garofalo et al.,
616 2019) could be lost by photolysis. Residual wildfire aerosol particles, likely stripped off by a
617 large fraction of its original organic content, remain in the stratosphere up to approximately one
618 year (Figure 9).

619
620 Finally, we investigate the stratospheric aerosol load from the wildfire by comparing with the
621 more studied volcanic impact (Table 1). The AOD growth, the average AOD over one year from
622 the fire/eruption subtracted by the average background AOD (2013 – 2014), is approximately 1/4
623 and 1/3 of that of two of the most important volcanic eruptions for the stratospheric aerosol in the
624 last 25 years (Sarychev 2009, Nabro 2011). The average excess aerosol during the year following
625 the fire corresponds to a radiative forcing of -0.06 W m^{-2} in the region $20 - 80^\circ \text{ N}$, using standard
626 conversion as an approximation (Solomon et al., 2011).

627 628 **Conclusions**

629
630 In this study we investigate massive injections of smoke into the stratosphere from the August
631 2017 North American wildfires using five satellite sensors. Methodology was developed to
632 correct CALIOP data for attenuation of the laser signal. The CALIOP AOD and extinction
633 coefficients were compared with OMPS-LP and SAGE III/ISS. From 1 – 2 months after the fire
634 we find that OMPS-LP and CALIOP AOD agree very well at altitudes above the 380 K
635 isentrope, where the former demonstrates high sensitivity with small statistical fluctuations. The
636 methods differ dramatically during the first 1 – 2 months after the fire when the smoke layers are
637 dense, because the long optical path through the smoke of the limb-oriented instruments OMPS-
638 LP and SAGE III/ISS cause event termination (“saturation”). This is clearly demonstrated by the
639 low daily maximum extinction coefficients of the two instruments, being orders of magnitude
640 lower than the peak extinction coefficients of CALIOP. The nadir viewing CALIOP experiences
641 a much shorter optical path, because the vertical extension of smoke layers usually are orders of
642 magnitude shorter than for limb orientation. We find that CALIOP is an indispensable tool for
643 studies of dense smoke layers entering the stratosphere after intense wildfires, providing signal
644 along the laser path that can be used to correct for attenuation. Once the smoke layers are
645 sufficiently thin, the limb technique OMPS-LP provide sensitive measurements of the AOD that
646 can be used together with CALIOP.

647

648 The AOD from the wildfire declines exponentially with a half-life of 6.5 days. This decline is
649 further studied by the evolution of the ratio of the aerosol and water vapor mixing ratios of the
650 smoke layers, resulting in a massive decline of 80 – 90% of the wildfire aerosol with a half-life of
651 approximately 10 days. We find transport out of the stratosphere, sedimentation, influence from
652 clouds or hygroscopic growth/shrinkage to be highly unlikely explanations for the rapid decline
653 of wildfire aerosol in the stratosphere. Based on strong experimental evidence we hypothesize
654 that photochemical loss of organic aerosol causes the rapid decline, which would mean that
655 almost the entire organic fraction of the wildfire aerosol would be lost in the exponential decline.
656 The half-life according to this study agrees well with results from laboratory studies and global
657 modeling. Our unique result could be obtained because of the long residence time of aerosol
658 particles in the stratosphere, whereas tropospheric studies of photochemical loss are extremely
659 difficult because it is masked by SOA formation and wet deposition due to short residence time.
660 The residual aerosol leaves the stratosphere within a year in the Brewer-Dobson circulation.
661 Despite the initial loss, the long-term effects of wildfire smoke on the stratospheric AOD and
662 radiative forcing are considerable. The ongoing climate change is projected to increase the
663 frequency of wildfires, prompting the need for inclusion of wildfire impact on the stratospheric
664 aerosol load in the climate models.

