**Abstract.** Previous Antarctic summer campaigns have shown unexpectedly high levels of oxidants in the lower atmosphere of the continental plateau as well as at coastal regions, with atmospheric hydroxyl radical (OH) concentrations up to  $4 \times 10^6 \text{ cm}^{-3}$ . Such high reactivity of the summer Antarctic boundary layer results in part from the emissions of nitrogen oxides ( $\text{NO}_x \equiv \text{NO} + \text{NO}_2$ ) produced during photo-denitrification of the snowpack, but its underlying mechanisms are not yet fully understood as some of the chemical species involved ( $\text{NO}_2$ , in particular) have not yet been measured directly and accurately. To overcome this crucial lack of information, newly developed optical instruments based on absorption spectroscopy (incoherent broadband cavity enhanced absorption spectroscopy or IBBCEAS) were deployed for the first time at Dome C (-75.10 lat., 123.33 long., 3,233 m a.s.l) during the 2019–2020 summer campaign to refine uncertainties in snow-air-radiation interaction. These instruments directly measure  $\text{NO}_2$  with a detection limit of 30 pptv (parts per trillion by volume or  $10^{-12} \text{ mol mol}^{-1}$ ) ( $3\sigma$ ). We performed two sets of measurements in December 2019 (4<sup>th</sup> to 9<sup>th</sup>) and January 2020 (16<sup>th</sup> to 25<sup>th</sup>) to capture the early and late photolytic season, respectively. Late in the season, the daily averaged  $\text{NO}_2$ :NO ratio ( $0.4 \pm 0.4$ ) matches that expected for photochemical equilibrium through Leighton's extended relationship involving  $\text{RO}_x$  ( $0.6 \pm 0.3$ ). In December, however, we observe a daily averaged  $\text{NO}_2$ :NO ratio of  $1.3 \pm 1.1$ , which is approximately twice the daily ratio of  $0.7 \pm 0.4$  calculated for Leighton equilibrium. This suggests that more  $\text{NO}_2$  is produced from the snowpack early in the photolytic season (December 4<sup>th</sup> to 9<sup>th</sup>) possibly due to stronger *UV* irradiance caused by a smaller solar zenith angle near the solstice. Such a high sensitivity of the  $\text{NO}_2$ :NO ratio to the sun's position is of importance for consideration in atmospheric chemistry models.

## 1 Introduction

Intense field campaigns over the past three decades have studied the Arctic and Antarctic boundary layer composition and photochemistry (Bauguitte et al. (2012), and references therein). The collection and interpretation of polar ice cores has led to the growing interest in the atmospheric chemistry of these regions, as well as their relatively unpolluted nature free of local anthropogenic emissions (Wolff, 1995). Antarctica, in particular, is the most isolated continent on Earth; therefore, providing the last continent scale laboratory for studying past and present natural atmospheric cycles (EPICA community members, 2004). Because of this presumed pristineness, the scientific community was puzzled by initial observations of high oxidative

capacity in the polar boundary layer, i.e., an oxidation process initiated by oxidants, (including ozone, hydroxyl and peroxy  
 25 radicals, hydrogen peroxide, halogen radicals), which resembled those seen in urban environments (Beine et al., 2002; Mauldin  
 et al., 2001; Davis et al., 2001; Jones et al., 2008; Kukui et al., 2014; Preunkert et al., 2012; Saiz-Lopez et al., 2008). It is today  
 well established that such high reactivity of the summer Antarctic boundary layer results from the presence of highly reactive  
 species, such as nitrogen oxides ( $\text{NO}_y \equiv \text{NO}, \text{NO}_2, \text{HONO}, \text{HO}_2\text{NO}_2, \text{HNO}_3$  etc.), hydroxyl, and peroxy radicals ( $\text{RO}_x \equiv$   
 $\text{OH}, \text{HO}_2, \text{RO}_2$ ), and halogen oxides ( $\text{XO} \equiv \text{BrO}, \text{IO}, \text{ClO}$ ), due to precursor emissions from the snowpack. Despite their short  
 30 lifetime and low abundance in the atmosphere, they control the oxidative capacity and the composition of the atmospheric  
 chemistry of these regions due to their high reactivity. Today, this phenomenon is still not yet fully understood due to the  
 difficulty of performing accurate and free of interference  $\text{NO}_x$  measurements, combined with a complex oxidation/reduction  
 reaction involving  $\text{NO}_x, \text{O}_3$ , and radicals in the snow and atmosphere (Fig. 1).

**Figure 1.** Schematic of the  $\text{NO}_x$  chemistry in the Antarctic Plateau. The  $\text{NO}_x$  cycle and the  $\text{NO}_x$  direct snow-sources are shown in bold.

The photolysis of nitrate ions ( $\text{NO}_3^-$ ) in the snow produces  $\text{NO}_x$  ( $\equiv \text{NO}_2 + \text{NO}$ ) (Grannas et al., 2007). Gas phase nitrogen  
 35 dioxide ( $\text{NO}_2$ ) photolyzes to produce nitrogen oxide ( $\text{NO}$ ), which also results in production of ozone ( $\text{O}_3$ ), which then reacts  
 together to reform  $\text{NO}_2$  (bold cycle in Fig. 1). In this recycling reaction, no net production or loss of any species is involved.  
 However, in the presence of other species, such as peroxy radicals ( $\text{RO}_x$ ) or halogenated radicals ( $\text{XO}$ ),  $\text{NO}$  can produce  
 $\text{NO}_2$  without consuming  $\text{O}_3$  (Fig. 1).  $\text{NO}_2$  can also be consumed by reacting with hydroxyl or halogenated radicals to form

