11 **Abstract**

12 A remote sensing method, based on fluorescence lidar measurements, that allows to detect and to
13 quantify the smoke content in upper troposphere and lower stratosphere (UTLS) is presented. The
14 unique point of this approach is that, smoke and cirrus properties are observed in the same air
15 volume simultaneously. In this article, we provide results of fluorescence and multiwavelength
16 Mie-Raman lidar measurements performed at ATOLL observatory from Laboratoire d'Optique
17 Atmosphérique, University of Lille, during strong smoke episodes in the summer and autumn
18 seasons of 2020. The aerosol fluorescence was induced by 355 nm laser radiation and the
19 fluorescence backscattering was measured in a single spectral channel, centered at 466 nm and
20 having 44 nm width. To estimate smoke particle properties, such as number, surface area and
21 volume concentration, the conversion factors, which link the fluorescence backscattering and the
22 smoke microphysical properties, are derived from the synergy of multiwavelength Mie-Raman and
23 fluorescence lidar observations. Based on two case studies, we demonstrate that the fluorescence
24 lidar technique provides the possibility to estimate the smoke surface area concentration within
25 freshly formed cirrus layers. This value was used in smoke INP parameterization scheme to predict
26 ice crystal number concentrations in cirrus generation cells.

27

28 **Introduction**

29 Aerosol particles in the upper tropospheric and lower stratospheric (UTLS) height regime
30 play an important role in processes of heterogeneous ice formation, however our current
31 understanding of these processes is still insufficient for a trustworthy implementation in numerical

32 weather and climate prediction models. The ability of aerosol particles to act as ice nucleating
33 particles (INP) depends on meteorological factors such as temperature and ice supersaturation (as
34 a function of vertical velocity), as well as on the aerosol type in the layer in which cirrus developed
35 (Kanji et al., 2017). Heterogeneous ice nucleation initiated by insoluble inorganic materials such
36 as mineral dust has been studied since a long time (e.g., DeMott et al 2010, 2015; Hoose and
37 Möhler, 2012; Murray et al., 2012; Boose et al., 2016; Schrod et al., 2017; Ansmann et al. 2019b),
38 while the potential of omnipresent organic particles, especially of frequently occurring aged, long-
39 range-transported wildfire smoke particles, to act as INP is less well explored and thus not well
40 understood (Knopf et al., 2018). Wildfire smoke can reach the lower stratosphere via pyro-
41 cumulonimbus (pyroCb) convection (Fromm et al., 2010; Peterson et al., 2018, 2021; Hu et al.,
42 2019; Khaykin et al., 2020) or via self-lifting processes (Boers et al., 2010, Ohneiser et al., 2021).
43 It is widely assumed that the ability of smoke particles to serve as INP mainly depends on the
44 organic material (OM) in the shell of the coated smoke particles (Knopf et al., 2018), but may also
45 depend on mineral components in the smoke particles (Jahl et al., 2021). The ice nucleation
46 efficiency may increase with increasing duration of the long-range transport as Jahl et al. (2021)
47 suggested. Disregarding the progress made in this atmospheric research field during the last years,
48 the link between ice nucleation efficiency and the smoke particle chemical and morphological
49 properties is still largely unresolved (China et al., 2017; Knopf et al., 2018).

50 To contribute to the field of smoke-cirrus-interaction research, we present a laser remote
51 sensing method that allows us simultaneously to detect and quantify the smoke particles amount
52 inside of cirrus layers together with cirrus properties and to provide INP estimates in regions close
53 to the cloud top where ice formation usually begins. The unique point of our approach is that, for
54 the first time, smoke and cirrus properties are observed in the same air volume simultaneously.
55 Recently, a first attempt (closure study) was performed to investigate the smoke impact on High
56 Arctic cirrus formation (Engelmann et al. 2021). However, the aerosol measurements had to be
57 performed outside the clouds layers, and then an assumption was needed that the estimated aerosol
58 (and estimated INP) concentration levels also hold inside the cirrus layers. Now, we propose a
59 method to directly determine INP-relevant smoke parameters inside the cirrus layer during ice
60 nucleation events. This also offers the opportunity to illuminate whether an INP reservoir can be
61 depleted in cirrus evolution processes or not. Furthermore, this new lidar detection method permits
62 a clear discrimination between, e.g., smoke and mineral dust INPs.