665

666 **Acknowledgements**

667 Aerosol products from the CALIOP sensor and SAGE III/ISS were produced by NASA Langley
668 Research Center. The official NASA aerosol index from the OMPS Nadir Mapper, the aerosol
669 scattering from OMPS Limb Profiler and water vapor profiles from MLS are supplied by
670 Goddard Earth Sciences Data and Information Services Center. We gratefully acknowledge
671 financial support from the Swedish Research Council for Environment, Agricultural Sciences and
672 Spatial Planning (contract 2018-00973), the Swedish National Space Board (contracts 130/15 and
673 104/17), and the Crafoord foundation (contract 20190690).

674

675 **Author Contributions**

676

677 B.G.M. designed the study, designed methodology, undertook part of the data analysis, and wrote
678 most of the paper. J.F. contributed to the design of the study, designed methodology, did part of
679 the data analysis, and wrote parts of the text. O.S.S. contributed to the data analysis and M.K.S.
680 contributed to the design of methodology. In addition, all authors participated in discussions and
681 commented on the manuscript.

682

683 **Data availability**

684

685 CALIOP V4.10 lidar data (<https://search.earthdata.nasa.gov/search?fp=CALIPSO>) are publicly
686 available.

687 OMPS-NM UV aerosol index was obtained from the publicly available site

688 <https://worldview.earthdata.nasa.gov/>.

689 OMPS-LP stratospheric aerosol optical depths were obtained from

690 https://disc.gsfc.nasa.gov/datasets/OMPS_NPP_LP_L2_AER_DAILY_2/summary

691 MLS water vapor concentrations were obtained from
692 https://disc.gsfc.nasa.gov/datasets?page=1&keywords=ML2H2O_005
693 SAGE III/ISS aerosol data were obtained from
694 https://asdc.larc.nasa.gov/project/SAGE%20III-ISS/g3bssp_51.

695

696 **Competing Interest**

697

698 The authors declare no competing interests.

699

700 **Additional Information**

701

702 Correspondence and requests for materials should be addressed to B.G.M.

703

704 **References**

1015 **Tables**

1016

1017 Table 1. Maximum and yearly average stratospheric AOD during background conditions and
1018 during one year after the fire and after the two volcanic eruptions in Figure 9.

Year	Background 2013	Background 2014	Wildfire 2017	Sarychev 2009	Nabro 2011
AOD max	0.009	0.009	0.020	0.028	0.017
AOD	0.0075	0.0074	0.0097	0.0169	0.0138
AOD growth ^a	-	-	0.0023	0.0095	0.0064
RF ^b	-	-	-0.06	-0.24	-0.16

1019 ^aGrowth of AOD due to influence from wildfire/volcanism obtained by subtracting the average of 2013
1020 and 2014 AOD.

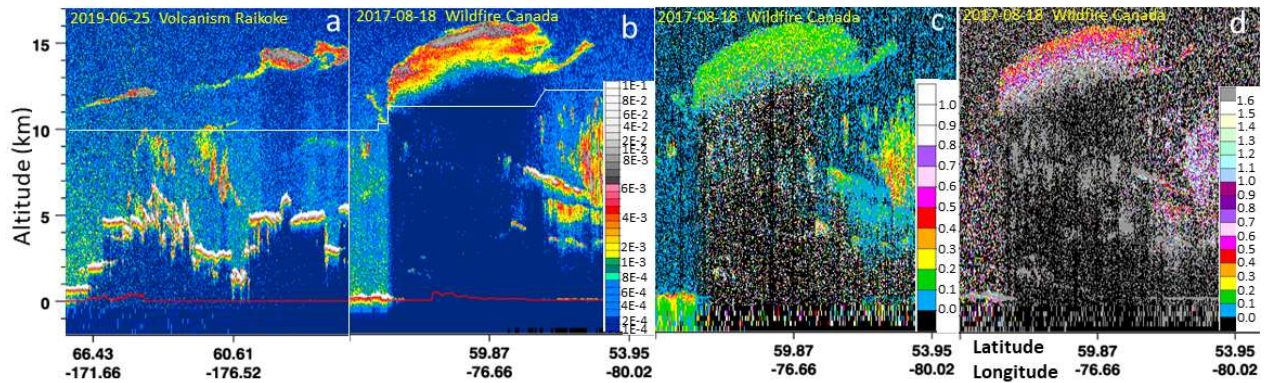

1021 ^bRadiative forcing ($W m^{-2}$) of the background-subtracted AOD.