HNO<sub>3</sub>, which will redeposit onto the snowpack surface. Additionally, NO can react with OH to form HONO, which was measured on the Antarctic Plateau during the OPALE campaign. HONO had been modeled to be present at around 8 to 12 pptv (parts per trillion by volume or 10<sup>-12</sup> mol mol<sup>-1</sup>) during the austral summer (Legrand et al., 2014). However, Legrand et al. (2014) showed that the oxidation of NO by the OH radical is not sufficient to explain the levels of HONO observed, and the main source of HONO comes from the snowpack emissions, as shown on Figure 1. The following list of campaigns and publications is not-exhaustive but gives an idea of the intensive studies of the Antarctic atmospheric chemistry for evaluating the air-snow transfer-function. ISCAT 2000 (Investigation of Sulfur Chemistry of the Antarctic Troposphere) at South Pole station in 2000 (Berresheim and Eisele, 1998; Davis et al., 2004), revealed a strong oxidizing environment at South Pole (SP), in the Antarctic Plateau. The measurements established the recycling of reactive nitrogen as a critical component of this unique environment. ANTCI (The Antarctic Tropospheric Chemistry Investigation) deployed two field studies between 2003 and 2005 with large ground-based winter-over sampling components at SP station and aircraft chemistry and photochemistry measurements (Davis et al., 2008; Eisele et al., 2008; Helmig et al., 2008; Wang et al., 2007). CHABLIS (CHemistry of the Antarctic Boundary Layer and the Interface with Snow) measurement campaign was conducted at Halley station, in coastal Antarctica, from January 2004 through February 2005 (Anderson and Bauguitte, 2007; Bauguitte et al., 2012; Bloss et al., 2007, 2010; Jones et al., 2008, 2011; Mills et al., 2007; Read et al., 2008; Saiz-Lopez et al., 2008; Salmon et al., 2008; Wolff et al., 2008). SUNITE DC (Sulfate and NItroTe surface snow Evolution at Dome C) aimed to document and use isotopic anomalies of oxyanions (sulfate and nitrate) to constrain the sources, transformations, and transports of these compounds to the polar regions where they are archived over thousands of years (Bock et al., 2016; Erbland et al., 2013; Meusinger et al., 2014; Savarino et al., 2007; Vicars and Savarino, 2014; Frey et al., 2009). OPALE (Oxidative Production over Antarctic Land and its Export) campaign took place at both coastal Antarctica (Terre Adélie, Dumont D'Urville station) and the plateau (Dome C, Concordia station), with the aim to quantify, understand, and model the level of oxidants present in the lower atmosphere of East Antarctica (Berhanu et al., 2015; Erbland et al., 2015; Frey et al., 2013, 2015; Gallée et al., 2015a, b; Kukui et al., 2014; Legrand et al., 2014, 2016; Preunkert et al., 2012, 2015; Savarino et al., 2016). Despite the numerous observations of nitrogen-bearing species, HONO, NO<sub>x</sub> and NO, collected during those cited previous campaigns, no direct NO<sub>2</sub> measurements free of interferences were so far performed on the Antarctic plateau. Indeed, previous studies used chemiluminescent detectors (CLDs), which directly measure NO, and NO<sub>y</sub> after photolytic conversion to NO, conversion subject to interferences. This absence hinders our efforts to correctly evaluate the NO<sub>x</sub> cycle over the snowpack, leaving significant uncertainties in modeled values, which affect our full understanding of snow-air-radiation interactions. To overcome this lack of information, direct and accurate NO<sub>2</sub> measurements with simultaneous detection of NO are needed. Here, we deployed newly developed optical instruments in the field that allow direct measurement of NO<sub>2</sub> and indirect measurement of NO with detection limits of 30 and 63 pptv (3σ), respectively (Barbero et al., 2020). Although indirect, the NO measurement is well constrained. Potential artifacts have been identified and discussed in Barbero et al. (2020). Even though they may occur during night-time in an urban polluted environment, caused by the presence of N<sub>2</sub>O<sub>5</sub>, they are negligible during the summer period in Antarctica. We present new results on summer NO<sub>2</sub>:NO variability over the Antarctic Plateau and explore the mechanisms involved in the atmospheric boundary layer of the Antarctic Plateau during the photolytic season in light of these new data. While the overall NO<sub>2</sub>:NO

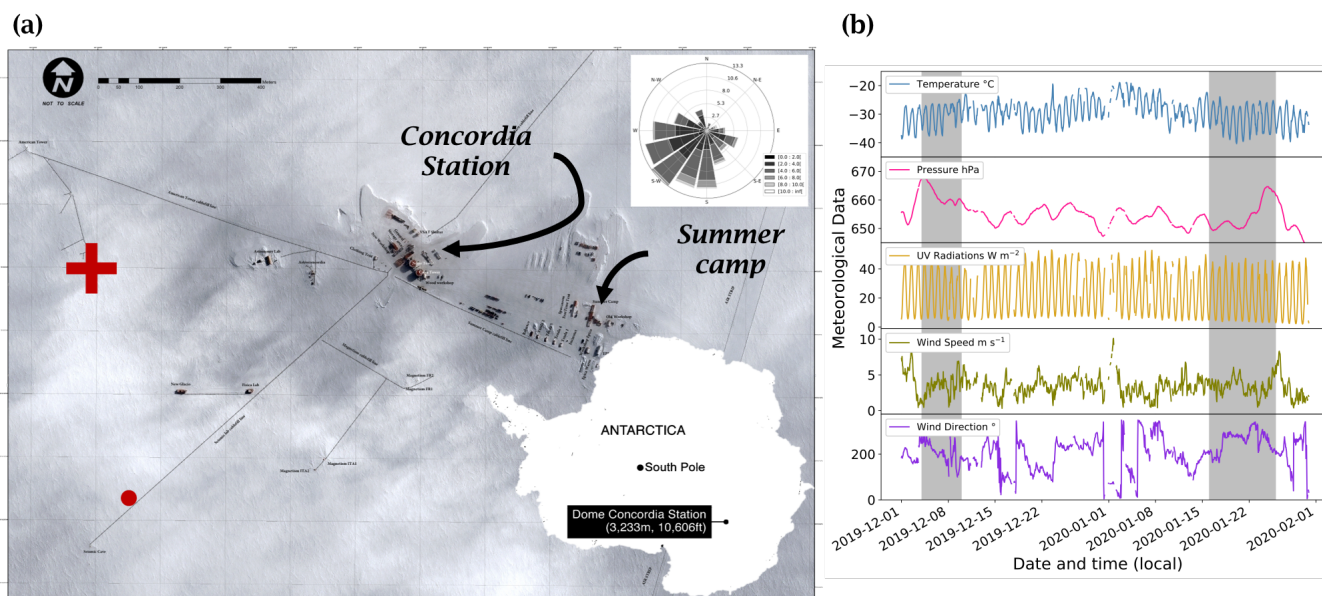

ratio can be explained by the extended Leighton's relationship, a high  $\text{NO}_2:\text{NO}$  ratio was estimated in the morning during  
75 the early photolysis season, deviating from steady state equilibrium and not explained by the extended Leighton's relationship  
taken from Ridley et al. (2000). Calculations show that the assumption of an additional conversion of  $\text{NO}$  to  $\text{NO}_2$  through  $\text{XO}$   
or  $\text{RO}_x$  seems insufficient to fully explain the observations. Additionally, using results of dynamic flux chamber experiments,  
the  $\text{NO}_x$  snow-source was better characterized highlighting that the  $\text{NO}_2:\text{NO}$  ratio is very sensitive to the position of the sun,  
were a 5 % difference in the solar zenith angle (SZA) between December and January may explain the equilibrium deviation  
80 observed on the  $\text{NO}_2:\text{NO}$  ratio.

## 2 Methods

### 2.1 Site Description, sampling location, and set-up

Atmospheric  $\text{NO}_x$  measurements were conducted for a total of 16 days, from 4 to 9 December 2019 and from 16 to 25  
January 2020, at the French-Italian Concordia Station, Dome C, Antarctica (-75.10 lat., 123.33 long., 3,233 m a.s.l). This  
85 year-round operating station is located on the Antarctic Plateau at a distance of 1,100 km from the coast and provides an  
exceptional site for studying polar atmospheric chemistry. The station experiences polar night during the austral winter when  
the sun remains below the horizon from May to August, while in summer (November to January) the SZA has a minimum  
of  $52^\circ$ , i.e., the sun is at maximum  $38^\circ$  above the horizon. The local weather is generally dominated by cold, clear, and calm  
conditions. The annual wind speed is low due to its sitting at the top of a dome at an altitude of more than 3,200 m. Occasional  
90 regional storm systems can advect more coastal air masses associated with higher wind speeds and relatively warmer and  
cloudier weather (Genthon et al., 2010). The meteorological conditions encountered during the summer campaign (Fig. 2) were  
typical of summer climatology (November to February) observed at Dome C:  $T_{mean} = -29 \pm 4^\circ\text{C}$ ;  $P_{mean} = 655 \pm 4\text{ hPa}$ ;  $W_{speed-mean} = 3.5 \pm 1.5\text{ m s}^{-1}$ ;  $W_{dir-mean} = 206 \pm 71^\circ$ ; and  $UV_{mean} = 24 \pm 15\text{ W m}^{-2}$  (spectral range 305–385 nm).  
Five-day back-trajectories conducted by the HYSPLIT (Hybrid Single-Particle Lagrangian Integrated Trajectory) transport  
95 and dispersion model (Stein et al. (2015); Rolph et al. (2017), <https://www.ready.noaa.gov>) show that the air masses were  
principally coming from the continent during the measurement periods (more information is provided in Appendix A). The  
meteorological conditions encountered during both atmospheric measurement periods can be found in Appendix B.