63 Multiwavelength Mie-Raman lidars or High Spectral Resolution lidars (HSRL) are
64 favorable instruments to provide the vertical profiles of the physical properties of tropospheric
65 aerosol particles. In particular, the inversion of the so-called $3\beta+2\alpha$ lidar observations, based on
66 the measurement of height profiles of three aerosol backscatter coefficients at 355, 532, and 1064
67 nm and two extinction coefficients at 355 and 532 nm, allows us to estimate smoke microphysical
68 properties (Müller et al., 1999, 2005; Veselovskii et al., 2002, 2015). However, the aerosol content
69 in UTLS height range can be low, so that particle extinction coefficients cannot be determined
70 with sufficient accuracy and are thus not available in the lidar inversion data analysis. To resolve
71 this issue Ansmann et al. (2019a, 2021) used the synergy of polarization lidar measurements and
72 Aerosol Robotic Network (AERONET) sunphotometer observations (Holben et al., 1998) to
73 derive conversion factors (to convert backscatter coefficients into microphysical particle
74 properties) and to estimate INP concentrations for dust and smoke aerosols with the retrieved
75 aerosol surface area concentration as aerosol input.

76 Dust particles are very efficient ice nuclei in contrast to wildfire smoke particles. In this
77 context, the question arises: How can we unambiguously discriminate smoke from dust particles?
78 This is realized by integrating a fluorescence channel into a multiwavelength aerosol lidar
79 (Reichardt et al., 2017; Richardson et al., 2019; Veselovskii et al., 2020; 2021). The fluorescence
80 capacity of smoke (ratio of fluorescence backscattering to the overall aerosol backscattering),
81 significantly exceeds corresponding values for other types of aerosol, such as dust or
82 anthropogenic particles (Veselovskii et al., 2020; 2021), and thus allows us to discriminate smoke
83 from other aerosol types. The fluorescence technique provides therefore the unique opportunity to
84 monitor ice formation in well identified wildfire smoke layers, and thus to create a good basis for
85 long-term investigations of smoke cirrus interaction.

86 In this article, we present results of fluorescence and multiwavelength Mie-Raman lidar
87 measurements performed at the ATOLL (ATmospheric Observation at liLLe) of the Laboratoire
88 d'Optique Atmosphérique, University of Lille, during strong smoke episodes in the summer and
89 autumn seasons of 2020. The results demonstrate that the fluorescence lidar is capable to monitor
90 the smoke in the UTLS height range and inside the cirrus clouds formed at or below the tropopause.
91 We start with a brief description of the experimental setup in Sect.2. In the first part of the result
92 section (Sect.3.1 and 3.2), it is explained how smoke optical properties can be quantified by using
93 fluorescence backscattering information and how we can estimate smoke microphysical properties

94 (volume, surface area, and number concentration) from measured fluorescence backscatter
95 coefficients. In this approach, multiwavelength Mie-Raman aerosol lidar observations are used in
96 addition. The retrieved values of the smoke particle surface area concentration are then the aerosol
97 input in the smoke INP estimation. A case study is discussed in Sect.3.2. Two case studies are then
98 presented in Sect.3.3 to demonstrate the capability of a fluorescence lidar to monitor ice formation
99 in extended smoke layers and to provide detailed information on aerosol microphysical properties
100 and smoke-relate INP concentration levels.

101

102 **2. Experimental setup**

103 The multiwavelength Mie-Raman lidar LILAS (Lille Lidar AtmosphereS) is based on a
104 tripled Nd:YAG laser with a 20 Hz repetition rate and pulse energy of 70 mJ at 355 nm.
105 Backscattered light is collected by a 40 cm aperture Newtonian telescope and the lidar signals are
106 digitized with Licel transient recorders of 7.5 m range resolution, allowing simultaneous detection
107 in the analog and photon counting mode. The system is designed for simultaneous detection of
108 elastic and Raman backscattering, allowing the so called $3\beta+2\alpha+3\delta$ data configuration, including
109 three particle backscattering (β_{355} , β_{532} , β_{1064}), two extinction (α_{355} , α_{532}) coefficients along with
110 three particle depolarization ratios (δ_{355} , δ_{532} , δ_{1064}). The particle depolarization ratio, determined
111 as a ratio of cross- and co-polarized components of the particle backscattering coefficient, was
112 calculated and calibrated in the same way as described in Freudenthaler et al. (2009). The aerosol
113 extinction and backscattering coefficients at 355 and 532 nm were calculated from Mie-Raman
114 observations (Ansmann et al., 1992), while β_{1064} was derived by the Klett method (Fernald, 1984;
115 Klett, 1985). Additional information about atmospheric parameters was available from radiosonde
116 measurements performed at Herstmonceux (UK) and Beauvecchain (Belgium) stations, located
117 160 km and 80 km away from the observation site respectively.