1022

1023

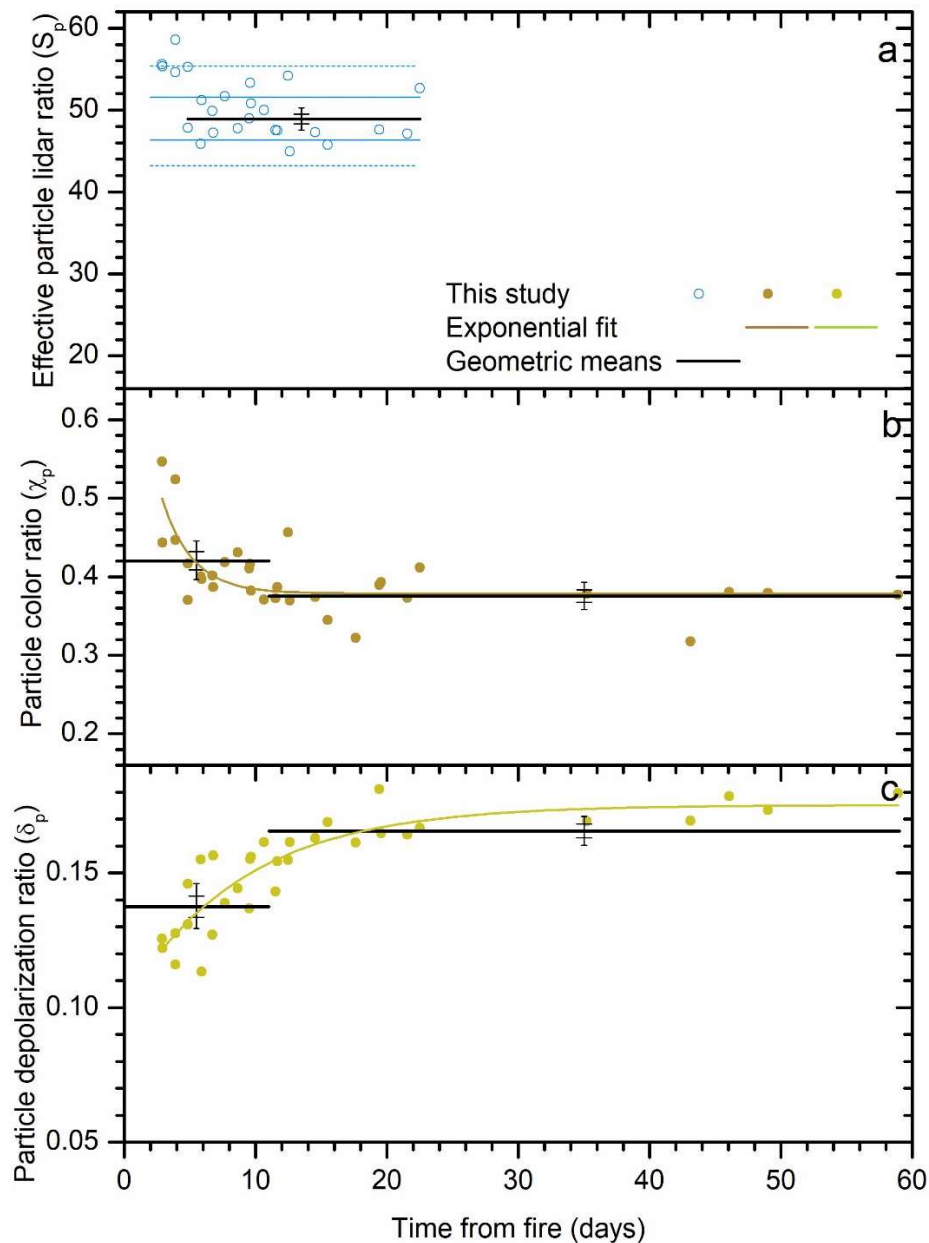

1024
1025
1026

Figures

1027
1028

1029 Figure 1. CALIOP curtains of total attenuated backscatter ($\text{km}^{-1} \text{sr}^{-1}$) at 532 nm from a) volcanic
1030 aerosol layers in the stratosphere three days after the 2019 Raikoke eruption and b) a
1031 stratospheric smoke layer from the August 12, 2017, North American wildfire, where “aE-b” in
1032 the scale refers to $a10^{-b}$. c) Volume depolarization ratio at 532 nm and d) attenuated color ratio
1033 (1064 to 532 nm) for the curtain in b). The white lines in a) and b) show the position of the
1034 tropopause.