**Figure 2.** (a) Satellite view of the station: the red cross marks the position of the atmospheric observations and the red dot the location of the automatic weather station (AWS– Vaisala Milos 520). The wind rose for the period 01/12/2019 to 31/01/2020 is shown in the upper right-hand corner. Pléiade Satellite Image – Concordia Station, Antarctica @ CNES 2016, Distribution Airbus DS. (b) Local meteorological conditions (2-m observations) measured for the period 01/12/2019 to 31/01/2020 by the local automatic weather station (AWS– Vaisala Milos 520) completed with a broadband *UV* radiometer (spectral range 305–385 nm). The shaded areas represent the periods when atmospheric chemistry measurements were conducted.

Atmospheric sampling was done in the station's clean area sector (a zone less subject to pollution linked to the station's activities), about 1 km south-west and upwind of the main station buildings (Fig. 2). A container buried under the snow and maintained at a temperature of 8 °C was used to host the measuring instruments and all the equipment necessary for the observations (Fig. 3).

**Figure 3.** Set-up schematic: the photolysis rate constant of NO<sub>2</sub> and O<sup>1</sup>D are measured by a 2π spectral radiometer (MetCon) placed 2 meters above the snow surface and measuring the downwelling flux, (i.e. facing the sky) ; the atmospheric sampling of NO<sub>2</sub>, NO<sub>x</sub>, and O<sub>3</sub> were made 1 meter above the snow surface through  $\frac{1}{4}$ " PTFE tubing. Note that 5 μm particle filters (PF) were placed at the inlets to protect the optics of the instruments measuring cells.

## 2.2 Instrumentation and data processing

### 2.2.1 Measurement of atmospheric NO<sub>x</sub> and O<sub>3</sub>

The twin instruments described in Barbero et al. (2020) were used for NO<sub>x</sub> detection in the 400–475 nm wavelength region. These instruments are based on incoherent broadband cavity-enhanced absorption spectroscopy (IBBCEAS) with a high-power LED source injected in a high-finesse cavity ( $F \approx 33,100$ ), and the transmission signal is detected by a compact spectrometer equipped with a charge-coupled device (CCD) camera. Through this, we achieved direct detection of NO<sub>2</sub> with a detection limit of 30 pptv at 3σ precision within  $\approx 20$  min of measurement. To indirectly measure NO, we installed a compact ozone generator (based on water electrolysis) that converts all ambient NO into NO<sub>2</sub> via the reaction  $\text{NO} + \text{O}_3 \rightarrow \text{NO}_2 + \text{O}_2$ . Additionally, the instrument configuration allows the spectrometer to operate at low temperature, making potential interferences from the thermal degradation of HO<sub>2</sub>NO<sub>2</sub>, for example, negligible (estimated at 1 pptv at 10 °C). Furthermore, very limited NO<sub>2</sub> (0.001 pptv) would be produced by the reaction of HONO + OH  $\rightarrow$  NO<sub>2</sub> + H<sub>2</sub>O and less than 8 to 16 ppqv for 200 pptv of NO<sub>2</sub> would be formed through the heterogenous reaction of NO<sub>2</sub> and H<sub>2</sub>O. The possible interference due to NO<sub>2</sub>, NO or NO<sub>3</sub> should be limited because their rate constant is several orders of magnitudes less than that for the NO oxidation. Finally, spectral interferences were studied as small imperfections on the fit could lead to large effects on the NO<sub>2</sub> retrieved mixing ratio, particularly at sub-ppb levels, but no substantial effects of potential artifacts were observed when O<sub>3</sub> mole

fractions up to 8 ppmv were used, and, applied O<sub>3</sub> mole fractions were kept below 6 ppmv ( $5.6 \pm 1.5$  and  $4.3 \pm 0.5$  ppmv in December and January, respectively) during this field study. Ultimate detection limits of 33 and 63 pptv ( $3\sigma$ ) for NO<sub>x</sub> and NO (taking into account the propagation error), respectively, are also achieved within  $\approx 20$  min of measurement (Barbero et al., 2020), according to an Allan-Werle statistical method (Werle et al., 1993). The instruments were calibrated prior and after field deployment using a stable reference NO<sub>2</sub> source (FlexStream™ Gas Standards Generator, KINTEK Analytical, Inc.), covering a large range of concentrations from the pptv to ppbv range (Barbero et al., 2020). In the field, a shorter time average of 10 min was used, which included the acquisition of the reference ( $I_0$ ) and absorption ( $I$ ) spectra. This shorter measurement still provides excellent detection limits of 54 and 48 pptv ( $3\sigma$ ) for NO<sub>x</sub> and NO<sub>2</sub>, respectively, while providing a higher resolution dataset, more profitable for removing possible polluted events from the dataset. Field calibrations were made using NO<sub>2</sub> and NO gas bottles (Air Liquide - 1 ppm NO<sub>2</sub> in N<sub>2</sub>; Messer – 1 ppm NO in N<sub>2</sub>) diluted with a zero-air flow for multi-point calibrations. Additionally, the NO<sub>2</sub> bottle was calibrated prior the field campaign against the same NO<sub>2</sub> source as the laboratory calibrations. The zero-air was produced by pumping outdoor air through two zero-air cartridges connected in series (TEKRAN, 90-25360-00 Analyzer Zero Air Filter) and pushed into the dilution line controlled by two mass flow controllers (MKS - Mass Flow Controller at 0.01 and 10 standard liter per minute for the NO<sub>2</sub> flow and the zero-air flow, respectively). The NO<sub>x</sub> measurements from the IBBCEAS were synchronized in time for a more accurate estimate of the NO mixing ratio ( $\text{NO} = \text{NO}_x - \text{NO}_2$ ). To limit the impact of variable weather and atmospheric conditions on our NO<sub>2</sub> and NO observations and approximate a steady state to use Leighton's relationship (Leighton, 1961), we restricted data to when the wind was between 135° and 338° (i.e., not coming from the direction of the station) with a speed below 5 m s<sup>-1</sup>. These constraints resulted in 17 % rejection rate for the first observation period and 11 % for the second period. During the second period, approximately 4 days of measurements were further rejected because the instruments were being used for intercomparison and calibration purpose. After this quality control, the accepted data observations were then aggregated to hourly means in order to reduce the sensitivity. Atmospheric ozone was monitored using a UV Photometric O<sub>3</sub> analyzer (Thermo Scientific™, Model 49i) that has a 1.5 ppbv ( $3\sigma$ ) detection limit for 60 s data. The instrument was calibrated on site with an O<sub>3</sub> calibration source (2B Technologies Model 306 Ozone Calibration Source™) and connected to an existing air sampling tower at 1 meter above the snow surface (Helmig et al., 2020) (Appendix C). Here, samples were drawn sequentially at typical flows of  $\approx 1$ -2 slpm through a series of switching valves connected to several inlet lines, following a 2-hour duty cycle of 8 minutes measurements on each inlet. To account for the switching manifold response time, only the last three minutes of measurements of steady-state concentrations were used and averaged, giving one measurement of ozone mixing ratio every 2 hours. A linear data interpolation on the O<sub>3</sub> measurements was applied to match the resolution of the NO<sub>x</sub> and NO<sub>2</sub> measurements. Particle filters (Whatman™ PTFE membrane filters – TE 38, 5 μm, 47 mm) were placed in the inlet lines (IBBCEAS and Thermo 49i) for removing aerosol particles.

## 2.2.2 Ancillary data

Standard meteorological data were collected from an automatic weather station (AWS) located one kilometer away from the atmospheric measurements (Fig. 2). The  $UV$  radiation spectrum was analyzed with a broadband  $UV$  radiometer (Kipp & Zonen –  $CUV$  4, spectral range 305–385 nm) deployed near the clean sector.