118 This lidar system is also capable to perform aerosol fluorescence measurements. A part of
119 the fluorescence spectrum is selected by a wideband interference filter of 44 nm width centered at
120 466 nm (Veselovskii et al., 2020; 2021). The strong sunlight background at daytime restricts the
121 fluorescence observations to nighttime hours. To characterize the fluorescence properties of
122 aerosol, the fluorescence backscattering coefficient β_F is calculated from the ratio of fluorescence
123 and nitrogen Raman backscatters, as described in Veselovskii et al. (2020). This approach allows
124 to evaluate the absolute values of β_F , if the relative sensitivity of the channels is calibrated and the

125 nitrogen Raman scattering differential cross section σ_R is known. In our research we used
126 $\sigma_R=2.744*10^{-30}$ cm²sr⁻¹ at 355 nm from Venable et al. (2011). All β_F profiles presented in this
127 work were smoothed with the Savitzky – Golay method, using second order polynomial with 21
128 points in the window. The efficiency of fluorescence backscattering with respect to elastic
129 backscattering β_{532} is characterized by the fluorescence capacity $G_F = \frac{\beta_F}{\beta_{532}}$.

130 For most of atmospheric particles β_F is proportional to the volume of dry matter, while dependence
131 of β_{532} on particle size is more complicated. As a result, G_F depends not only on aerosol type, but
132 also on particle size and the relative humidity RH. Uncertainty of β_F calculation depends on the
133 chosen value of σ_R and on relative transmission of optical elements in fluorescence and nitrogen
134 channels. These system parameters do not change with time. The relative sensitivity of PMTs,
135 however, may change. Regular calibration of the channels relative sensitivity (Veselovskii et al.,
136 2020), demonstrates that corresponding uncertainty can be up to 10%. At high altitudes the
137 statistical uncertainty becomes predominant. We recall also, that only a part of the fluorescence
138 spectra was selected by the interference filter in the receiver, so provided values of β_F and G_F are
139 specific for the filter used. Analyzing the fluorescence measurements we should keep in mind, that
140 the sensitivity of this technique can be limited by the fluorescence of optics in the lidar receiver.
141 The minimal value of G_F , which we measured during observation in cloudy conditions in the lower
142 troposphere was about 2×10^{-8} . Thus, at least, in the measurements with G_F above this value, the
143 contribution of optics fluorescence can be ignored.

144

145 **3. Results of the measurements**

146 **3.1. Observation of smoke particles in UTLS**

147 Smoke particles produced by intensive fires and transported across the Atlantic are
148 regularly observed in the UTLS height range over Europe (Müller et al., 2005; Hu et al., 2019;
149 Baars et al., 2019, 2021). One of such events, observed over Lille in the night of 4-5 November
150 2020, is shown in Fig.1. The figure provides height – time displays of the range corrected lidar
151 signal and the volume depolarization ratio at 1064 nm together with the fluorescence
152 backscattering coefficient. A narrow smoke layer occurred in the upper troposphere in the period
153 from 23:00 – 06:00 UTC. The smoke was detected at heights above 12 km after midnight. The
154 particles caused a low volume depolarization ratio (<5%) at 1064 nm and strong fluorescence

155 backscattering ($\beta_F > 1.2 \times 10^{-4} \text{ Mm}^{-1} \text{sr}^{-1}$). The backward trajectory analysis indicated that the aerosol
156 layer was transported over the Atlantic and contained products of North American wild fires.