1035
1036

1037 Figure 2. Particle optical properties during the first 60 days after the fire. Black error bars show
 1038 standard error and the double-sided 95% probability range of the geometric means. a) Particle
 1039 lidar ratios for 532 nm where data points with fitting error exceeding 25% are discarded. The
 1040 black line shows the geometric mean after day 4, and the full and dotted blue lines show the
 1041 standard deviation and the double-sided 95% probability range of the distribution. b) Particle
 1042 color ratio (1064 nm divided by 532 nm wavelength backscattering) with exponential fit ($R^2 =$
 1043 0.48 , $P < 10^{-10}$), and c) particle depolarization ratio with exponential fit ($R^2 = 0.76$, $P < 10^{-10}$).
 1044 The color and depolarization ratios were divided in two equal groups by number of observations
 1045 to illustrate the highly significant changes with time of the optical properties, where the long and
 1046 short error bars are the standard error and the double-sided 95% probability range of the
 1047 geometric means.

1049
 1050 Figure 3. Illustration of methodology and its effect. a) The attenuated and corrected scattering
 1051 ratios as a function of altitude. Example of methodology for one smoke layer, where the
 1052 scattering ratio between 7.5 – 10 km altitude, below the smoke layer at 10.5 – 14 km, is targeted
 1053 to a value of 1.08 (explained in the method section) by iteratively fitting the lidar ratio for 532 nm
 1054 wavelength. b) The attenuated layer AOD (AOD_{att}) related to the layer AOD corrected for
 1055 attenuation. The 1:1 relation is shown by the full line.
 1056

1057
 1058 Figure 4. OMPS-LP layer AODs averaged over 20 to 80° North for 745 nm wavelength using
 1059 data filtered and not filtered from clouds and polar stratospheric clouds, and with and without
 1060 data flagged for data quality. Layer AOD for a) the upper Brewer-Dobson branch (470 K
 1061 isentrope – 35 km), b) the lower brewer-Dobson branch (380 – 470 K) and c) the LMS
 1062 (tropopause – 380 K) are shown.