## 2.2.3 The photolysis rate coefficients $J_{NO_2}$ and $J_{O^1D}$

The photolysis rate coefficients,  $J_{NO_2}$  and  $J_{O^1D}$  were calculated from measurements made by a MetCon  $2\pi$  spectral radiometer with a charge coupled device. The spectral radiometer was mounted on a mast at 2 m from the snow surface on a mast (Fig. 3), and downwelling radiance was recorded over the full spectral range of the radiometer from 285 to 700 nm. Unfortunately, unstable power supply issues resulted in irregular operation during the summer campaign, particularly during local nighttime hours, and a continuous signal was reconstructed using the broadband  $UV$  radiometer to scale the data from the  $2\pi$  spectral radiometer. Later, the total  $4\pi$  steradian radiance was calculated by multiplying the measurements by 1.9, as this factor was determined from downwelling and upwelling radiance measurements during the OPALE campaign (Kukui et al., 2014). The estimated  $J_{NO_2}$  for both measurement periods is shown in Figure 4, and details on the fit analysis are provided in Appendix D. Due to the intermittent measurements, differences between the fit analysis and the  $J_{NO_2}$  measurements were found to be around  $1 \pm 7\%$  ( $1\sigma$ ) in December and  $4 \pm 15\%$  ( $1\sigma$ ) in January.

**Figure 4.**  $J_{NO_2}$  (blue solid lines) reconstruction following the 2 degrees polynomial regression fit (shown in Appendix D) with  $UV$  radiation (shaded orange) measured by a broadband  $UV$  radiometer (spectral range 305–385 nm) for both the December (a) and January (b) observation periods.

These extrapolations agree well with previous measurements done during the 2011–2012 OPALE campaign using the same  $2\pi$  spectral radiometer. Kukui et al. (2014) found a median value of  $J_{NO_2} = 1.3 \times 10^{-2} \text{ s}^{-1}$  ( $0.4$  to  $2.1$ ) from the 19/12/2011 to the 10/01/2012, very close to the one found in this work:  $1.2 \times 10^{-2} \text{ s}^{-1}$  ( $0.3 \times 10^{-2} \text{ s}^{-1}$  to  $1.9 \times 10^{-2} \text{ s}^{-1}$ ). In a similar manner, we calculated  $J_{O^1D}$  (median value of  $1.6 \times 10^{-5} \text{ s}^{-1}$ , range  $0.2 \times 10^{-5} \text{ s}^{-1}$  to  $5.4 \times 10^{-5} \text{ s}^{-1}$ ) from the  $UV$  radiation data (please refer to Appendix D for more information).

### 2.3 NO<sub>2</sub>:NO ratio analysis

If in steady state the relationship between the reactions NO + O<sub>3</sub> and NO<sub>2</sub> photolysis, known as the simple Leighton's relationship (Leighton, 1961), can be described by Equation 1:

$$NO_2 : NO = \frac{k_{NO+O_3}[O_3]}{J_{NO_2}} \quad (1)$$

with [O<sub>3</sub>], the ozone concentration in molecules cm<sup>-3</sup>;  $k_{NO+O_3} = 1.4 \times 10^{-12} \exp(\frac{-10.89}{RT})$ , the constant rate of the reaction NO + O<sub>3</sub> (Atkinson et al., 2004) and expressed in cm<sup>3</sup> molecules<sup>-1</sup> s<sup>-1</sup>; and  $J_{NO_2}$ , the NO<sub>2</sub> photolysis rate constant in s<sup>-1</sup>, measured with the MetCon instrument and reconstructed as explained in Section 2.2.3. However, as illustrated in Figure 1, the simple Leighton's relationship can be perturbed by other species such as peroxy radicals and halogenated radicals. Therefore, the NO<sub>2</sub>:NO ratio can also be calculated from an extended Leighton mechanism also including peroxy radicals as described in Equation 2 (Ridley et al., 2000):

$$NO_2 : NO = \frac{k_{NO+O_3}[O_3] + \sum k_{NO+RO_x}[RO_x]}{J_{NO_2}} \quad (2)$$

Kukui et al. (2014) measured the RO<sub>x</sub> at Dome C during the OPALÉ campaign at 1 m above the snow surface. They assumed that HO<sub>2</sub> and CH<sub>3</sub>O<sub>2</sub> radicals represent the major part of all RO<sub>2</sub> radicals at Dome C, with a ratio of HO<sub>2</sub>:RO<sub>2</sub> = 0.67 ± 0.05. Additionally, Kukui et al. (2014) found a linear correlation between the  $J_{NO_2}$ , measured with the same MetCon instrument, and the concentrations of RO<sub>2</sub> (see Figure 3 of their study). Here, we used the same correlation and the ratio of 0.67 to estimate RO<sub>2</sub> and HO<sub>2</sub> atmospheric concentrations, respectively (more information can be found in Appendix E). The reactions between those dominating peroxy radicals, RO<sub>2</sub> and HO<sub>2</sub>, and nitrogen oxide are rapid with respect to NO + O<sub>3</sub>, with mean rate coefficients of  $(1.10 \pm 0.02) \times 10^{-11}$  cm<sup>3</sup> molecules<sup>-1</sup> s<sup>-1</sup> and  $(0.91 \pm 0.02) \times 10^{-11}$  cm<sup>3</sup> molecules<sup>-1</sup> s<sup>-1</sup>, respectively, while  $k_{NO+O_3} = (6.35 \pm 0.53) \times 10^{-15}$  cm<sup>3</sup> molecules<sup>-1</sup> s<sup>-1</sup>, in Dome C daily conditions. Therefore, Equation 3 is used to consider those reactions and calculate NO<sub>2</sub>:NO ratios from O<sub>3</sub> in-situ measurements and RO<sub>x</sub> observations taken from Kukui et al. (2014).

$$NO_2 : NO = \frac{k_{NO+O_3}[O_3] + k_{NO+CH_3O_2}[CH_3O_2] + k_{NO+HO_2}[HO_2]}{J_{NO_2}} \quad (3)$$

### 2.4 Atmospheric dynamic and polar boundary layer effect

In an attempt to decipher the mechanisms occurring at Dome C during our observation periods, we decided to account for the dilution effect due to the diurnal variation of the planetary boundary layer (PBL). To do so, in the second part of the results section we referred our measurements to the total number of molecules using Equation 4 hereafter:

$$N_i = [i] \times V \quad (4)$$

with  $N_i$ , the total number of molecules of the specie  $i$  ( $i = NO_x, NO, NO_2, HO_2, RO_2$  and  $O_3$ );  $[i]$ , its concentration expressed in molecule cm<sup>-3</sup>; and  $V$ , an arbitrary volume expressed as  $1 \text{ cm} \times 1 \text{ cm} \times H_{PBL}$ , with  $H_{PBL}$ , the boundary layer height in cm

retrieved using the MAR regional model (see Appendix F for details). This calculation assumes a homogeneous concentration distribution of the species within the PBL, an assumption supported by the flat concentration profiles observed by Frey et al. (2015) and Legrand et al. (2016) within the PBL during the OPALÉ campaign, where  $O_3$  and  $NO_x$  distribution are showing homogeneous mixing ratio within the entire polar boundary layer (PBL) except from 18:00 to 00:00 Local Time (LT) due to the collapse of the convective PBL.