157 Vertical profiles of aerosol β_{532} and fluorescence β_F backscattering coefficients for the
158 period from 02:00 - 05:30 UTC are shown in Fig.2a. The fluorescence capacity G_F in the center of
159 smoke layer (not shown) was about 4.5×10^{-4} . The depolarization ratio of aged smoke in the UTLS
160 height range usually shows a strong spectral dependence (Haarig et al., 2018; Hu et al., 2019). For
161 the case presented in Fig.2a the particle depolarization ratio in the center of the smoke layer
162 decreased from $16 \pm 4\%$ at 355 nm (δ_{355}) to $4 \pm 1\%$ at 1064 (δ_{1064}). The tropopause height H_{tr} was at
163 about 13000 m, thus the main part of the smoke layer was below the tropopause. By the end of day
164 the smoke layer became weaker ($\beta_F < 0.3 \times 10^{-4} \text{ Mm}^{-1} \text{sr}^{-1}$) and ascended up to 14500 m, which is
165 above the tropopause. The corresponding vertical profiles of β_{532} and β_F are shown in Fig.2b. The
166 fluorescence capacity in the center of the layer is about 4.5×10^{-4} , which is close to the value
167 observed during 02:00 - 05:30 UTC period.

168 An important advantages of the fluorescence lidar technique is the ability to monitor
169 smoke particles inside cirrus clouds. The results of smoke observations in the presence of ice
170 clouds are shown in Fig.3. Cirrus clouds occurred during the whole night in the height range from
171 6.0 km – 10.0 km. To quantify the fluorescence backscattering inside the cloud (which was rather
172 weak in this case), the lidar signals were averaged over the full 18:00 – 06:00 UTC time interval
173 in Fig.3a. The fluorescence backscatter coefficient shown in Fig.3c decreased from $\beta_F = 0.015 \times 10^{-4}$
174 $\text{Mm}^{-1} \text{sr}^{-1}$ at 5000 m (near the cloud base) to a minimum value of $0.01 \times 10^{-4} \text{ Mm}^{-1} \text{sr}^{-1}$ at 7000 m
175 inside the cirrus layer. Above the tropopause the fluorescence backscattering increased strongly
176 and reached the maximum (about $0.3 \times 10^{-4} \text{ Mm}^{-1} \text{sr}^{-1}$) in 11000 m -13000 m height.

177 The analysis of fluorescence measurements performed during strong smoke episodes in the
178 summer and autumn of 2020, when smoke layers from North American fires frequently reached
179 Europe, demonstrates that the fluorescence capacity varied within the range of 2.5×10^{-4} to 4.5×10^{-4}
180 $\text{Mm}^{-1} \text{sr}^{-1}$. The variations are a function of smoke composition, relative humidity and particle size.
181 However, in the upper troposphere, where relative humidity is low, G_F was normally close to
182 4.5×10^{-4} . This relatively low range of G_F variations allows the estimation of the backscattering
183 coefficient attributed to the smoke particles from fluorescence measurements as:

184
$$\beta_{532}^s = \frac{\beta_F}{G_F}. \quad (1)$$

185 Fig.3d shows the smoke backscattering coefficient β_{532}^s , calculated from β_F for $G_F=4.5 \times 10^4$
 186 ⁴, together with β_{532} . The dynamical range of β_{532} variations is high. To make smoke backscattering
 187 visible above H_{Tr} , β_{532} is plotted in expanded scale in Fig.3d. The β_{532}^s values, though being
 188 strongly oscillating above the tropopause, match the β_{532} indicating that the smoke contribution to
 189 backscattering was predominant.

190

191 3.2. Estimation of smoke particles content based on fluorescence measurements

192 The possibility to detect fluorescence backscattering inside the cirrus clouds reveals also
 193 the opportunity for a quantitative characterization of the smoke content. This can be realized by a
 194 synergistic use of fluorescence and multiwavelength Mie – Raman lidar observations. The flow
 195 chart, summarizing the main steps of this procedure, is presented in **Appendix 1**. For the smoke
 196 layers with sufficient optical depth, the number N , surface area S and volume V concentrations can
 197 be evaluated, by inverting the $3\beta+2\alpha$ observations consisting of three backscatter coefficients
 198 (355, 532, 1064 nm) and two extinction coefficients (355, 532 nm) (Müller et al., 1999;
 199 Veselovskii et al., 2002; Pérez-Ramírez et al., 2013). The conversion factors C_N , C_S , C_V , introduced
 200 as

$$201 \quad C_N = \frac{N}{\beta_F}, \quad C_S = \frac{S}{\beta_F}, \quad C_V = \frac{V}{\beta_F}, \quad (3)$$

202 allow the estimation of smoke particle concentration inside the clouds from fluorescence
 203 backscattering, assuming that smoke contribution to the fluorescence is predominant. Moreover,
 204 it allows estimation of the particles concentration in weak smoke layers in UTLS, where $3\beta+2\alpha$
 205 observations are normally not available.