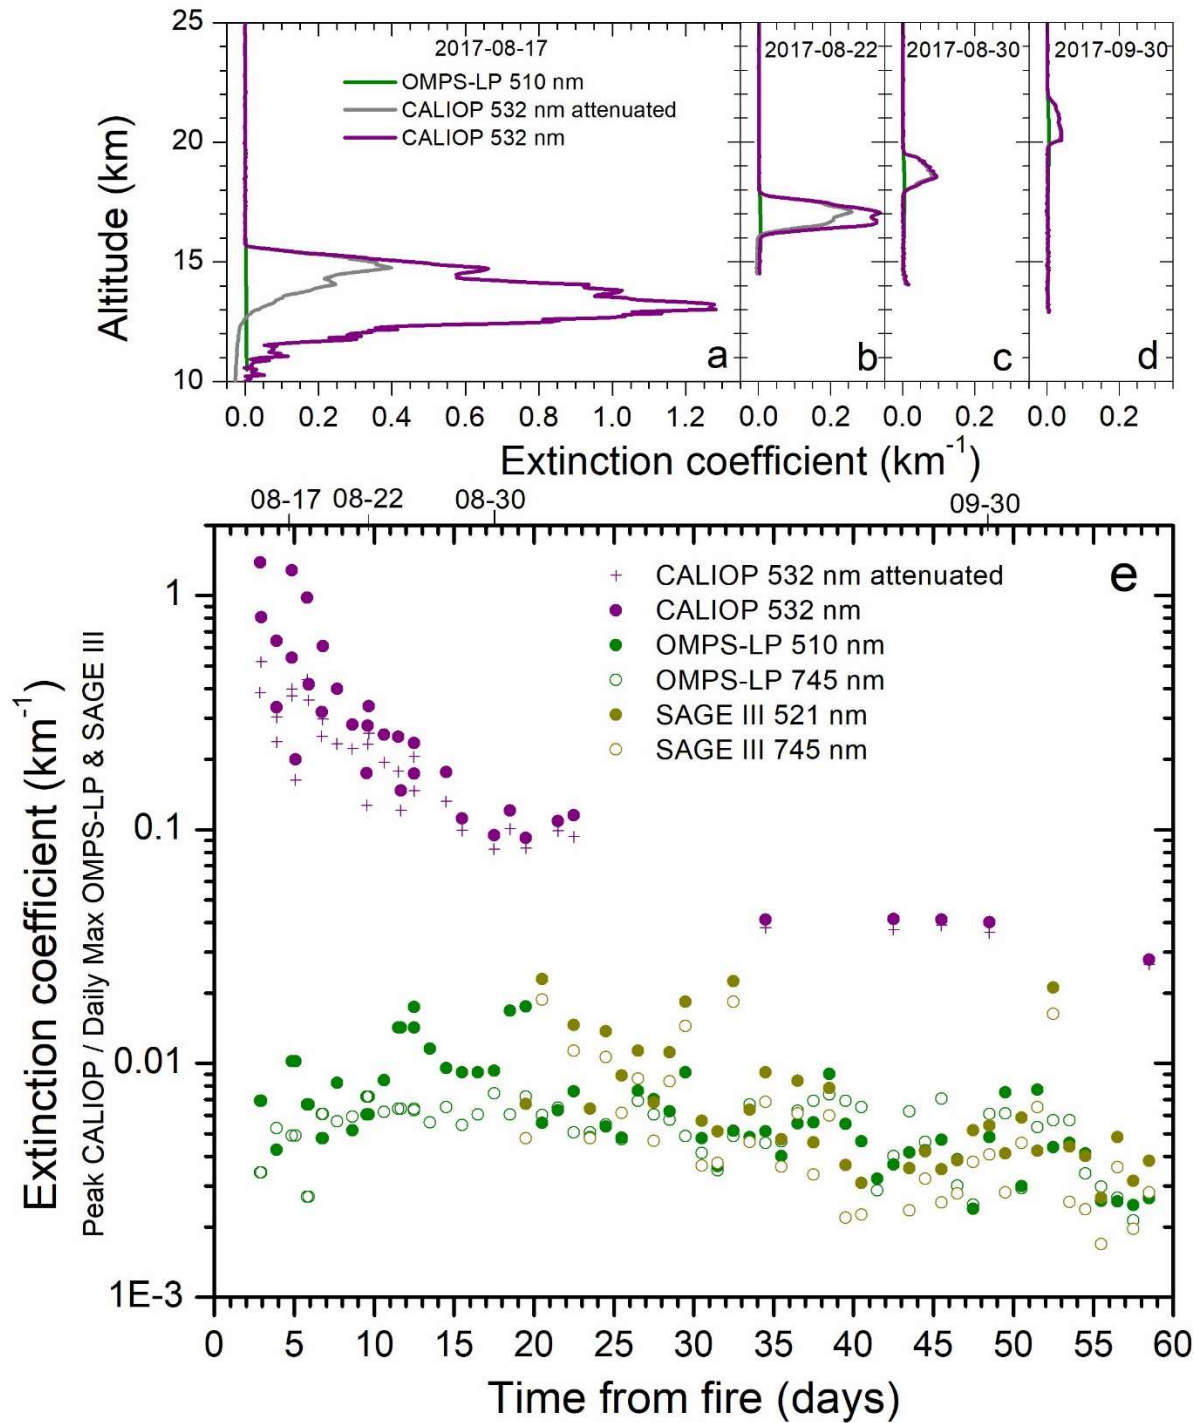

1063

1064 Figure 5. AOD evolution of the stratospheric AOD (daily average) from 75 days before to 310
 1065 days after the 2017 western North American fires. Comparisons of AOD from CALIOP (532 nm)
 1066 with OMPS-LP (510 and 745 nm) with cloud filtering and flags activated for a) the upper
 1067 Brewer-Dobson branch (470 K isentrope – 35 km, b) the lower Brewer-Dobson branch (380 –
 1068 470 K) c) the LMS (tropopause – 380 K), d) from 380 K to 35 km (sum of layers in a and b) and
 1069 e) the stratosphere of CALIOP from the tropopause to 35 km (sum of layers in a, b and c). The
 1070 black, full line is an exponential fit ($R^2 = 0.79$, $P < 10^{-10}$) to the AOD over days 10 – 115 after the
 1071 fire. The total stratospheric AOD half-life of the fit is 6.5 ± 0.9 days.