### 3 Results

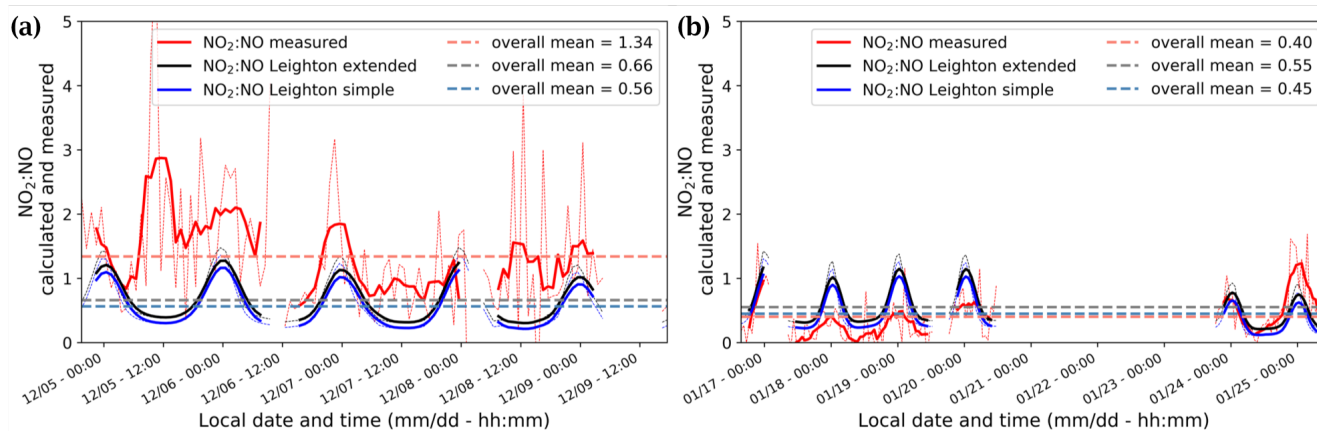

Both  $NO_2$  and  $NO$  exhibited diurnal variations, with highest concentrations in the afternoon and evening and lowest concentrations in the mid-morning to noon (Fig. 5), in association with the collapse and rise of the polar boundary layer (PBL) (Legrand et al., 2009; Frey et al., 2013, 2015). Generally, the rise and fall in  $NO_2$  lagged behind the  $NO$  peak by 4–6 hours. As a result, the  $NO_2:NO$  ratio had less diurnal amplitude than either  $NO_2$  or  $NO$ . Overall, the mean  $NO_2:NO$  ratio was  $1.3 \pm 1.1$  ( $1\sigma$ ) for December and  $0.4 \pm 0.4$  ( $1\sigma$ ) for January.

**Figure 5.** (top) Darkblue left-hand scale: mixing ratios (pptv) of  $NO_2$  (blue),  $NO$  (black) and  $NO_x$  (cyan) and red right-hand scale:  $NO_2:NO$  ratio. (bottom) Green left-hand scale: mixing ratio of  $O_3$  (ppbv) and orange right-hand scale:  $UV$  radiations ( $W m^{-2}$ ) measured with broadband radiometer, spectral range 305–385 nm. The signals are 6-hour running means (solid) on top of one hour means signals (dashed). Each day is marked with vertical black lines at 00:00 local time (LT).

The  $\text{NO}_2:\text{NO}$  ratios calculated from the extended and simple Leighton relationships (Eq. 1, 3) share similar diurnal patterns to the observed  $\text{NO}_2:\text{NO}$  ratios, but do not reflect the difference in mean value between December and January (Fig. 6). In  
 210 December, the observed  $\text{NO}_2:\text{NO}$  is systematically higher in the morning than the one estimated using simple and extended Leighton's equilibrium (Fig. 6a) while in January, it more closely matches the extended equilibrium estimations (Fig. 6b).

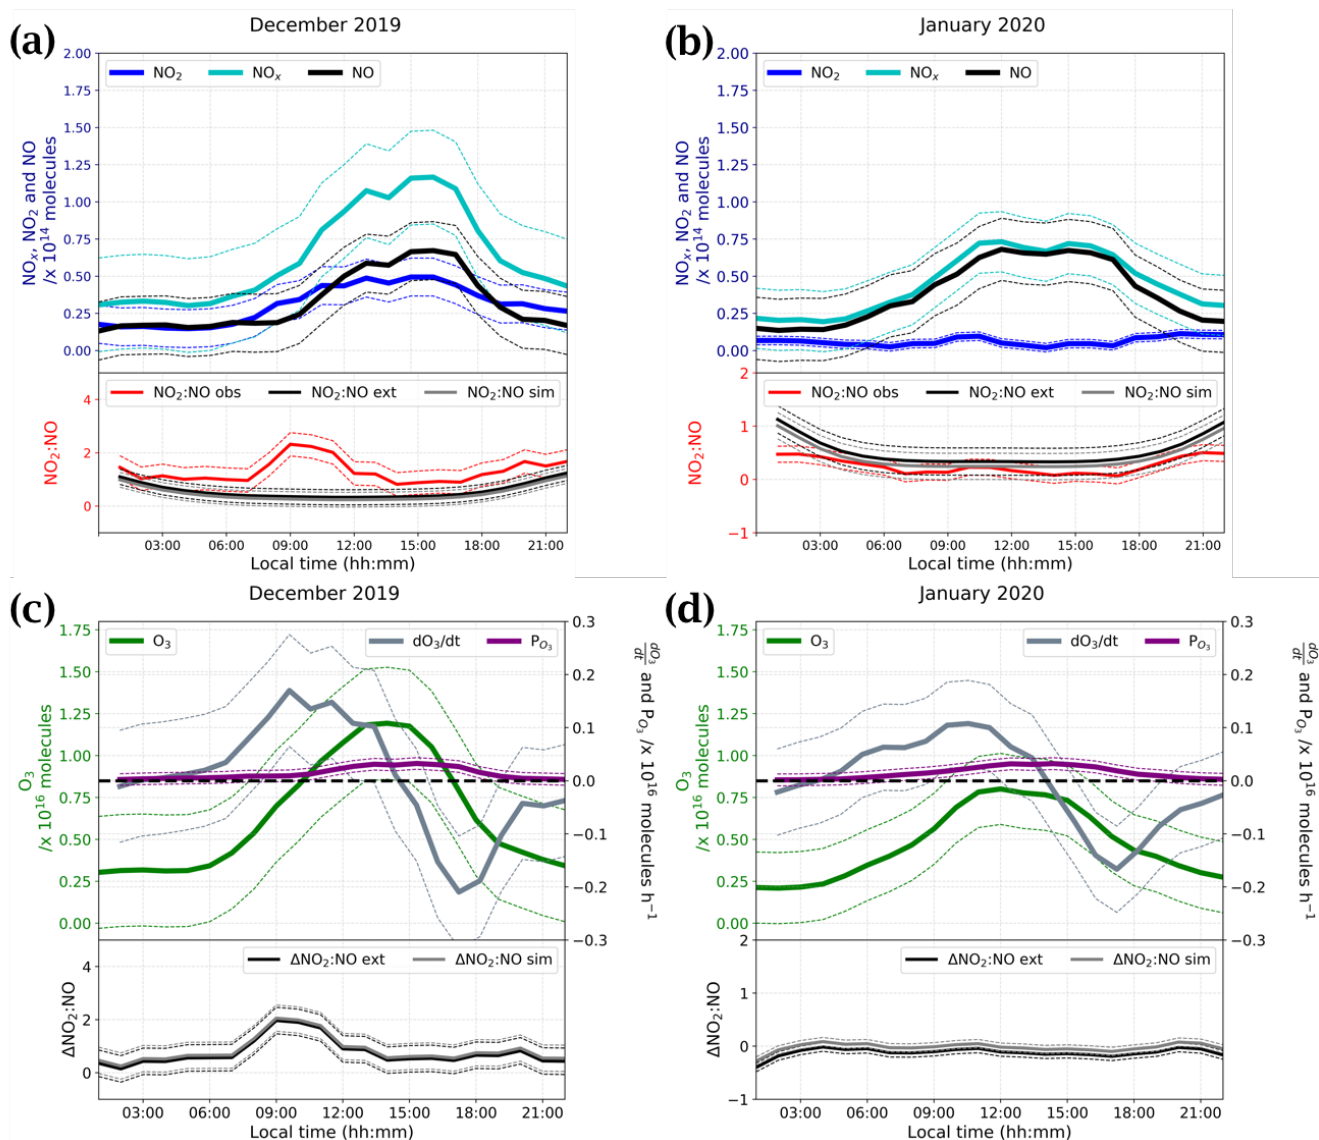

**Figure 6.**  $\text{NO}_2:\text{NO}$  ratios measured (red) and estimated from Eq. 1 (blue) and Eq. 3 (black) for both observation periods: December (a) and January (b). Solid lines represent the 6-hour running mean smoothed signals.