206 On 23-24 June 2020, a strong smoke layer was observed in 4500 – 5500 m height during
 207 the whole night (Fig.4). The vertical profiles of the aerosol backscattering and extinction
 208 coefficients ($3\beta+2\alpha$) are shown in Fig.5a, while the particle depolarization ratios δ_{355} , δ_{532} , δ_{1064}
 209 and the lidar ratios at 355 nm and 532 nm (LR_{355} , LR_{532}) are presented in Fig.5b. The depolarization
 210 ratio decreases with wavelength from $9 \pm 1.5\%$ at 355 nm to $1.5 \pm 0.3\%$ at 1064 nm and the lidar
 211 ratio at 532 nm significantly exceeds corresponding value at 355 nm (80 ± 12 sr and 50 ± 7.5 sr
 212 respectively), which is typical for aged smoke (Müller et al., 2005). The multiwavelength
 213 observations were inverted to determine the particle effective radius r_{eff} , number, surface area and

214 volume concentrations for seven height bins inside the smoke layer. The effective radius r_{eff} in
 215 Fig.5c increases through the layer from 0.15 μm to 0.2 μm simultaneously with the increase of the
 216 fluorescence capacity G_F from 2.8×10^{-4} to 3.6×10^{-4} . Retrieved values of N , S , V were used for the
 217 calculation of the conversion factors (Eq. 3) for each height bin. In the center of the smoke layer
 218 (at 4.9 km) the factors are: $C_N = 88 \times 10^4 \frac{\text{cm}^{-3}}{\text{Mm}^{-1}\text{sr}^{-1}}$, $C_S = 35 \times 10^4 \frac{\mu\text{m}^2 \text{cm}^{-3}}{\text{Mm}^{-1}\text{sr}^{-1}}$, and $C_V = 2.4 \times 10^4 \frac{\mu\text{m}^3 \text{cm}^{-3}}{\text{Mm}^{-1}\text{sr}^{-1}}$.

219 Thus, when β_F is given in $\text{Mm}^{-1}\text{sr}^{-1}$, the calculated values of N , S , and V are given in cm^{-3} , $\mu\text{m}^2 \text{cm}^{-3}$
 220 3 and $\mu\text{m}^3 \text{cm}^{-3}$ respectively. Fluorescence backscattering is proportional to the particle volume
 221 concentration, so C_V is not sensitive to the effective radius variation. The conversion factors C_N
 222 and C_S , on the contrary, depend on the particle size. Fig.5d shows the profiles of N , S , V obtained
 223 by inversion of $3\beta+2\alpha$ observations (symbols) together with corresponding values (N^S , S^S , V^S)
 224 obtained from β_F , using the mean conversion factors for seven height bins considered. The volume
 225 concentrations V and V^S agree well for all seven height bins. For the surface area concentrations
 226 the agreement is still good, but for N and N^S the difference is up to 30%. We need to emphasize,
 227 that the conversion factors presented are specific for our lidar system (for the interference filter
 228 installed in fluorescence channel). It is worthwhile to mention that the ratio V/α_{532} of the volume
 229 concentration V in Fig.5d to the extinction coefficient α at 532 nm in Fig.5a, as well as the ratio
 230 S/α_{532} , are very close to respective extinction-to-volume and extinction-to-surface-area-
 231 concentration conversion factors presented for aged wildfire smoke by Ansmann et al. (2021).

232 The conversion factors depend on the smoke composition. To estimate the variation range
 233 of C_N , C_S , C_V , several smoke episodes were analyzed and corresponding results are presented in
 234 Table 1. The table provides the fluorescence capacity G_F and the conversion factors at the heights,
 235 where $3\beta+2\alpha$ data could be calculated. Mean values of $\langle C_N \rangle$, $\langle C_S \rangle$, $\langle C_V \rangle$ derived for these
 236 episodes and corresponding standard deviations are:

$$237 \langle C_N \rangle = (61 \pm 32) \times 10^4 \frac{\text{cm}^{-3}}{\text{Mm}^{-1}\text{sr}^{-1}}; \langle C_S \rangle = (28 \pm 6.4) \times 10^4 \frac{\mu\text{m}^2 \text{cm}^{-3}}{\text{Mm}^{-1}\text{sr}^{-1}}; \langle C_V \rangle = (2.2 \pm 0.2) \times 10^4 \frac{\mu\text{m}^3 \text{cm}^{-3}}{\text{Mm}^{-1}\text{sr}^{-1}} \quad (4)$$