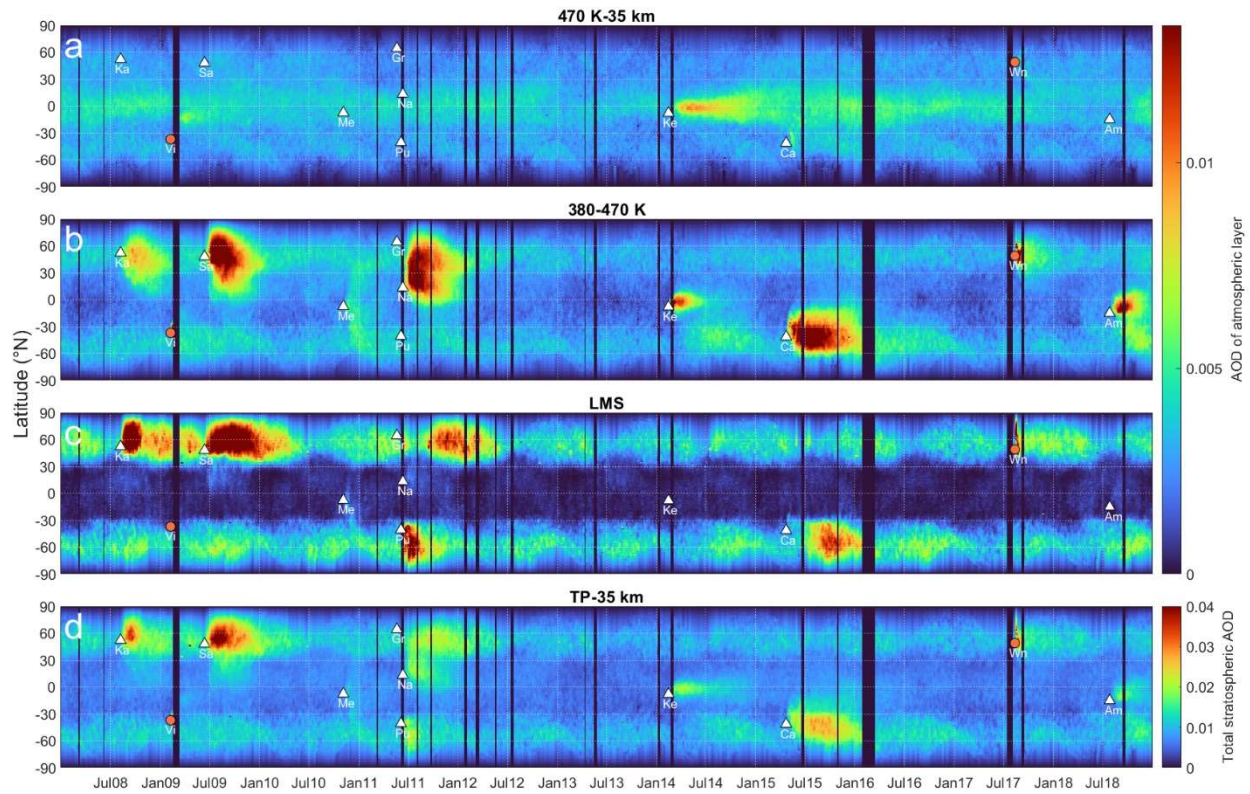

1072

1073 Figure 6. Daily OMPS-NM aerosol absorbing index (UV) August 14 – 22, 2017 over all
 1074 longitudes and latitudes 20 - 80° N. This index is sensitive to UV absorbing aerosol particles in
 1075 the upper troposphere and the stratosphere, where signals from tropospheric aerosol declines
 1076 faster than from stratospheric due to short residence time. The yellow lines indicate nighttime
 1077 swaths of the CALIPSO satellite, and the faint lines show CALIPSO daytime swaths.

1078
 1079 Figure 7. Extinction coefficients according to CALIOP, OMPS-LP and SAGE III/ISS in the 20 -
 1080 80° North latitude range during the first 60 days following the North American fire. a - d)
 1081 selected profiles (attenuated and corrected for attenuation) from CALIOP compared with closest
 1082 profiles according to OMPS-LP. e) Peak extinction coefficient from selected CALIOP profiles
 1083 compared with daily maximum extinction coefficients from OMPS-LP and SAGE III/ISS. Note
 1084 that SAGE III/ISS data are missing the first 19 days because of irregular coverage of the latitude
 1085 range of interest.