We observed a dramatic loss of  $\text{O}_3$  at the end of the measurement period, with the mean mixing ratio dropping from  $29.8 \pm 3.6$  ppbv in 16–20 January to  $14.3 \pm 0.8$  ppbv in 23–25 January. HYSPLIT 5-day backward trajectories between 14:00 and 20:00 local time (LT) on 23 January (Appendix A2) reveal that the air mass over Dome C originated from the east coast of  
 215 Antarctica, and this could explain the 10 ppbv drop of  $\text{O}_3$  observed between the two January periods shown in Figure 5. It is therefore possible that this air mass was partially affected by marine influences, as Legrand et al. (2009, 2016) concluded that  $\text{O}_3$  mixing ratios below 20 ppbv were observed when the air masses spent at least one day above the ocean during the previous five days. As a result, we excluded the 23–25 January data from the following discussions. Top panels of Figure 7a and 7b show daily averaged of  $N_{\text{NO}_x}$  (cyan),  $N_{\text{NO}}$  (black), and  $N_{\text{NO}_2}$  (blue), total number of molecules (Eq. 4) of each species  
 220 for both observation periods, December 2019 (Fig. 7a) and January 2020 (Fig. 7b) to cancel the PBL dynamic, as explained in Section 2.4. The  $\text{NO}_2:\text{NO}$  ratios observed (red) in comparison with the theoretical  $\text{NO}_2:\text{NO}$  calculated from Equation 1 ( $\text{NO}_2:\text{NO}$  simple, grey) and Equation 3 ( $\text{NO}_2:\text{NO}$  extended, black) are reported in the lower panels of Figure 7a and 7b. With the objective of testing the consistency of the observed  $\text{NO}_2:\text{NO}$  ratios with ozone production and destruction, we also reported the total number of  $\text{O}_3$  molecules in a column of  $1 \text{ cm} \times 1 \text{ cm} \times 1 H_{\text{PBL}}$  [cm] (green, left-hand scale), Figure 7c and 7d,  
 225 with its variation over time,  $\frac{d\text{O}_3}{dt}$  in molecules  $\text{h}^{-1}$  (blue-gray, right-hand scale). Production of ozone,  $P_{\text{O}_3}$  [molecules  $\text{h}^{-1}$ ], calculated as the  $\text{NO}_2$  production rate from the reaction  $\text{RO}_2 + \text{NO} \rightarrow \text{NO}_2 + \text{RO}$  and  $\text{HO}_2 + \text{NO} \rightarrow \text{NO}_2 + \text{OH}$ , as reported by Kukui et al. (2014), is calculated following Equation 5 and reported in violet in Figure 7c and 7d.

$$P_{\text{O}_3} = (k_{\text{RO}_2+\text{NO}}[\text{RO}_2] + k_{\text{HO}_2+\text{NO}}[\text{HO}_2]) \times [\text{NO}] \times V \quad (5)$$

with  $k_{RO_2+NO}$  and  $k_{HO_2+NO}$  the kinetic rate coefficients of the reactions  $RO_2 + NO \rightarrow NO_2 + RO$  and  $HO_2 + NO \rightarrow$   
230  $NO_2 + OH$ , respectively, expressed in  $\text{cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ ;  $[RO_2]$  and  $[HO_2]$ , the species concentrations expressed in  
molecule  $\text{cm}^{-3}$  and derived from the correlation between  $J_{NO_2}$  and  $[RO_2]$  and the  $\frac{[RO_2]}{[HO_2]}$  ratio (Kukui et al., 2014);  $[NO]$  the  
concentration of NO expressed in molecule  $\text{cm}^{-3}$ ; and  $V$  the arbitrary volume expressed as  $1 \text{ cm} \times 1 \text{ cm} \times H_{PBL}$  cm with  
 $H_{PBL}$ , given by the MAR regional model (see Appendix F for details). The overall daily mean  $\frac{P_{O_3}}{V}$  calculated for this study  
( $\approx 0.22 \text{ ppbv h}^{-1}$ ) is close to the  $0.3 \text{ ppbv h}^{-1}$  calculated by Kukui et al. (2014) and to the  $0.2 \text{ ppbv h}^{-1}$  derived from the  
235 study of the ozone diurnal concentration by Legrand et al. (2009). In the lower panels of Figure 7c and 7d are reported the  
deviations of the observed ratio ( $NO_2:NO_{obs}$ ) from the simple and extended Leighton's equilibria,  $\Delta NO_2:NO_{sim} = NO_2:NO_{obs}$   
-  $NO_2:NO_{sim}$  and  $\Delta NO_2:NO_{ext} = NO_2:NO_{obs} - NO_2:NO_{ext}$ , for each period, respectively. Looking at Figure 7a and 7b, the  
 $NO_x$ , NO, and  $NO_2$  peaks are now more in phase with the variability of the  $UV$  radiation. The total number of NO molecules  
and their diurnal variability appear constant from December to January with a maximum from 11:00 to 17:00 LT.  $NO_2$  shows  
240 a similar trend in December with a maximum from 10:00 to 18:00 LT, while in January, the total number of  $NO_2$  molecules in  
the atmospheric boundary layer is somewhat constant during the day, with a slight increase from 09:00 to 12:00 LT.

**Figure 7.** (a) and (b) 3-hour running mean (solid lines)  $\pm 1\sigma$  (thin dashed lines) of the diurnal cycles of  $\text{NO}$  (black),  $\text{NO}_x$  (cyan) and  $\text{NO}_2$  (blue) total number of molecules in a column of  $1 \text{ cm} \times 1 \text{ cm} \times 1 H_{PBL}$  [cm] (top panels) and  $\text{NO}_2:\text{NO}$  ratios (bottom panels) observed (red) and equilibrium's calculations (simple Leighton in grey /extended Leighton in black) for December and January, respectively. (c) and (d) top panels represent the 3-hour running mean (solid lines)  $\pm 1\sigma$  (thin dashed lines) of the diurnal cycle of the total number of ozone molecules in a column of  $1 \text{ cm} \times 1 \text{ cm} \times 1 H_{PBL}$  [cm] (green), the  $\text{O}_3$  variations,  $\frac{d\text{O}_3}{dt}$ , in molecules  $\text{h}^{-1}$  (grey) and the ozone production,  $P_{\text{O}_3}$  (violet) in molecules  $\text{h}^{-1}$  calculated from the total number of  $\text{RO}_2$  and  $\text{NO}$  molecules; the bottom panels represent the differences between  $\text{NO}_2:\text{NO}$  observed and  $\text{NO}_2:\text{NO}$  calculated,  $\Delta\text{NO}_2:\text{NO}_{sim}$  in grey for simple Leighton and  $\Delta\text{NO}_2:\text{NO}_{ext}$  in black for extended Leighton.