238 Table 1 shows also the volume and surface area concentrations of the smoke particles obtained
 239 from the inversion of $3\beta+2\alpha$ observations (V , S) and calculated from β_F (V^S , S^S) using the
 240 conversion factors in Eq. (4). Standard deviations of V^S and S^S from corresponding values of $V_{3\beta+2\alpha}$
 241 and $S_{3\beta+2\alpha}$ are 10% and 25% respectively.

242 The mean conversion factors in Eq. (4) are now used to estimate the smoke microphysical
243 properties inside the cloud, assuming in addition that the predominant contribution to the
244 fluorescence is provided by the smoke. Table 2 summarizes the number, surface area, and volume
245 concentrations of smoke particles inside the ice clouds, estimated from fluorescence measurements
246 for four episodes considered in this paper. On September 12-13, 2020, the smoke layer with high
247 fluorescence and low depolarization ratio at 1064 nm (below 4%) was observed during the whole
248 night inside the 2.0 km – 5.0 km height range. The cirrus cloud occurred above 11000 m also
249 during the whole night. Fig.6a presents vertical profiles of the aerosol β_{532} and fluorescence β_F
250 backscattering coefficients. Fluorescence backscattering shows a maximum at 3.5 km, but it is
251 detected even inside the cloud. The smoke backscattering coefficient β_{532}^s , computed from β_F for
252 $G_F=3.6\times 10^{-4}$ agrees well with β_{532} inside the 2.0 – 10.0 km height range (Fig. 6b). The height profile
253 of the surface area concentration of the smoke particles S^s , calculated from β_F using the respective
254 conversion factor in Eq. (4), is shown in Fig.6c. In the smoke layer, S^s is up to $60 \mu\text{m}^2/\text{cm}^3$, while
255 in the center of the cloud in 12 km – 13 km height the average value of S^s is $1.6\pm 0.4 \mu\text{m}^2/\text{cm}^3$.
256 Corresponding values of number and volume concentrations in the cloud center are $3.5\pm 1.8 \text{ cm}^{-3}$
257 and $0.13\pm 0.013 \mu\text{m}^3/\text{cm}^3$.

258 The temperature in the cloud ranged from about -50°C to almost -70°C and was -68°C at
259 cirrus top in Fig.6b where ice nucleation usually starts. We applied the immersion freezing INP
260 parameterization of Knopf and Alpert (2013) for Leonardite (a standard humic acid surrogate
261 material) and assume that this humic compound represents the amorphous organic coating of
262 smoke particles. The INP parameterization for smoke particles is summarized for lidar applications
263 in Ansmann et al. (2021). The selected parameterization allows the estimation of the INP
264 concentration as a function of ambient air temperature (freezing temperature), ice supersaturation,
265 particle surface area, and time period for which a certain level of ice supersaturation is given. We
266 simply assume a constant ice supersaturation of around 1.45 during a time period of 600 s (upwind
267 phase of a typical gravity wave in the upper troposphere). The temperature at cirrus top height is
268 set to -68°C and the aerosol surface area concentration to $2.0 \mu\text{m}^2/\text{cm}^3$ as indicated in Fig.6c. The
269 obtained INP concentrations of $1\text{-}10 \text{ L}^{-1}$ for these meteorological and aerosol environmental
270 conditions can be regarded as the predicted number concentration of ice crystals nucleated in the
271 cirrus top region. Ice crystal number concentration of $1\text{-}10 \text{ L}^{-1}$ are typical values in cirrus layers
272 when heterogeneous ice nucleation dominates (typical values of INP concentrations and

273 supersaturation are discussed e.g. in Sullivan et al, (2016), Ansmann et al. (2019; 2021),
274 Engelmann et al. (2021)). It should be mentioned that the required very high ice supersaturation
275 levels of close to 1.5 (ice supersaturation of 1.1-1.2 is sufficient in case of mineral dust particles)
276 are still lower than the threshold supersaturation level of >1.5 at which homogeneous freezing
277 starts to dominate. At low updraft velocities around 10-25 cm/s, as usually given in gravity waves
278 in the upper troposphere (Barahona et al., 2017), heterogeneous ice nucleation very likely
279 dominates the ice production when cirrus evolves in detected aerosol layers.