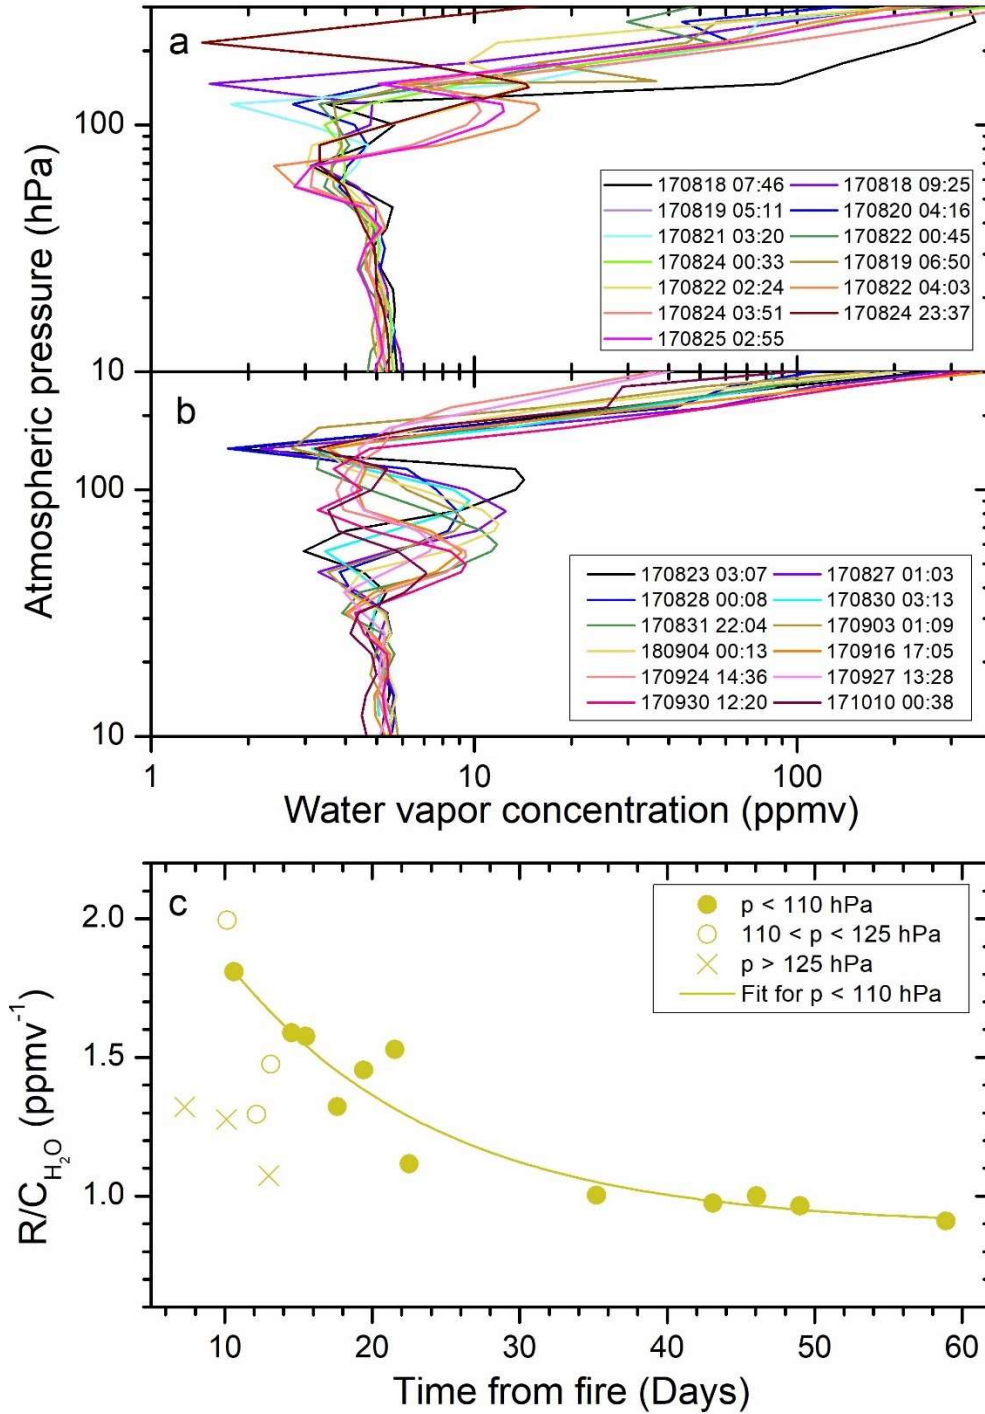

1086

1087 Figure 8. Zonally and eight-day moving average aerosol optical depth (AOD) of the stratosphere.
 1088 a - c) AOD in three layers obtained from CALIOP data (level 1B): a) 470 K potential temperature
 1089 to 35 km (deep Brewer-Dobson branch), b) 380 – 470 K (shallow Brewer-Dobson branch), c) the
 1090 tropopause to 380 K (LMS). d) The total AOD from the tropopause to 35 km altitude. Volcanic
 1091 eruptions marked by white triangles: Kasatochi (Ka), Sarychev (Sa), Merapi (Me), Grimsvötn
 1092 (Gr), Puyehue-Cordón Caulle (Pu), Nabro (Na), Kelut (Ke), Calbuco (Ca), and Ambae (Am), and
 1093 wildfires marked by orange circles: Victoria fire (Vi) and Western North American fires (Wn) at
 1094 time and latitude of eruption/fire. The AODs are corrected for attenuation.

1095
 1096 Figure 9. Evolution of the AOD in the 20 - 80° N interval (8-day moving average) over two
 1097 years: close to background conditions in the latitude interval studied (2013 – 2014), the year and
 1098 the following year of the August 12, 2017, fire (2017 – 2018), and the same for two volcanic
 1099 eruptions, the June 12, 2009, Sarychev (2009 – 2010) and June 12, 2011, Nabro (2011 – 2012)
 1100 eruptions.

1101
 1102 Figure 10. Water vapor in the smoke layer. Microwave Limb Sounder (MLS) measurements of
 1103 water vapor concentrations (ppmv) Vs. atmospheric pressure for smoke layers a) close to the
 1104 tropopause and b) well above the tropopause (atmospheric pressure < 110 hPa at the H₂O peak)
 1105 for individual smoke layers available days 6 – 60 after the fire. c) The peak scattering ratio (R)
 1106 according to CALIOP divided by the peak water vapor concentration (C_{H₂O}) from MLS. The full
 1107 line is an exponential fit ($R^2 = 0.88$, $P < 3 \times 10^{-10}$) to smoke layers peaking in water vapor
 1108 concentration at a pressure less than 110 hPa. The half-life of the fit is 9.7 ± 3.2 days.