## 4 Discussion

### 4.1 What is driving the observed patterns?

In December, the  $\text{NO}_2:\text{NO}$  is above the  $\text{NO}_2:\text{NO}$  predicted by Leighton's equilibria (simple and extended) with a peak in the morning, from 07:00 to 12:00 LT, but approaches equilibrium from noon onwards, inversely following the ozone signal. In January, it is following quite well the equilibrium except during nighttime, when it is approximately half the predicted value calculated at steady-state. The  $\text{O}_3$  variations measured in our study  $\frac{d\text{O}_3}{dt}$  show significant differences with the ozone production  $P_{\text{O}_3}$  calculated using  $\text{RO}_2$ ,  $\text{HO}_2$  and  $\text{NO}$  concentrations.  $P_{\text{O}_3}$  from Figure 7c and 7d, shows not only a factor 10 difference with the  $\text{O}_3$  daily variations, but a rather different behavior as well. Indeed, using  $\text{RO}_2$ ,  $\text{HO}_2$  and  $\text{NO}$  concentrations,  $\text{O}_3$  appears to be gradually produced, following the  $UV$  radiation, with a maximum production in the afternoon, from approximately 12:00 to 16:00 LT. However, this calculated production is largely insufficient to explain the observed variability of  $\text{O}_3$ . Observations show ozone production, (i.e., values above the dashed bold black line in Fig. 7), from around 02:00 to 14:00 LT, with the maximum reached at 11:00 (local solar noon) and destruction of ozone, (i.e., values under the dashed black line in Fig. 7), from 14:00 to midnight (LT), with the maximum consumption around 17:00 – 18:00 LT. While Legrand et al. (2009) attributed this behavior to the variability of the PBL, here, its impact is accounted for through the observation of a total number of molecules in a column within the boundary layer height. Therefore, the dynamic of the PBL is not the only explanation for the  $\text{O}_3$  variability and local chemical reactions play an important role in the diurnal  $\text{O}_3$  behavior. Even though the deviation ( $\Delta\text{NO}_2:\text{NO}$ ) from Leighton's equilibria is always positive, at those levels of  $\text{O}_3$ , a deviation of  $\Delta\text{NO}_2:\text{NO} = 0.5$  from steady-state might not be enough to maintain an  $\text{O}_3$  production (Fig. 7c). Additionally, the  $\Delta\text{NO}_2:\text{NO}$  peak in December is slightly shifted with respect to the  $\frac{d\text{O}_3}{dt}$  (Fig. 7c). This shift is explained by the chemical lifetime of the species.  $\text{NO}_2$  lifetime,  $\tau_{\text{NO}_2} = \frac{1}{J_{\text{NO}_2}}$  is varying from  $\approx 6$  min at 00:00 LT to  $\approx 1$  min at 11:00 LT, largely inferior to  $\text{O}_3$  chemical lifetime. Legrand et al. (2016) show that the main sink of  $\text{O}_3$  is the  $\text{HO}_2$  radical, therefore, driving its lifetime:  $\tau_{\text{O}_3} = \frac{1}{k_{\text{HO}_2+\text{NO}}[\text{HO}_2]}$  is varying from  $\approx 2$  years at 00:00 LT to  $\approx 0.4$  year at 11:00 LT. However, the  $\text{O}_3$  dry deposition was not considered in the  $P_{\text{O}_3}$  calculation. The  $\text{NO}_2:\text{NO}$  ratio seems to follow Leighton's equilibrium in January and since the  $\text{NO}$  trend remains the same between the two observation periods, it highlights the necessity of an additional primary source of  $\text{NO}_2$  other than the conversion of  $\text{NO}$  to  $\text{NO}_2$  by reactions with  $\text{O}_3$  and radicals as shown in Figure 1. Additionally, in January, the seemingly extended Leighton's equilibrium cannot explain the  $\text{O}_3$  loss observed from the  $\frac{d\text{O}_3}{dt}$  signal. The chemical lifetime of  $\text{O}_3$  with respect to its photolysis,  $\tau_{\text{O}_3} = \frac{1}{J_{\text{O}_3}}$ ,  $J_{\text{O}_3}$  reconstructed from the MetCon instrument, is estimated to be ranging from 7 hours to several days. Another sink of  $\text{O}_3$ , with chemical lifetime closer to  $\tau_{\text{NO}_2}$  is necessary to explain the  $\text{O}_3$  loss observed for both periods. In an attempt to explain the large  $\text{NO}_2$  excess observed at maximum sunlight in December, the  $\text{NO}_x$  snow-source is studied in light of the conclusions given in Barbero et al. (2021), where Flux chambers experiments carried out from December 10<sup>th</sup> to January 7<sup>th</sup> during the 2019–2020 campaign at Dome C, Antarctica suggested that the photolyzable nitrate present in the snow acts as a uniform source with similar photochemical characteristics and a robust average daily photolysis rate coefficient  $J_{\text{NO}_3^-}$  of  $(2.37 \pm 0.35) \times 10^{-8} \text{ s}^{-1}$  ( $1\sigma$ ) was estimated for the Antarctic Plateau photic zone (0–50 cm layer).

## 275 4.2 Comparison with previous studies

Previous studies as part of the NITEDC and OPALE missions estimated the  $\text{NO}_2:\text{NO}$  ratio at Dome C on the East Antarctic Plateau, and we can compare these estimates to our field observed data (Table 1). In this work, an average mixing ratio of  $158 \pm 68$  pptv ( $1\sigma$ ) was measured for NO during the December observation period, which is similar to the mixing ratios of  $169 \pm 115$  pptv and  $146 \pm 63$  pptv reported from the NITEDC and OPALE campaigns for a similar period (Frey et al., 2013, 2015).  
 280 However, levels of  $\text{NO}_x$  and  $\text{NO}_2$  from NITEDC and OPALE were  $\approx 30\%$  greater than that measured in this study (Table 1), and as a result, their  $\text{NO}_2:\text{NO}$  ratios are similarly greater than our ratio. For January, we found an average NO mixing ratio of  $188 \pm 63$  pptv ( $1\sigma$ ), and this is almost 2.5 times what Frey et al. (2013) measured ( $80 \pm 62$  pptv) in January 2010. Moreover, during the OPALE campaign, Frey et al. (2015) measured  $\approx 6$  times less NO but similar  $\text{NO}_2$  mixing ratios, leading to a high  $\text{NO}_2:\text{NO}$  of  $1.7 \pm 6.4$  relative to our ratio of  $0.3 \pm 0.3$ . The NITEDC results suggested that either an unknown process  
 285 enhancing  $\text{NO}_2$  was taking place at Dome C, or that peroxy and other radicals would be significantly higher than elsewhere in Antarctica.

**Table 1.** NO,  $\text{NO}_2$  and  $\text{NO}_x$  mixing ratios (pptv) and  $\text{NO}_2:\text{NO}$  ratios measured at Dome C during this campaign, in comparison with previous NITEDC and OPALE campaigns for similar periods (periods averages).