280

281 **3.3. Ice formation inside the smoke layers.**

282 During September 2020 we observed several episodes with ice cloud formation inside of
283 smoke layers. One of such episodes occurred on 11-12 September 2020 and is shown in Fig.7. The
284 height – time display of the fluorescence backscattering coefficient reveals the smoke layer in the
285 5.0 - 10.0 km height range. Inside this layer, we can observe a short time interval of 15 minutes
286 with a strongly increased depolarization ratio around 10.5 km height (red spots), indicating ice
287 cloud formation. Fig.8 shows vertical profiles of the aerosol backscattering coefficients β_{355} , β_{532} ,
288 and β_{1064} as well the particle depolarization ratios δ_{355} , δ_{532} , and δ_{1064} for two temporal intervals.
289 The first interval (23:00 – 00:30 UTC) is prior to ice cloud formation and the second one (01:20 –
290 01:45 UTC) covers ice occurrence period. The depolarization ratios at all three wavelengths were
291 $< 5\%$ below 6 km height. Above that height δ_{355} significantly increased reaching the value of 10%
292 at 7 km (Fig.8b), which is indicative of a change of the particle shape (from spherical to irregular
293 shape). The fluorescence capacity also changed with height, being about $G_F=4.5\times 10^{-4}$ at 5.5 km
294 and it decreases to 3.5×10^{-4} by 8 km. The profile of β_{532}^s shown in Fig.8c is calculated assuming
295 $G_F=4.0\times 10^{-4}$ and it matches well the profile of β_{532} for the whole height range. The aerosol layer
296 at 10.5 km is thus a pure smoke layer. Ice formation at 10.5 km (Fig.8d-f) leads to a significant
297 increase of β_{532} while β_{532}^s (or the respective fluorescence backscatter coefficient β_F) remains low
298 and at the same level as observed below the cirrus layer, i.e., below 10 km height. The
299 depolarization ratios at all three wavelengths increases to typical cirrus values around 40%. The
300 temperature at 10.5 km is about $-50\text{ }^\circ\text{C}$, and the surface area concentration of the smoke particles
301 inside the cloud, estimated from β_F , is about $10\text{ }\mu\text{m}^2/\text{cm}^3$ (see Fig.8f, thin blue line). For these
302 temperature and aerosol conditions we yield smoke INP concentrations of $1\text{-}10\text{ L}^{-1}$ for ice

303 supersaturation values even below 1.4 (1.38-1.4) and updraft duration of 600 s. When comparing
304 Fig.8c and 8f at cirrus level it seems to be that ice nucleation on the smoke particles widely
305 depleted the smoke INP reservoir.

306 Another case of ice formation in the smoke layer was observed on 17-18 September 2020.
307 Strong smoke layers occurred in the 5.0 km – 9.0 km height range as shown in Fig.9. During the
308 period from 22:30 – 00:00 UTC, the depolarization increased at 8.5 km height, indicating ice
309 formation. Vertical profiles of the particle parameters prior and during ice formation are shown in
310 Fig.10. The β_{532}^s calculated for $G_F=3.5\times 10^{-4}$ matches well with β_{532} below 6.9 km and above 8.0
311 km (Fig.10c), but inside the 7.0 km – 8.0 km height range $\beta_{532} > \beta_{532}^s$, meaning that G_F was
312 decreased. The depolarization ratio in the 7.0 km – 8.0 km height range shows some enhancement
313 (Fig.10b): in particular, δ_{532} increased from 10% to 12%. Cloud formation at 8.5 km (Fig.10d) led
314 to a significantly smaller increase of the depolarization ratio, compared to the case on 11-12
315 September. Prior to the cloud formation the values of δ_{1064} , δ_{532} , and δ_{355} at 8.5 km were of 3%,
316 10%, and 13% respectively (Fig.10b) and in the cloud corresponding depolarization ratios increase
317 up to 9%, 15%, 20%. The reason is probably that the signal averaging period from 22:45 to 23:45
318 UTC includes cloud-free section. Three gravity waves obviously crossed the lidar field site and
319 triggered ice nucleation just before 23 UTC, 15-30 minutes after 23 UTC, and around mid night
320 (00:00 UTC). The temperature at cloud top at about 8.5-8.6 km height was close to -35°C. For this
321 high temperature and the high particle surface area concentration of 200 $\mu\text{m}^2/\text{cm}^3$ (see Fig.10d,
322 thin blue line) we yield smoke INP concentrations of 1-10 L^{-1} for a relatively low ice
323 supersaturation of 1.30-1.33 and an updraft period of 600 s. Again, a depletion of the INP reservoir
324 is visible after formation of the cirrus layer (see Figs.6c and 6d around and above 8.5 km height).

325

326 **Conclusion**

327 The operation of a fluorescence channel in the LILAS lidar during strong smoke events in
328 the summer and autumn seasons of 2020 has demonstrated the ability of the fluorescence lidar
329 technique to discriminate ice from smoke particles in atmospheric layers in the UTLS height range
330 in large detail. The fluorescence capacity G_F of smoke particles during this period varied within a
331 relatively small range: $2.5\text{-}4.5\times 10^{-4}$, thus the use of the mean value of G_F allows to estimate the
332 contribution of smoke to the total particle backscattering coefficient. The fluorescence lidar

333 technique makes it possible to estimate smoke parameters, such as number, surface area and
334 volume concentration in UTLS height range in a quantitative way by applying conversion factors
335 (C_N , C_S , C_V) which link the fluorescence backscattering and the smoke microphysical properties.
336 These factors, derived from the synergy of multiwavelength Mie-Raman and fluorescence lidar
337 observations, show some variation from episode to episode, however, the use of mean values
338 $\langle C_N \rangle$, $\langle C_S \rangle$, $\langle C_V \rangle$ allows estimation of smoke properties in UTLS height regime with reasonable
339 accuracy. Based on two case studies, we demonstrated that the fluorescence lidar technique
340 provides the unique possibility to characterize the smoke particles and their amount inside cirrus
341 cloud layers. The smoke input parameter (surface area concentration) in smoke INP
342 parameterization schemes that are used to predict ice crystal number concentrations in cirrus
343 generation cells, can now be estimated within freshly formed cirrus layers.

344 The smoke parameters such as fluorescence capacity and conversion factors were derived
345 from observations of aged wildfire smoke, transported over Atlantic in 2020. However, smoke
346 composition, depends on many factors, such as burning materials type, flame temperature and
347 environmental conditions, thus the smoke fluorescence properties may also vary. Hence, it is
348 important to perform the measurements for different locations and seasons. The fluorescence
349 backscattering in UTLS height range is quite weak, so to perform measurements with higher
350 temporal resolution more powerful lidar systems are needed. A dedicated high power Lidar, LIFE
351 (Laser Induced Fluorescence Explorer), will be designed and operated at ATOLL, in the frame of
352 OBS4CLIM/ACTRIS-France .

353

354

355 **Acknowledgement**

356 We acknowledge funding from the CaPPA project funded by the ANR through the PIA under
357 contract ANR-11-LABX-0005-01, the “Hauts de France” Regional Council (project CLIMIBIO)
358 and the European Regional Development Fund (FEDER). Development of algorithm for analysis
359 of fluorescence observations was supported by Russian Science Foundation (project 21-17-
360 00114). ESA/QA4EO program is greatly acknowledged for his support to the observation activity
361 at LOA.

542 **Appendix A.** Estimation of smoke parameters from Mie-Raman and fluorescence lidar
 543 measurements.

544
 545 Fig.A. Flow chart showing the main steps of the procedure of smoke parameters estimation from
 546 multiwavelength Mie-Raman and fluorescence lidar measurements. Procedure includes the
 547 following steps. (i) For a strong smoke layer the $3\beta+2\alpha$ data set, derived from multiwavelength
 548 Mie-Raman lidar observations, is inverted to the particle number N , surface S and volume V
 549 density. (ii) Conversion factors C_N , C_S , C_V are calculated from Eq.(3) by using the fluorescence
 550 backscattering coefficient β_F . (iii) Different smoke events are analyzed to get mean values of
 551 conversion factors $\langle C_N \rangle$, $\langle C_S \rangle$, $\langle C_V \rangle$. These mean values are used to estimate smoke
 552 concentration in weak layers in UTLS and inside cirrus clouds in regular observations. The mean
 553 value of smoke fluorescence capacity $\langle G_F \rangle$ allows estimation of smoke contribution β_{532}^s to the
 554 total backscattering coefficient β_{532} .