<sup>a</sup> From Frey et al. (2013)

<sup>b</sup> From Frey (2021)

While differences in atmospheric dynamics and snow cover during the different campaigns could explain the discrepancy observed in December and January, where "atmospheric composition above the East Antarctic plateau depends not only on atmospheric mixing but also critically on  $\text{NO}_3^-$  concentration and availability to photolysis in surface snow as well as incident  
 290 UV irradiance", as explained in Frey et al. (2015); it may also be due to different detection techniques being used. For NITEDC and OPALE (Frey et al., 2013, 2015),  $\text{NO}_x$  was measured with a 2-channel chemiluminescence detector (CLD), based on the reaction of NO with excess  $\text{O}_3$  to produce  $\text{NO}_2$ . One channel was dedicated to NO and the other to  $\text{NO}_x$ , atmospheric  $\text{NO}_2$  concentrations were then calculated as the signal difference between those two channels (Bauguitte et al., 2012). In our study,  $\text{NO}_2$  is measured directly by the IBBCEAS. However, the NO measurement is made indirectly through the detection of  $\text{NO}_x$   
 295 after quantitative conversion of all ambient NO to  $\text{NO}_2$  via  $\text{NO} + \text{O}_3 \rightarrow \text{NO}_2 + \text{O}_2$ , in a way, it is the opposite of what is done in the CLD technique. The possible interferences on  $\text{NO}_2$  measurements from the presence of high  $\text{O}_3$  levels are discussed in Barbero et al. (2020), as several reactions could be triggered at elevated  $\text{O}_3$  concentrations, as discussed in Section 2.2.1. The discrepancies observed between the IBBCEAS measurements and the previous CLD measurements could be explained by

positive and negative interferences on the CLD technique. Indeed, the indirect measurement of  $\text{NO}_2$  by the CLD may suffer  
300 from interferences due to the presence of other gaseous species, such as HONO and  $\text{HO}_2\text{NO}_2$ , in the inlet lines which will be  
then photolytically converted. Reed et al. (2016) suggested that measurements of  $\text{NO}_2$  using CLD systems may be significantly  
biased in low- $\text{NO}_x$  environments, especially in pristine environments, such as Dome C, where the  $\text{NO}_y$  to  $\text{NO}_x$  ratio may be  
high. The thermal decomposition of  $\text{NO}_y$  species within the  $\text{NO}_2$  converter can produce unreasonably high measurements.  
Additionally, the photolytic conversion unit of the CLD instrument used in previous campaigns was at  $30^\circ\text{C}$ , therefore the  
305 thermal decomposition of  $\text{HO}_2\text{NO}_2$  could indeed be an important source of interference. Frey et al. (2013, 2015) discussed this  
possible interference and estimated it to 8-16 % of the average  $\text{NO}_2$  measurement at 1 m from the snowpack. This interference  
might indeed partially explain the higher  $\text{NO}_2:\text{NO}$  ratio observed during previous campaigns in respect to our study.

### 4.3 Presence of halogenated radicals

During the OPALE campaign, bromine oxide (BrO) column amounts were measured using a ground base UV-visible spec-  
310 trometer (MAX-DOAS, Roscoe et al. (2014)). After a complex analysis of the spectra, Frey et al. (2015) estimated a BrO  
median daily value of 2-3 pptv near the surface at Dome C. Additionally, Schönhardt et al. (2012) observed via satellite the  
presence of BrO and IO over Antarctica. However, the monthly maps of IO vertical column amounts (Fig. 4 of the study) show  
the presence of IO in the Antarctic Plateau late in spring (September-October) around  $1.0$  to  $1.5 \times 10^{12}$  molecules  $\text{cm}^{-2}$ . In  
contrast, in summer, they found a column amount of IO below the limit of detection, i.e. below 0.7 pptv once converting the  
315 column amount to volume mixing ratio (satellite observations averaged over six subsequent years 2004-2009) (Schönhardt  
et al., 2008). Vertical concentrations of BrO were found to be similar between December and January, ranging from  $6.0 \times$   
 $10^{13}$  to  $7.0 \times 10^{13}$  molecules  $\text{cm}^{-2}$  (Fig. 5 of the 2012 Schönhardt et al. study). To our knowledge, there are no reports of  
near-surface ClO measurement in Antarctica. The reactions  $\text{NO} + \text{XO} \rightarrow \text{NO}_2 + \text{X}$  ( $\text{X} \equiv \text{Br, I or Cl}$ ) show very similar  
reactions rate coefficients. Therefore, we consider here an average of all halogenated radicals XO to have a daily average rate  
320 coefficient of  $(2.5 \pm 0.4) \times 10^{-11}$   $\text{cm}^3$  molecules $^{-1}$  s $^{-1}$ . The necessary amount of XO to reach steady-state in December was  
calculated following Equation 6:

$$\text{NO}_2 : \text{NO} = \frac{k_{\text{NO}+\text{O}_3}[\text{O}_3] + k_{\text{NO}+\text{HO}_2}[\text{HO}_2] + k_{\text{NO}+\text{CH}_3\text{O}_2}[\text{CH}_3\text{O}_2] + k_{\text{NO}+\text{XO}}[\text{XO}]}{J_{\text{NO}_2}} \quad (6)$$

which is rearranged and simplified to Equation 7:

$$[\text{XO}] = \Delta\text{NO}_2 : \text{NO} \left( \frac{J_{\text{NO}_2}}{k_{\text{NO}+\text{XO}}} \right) \quad (7)$$

325 Daily mean average of XO of 17 pptv were estimated, with a peak of 64 pptv at 11:00 LT. If such high levels of XO were  
present, they would have been detected by Frey et al. (2015) MAX-DOAS as XO is suspected to be mainly BrO at Dome C.  
Additionally, such high levels of XO would induce a fast destruction of  $\text{O}_3$ , which was not observed either, and last, NO levels  
should have been lower in December than in January. Therefore, the assumption of an additional conversion of NO to  $\text{NO}_2$   
through XO or  $\text{RO}_x$  seems insufficient to explain the observations, and only the increased production of  $\text{NO}_2$  from primary  
330 sources of  $\text{NO}_2$  by a factor of two may justify the  $\text{NO}_2$  excess observed in December and not in January. In the following

sections, the  $\text{NO}_x$  snow-source is studied in the light of the conclusions of Barbero et al. (2021), where dynamic flux chamber experiments allowed a new parameterization of the snow nitrate photolysis occurring at Dome C.

#### 4.4 $\text{NO}_2$ snow source

In Barbero et al. (2021), results of dynamic flux chamber experiments deployed on the Antarctic Plateau at Dome C are presented. A nitrate daily average photolysis rate constant,  $J_{\text{NO}_3^-} = (2.37 \pm 0.35) \times 10^{-8} \text{ s}^{-1}$  for all different snow samples (depth and location) of the Antarctic Plateau (from the 10<sup>th</sup> of December to the 07<sup>th</sup> of January) is estimated. In the light of this new estimate, the  $\text{NO}_x$  snow-source is studied here to evaluate the  $\text{NO}_x$  fluxes,  $F_{\text{NO}_x}$  and  $\text{NO}_x$  production rate,  $P_{\text{NO}_x}$  in December and January using Equation 8:

$$F_{\text{NO}_x} = \int_z^0 J_{\text{NO}_3^-} [\text{NO}_3^-] dz \quad (8)$$

with  $[\text{NO}_3^-]$  the concentration of nitrate in molecules  $\text{cm}^{-3}$  of snow available in the photic zone, defined as  $z = -50 \text{ cm}$  (Erbland et al., 2013).

**Figure 8.** (a) Adjusted  $J_{\text{NO}_3^-} [\text{s}^{-1}]$  from December (red) and January (blue) estimated from Barbero et al. (2021), results. (b) Mean surface relative actinic flux,  $I_{act}$ , profile at 305 nm, calculated using the TARTES model (Libois et al., 2013, 2014). The actinic flux describes the number of photons incident at a point.

The nitrate photolysis rate coefficients were adjusted for the SZA variations, and corrective factors of 0.987 and 0.938 were found for December and January, respectively. At maximum sunlight, the  $J_{NO_3^-}$  is slightly lower in January than in December as the greater SZA in January lowers the maximum peak of  $UV$  radiation (Fig. 8a). Figure 8b shows the mean surface relative  $I_{act}$  profile over the photic zone extracted from the SBDART model, Libois et al. (2013, 2014), at 305 nm, the optimal wavelength for nitrate photolysis. The attenuation of  $J_{NO_3^-}$  in the photic zone is driven by the attenuation of the  $I_{act}(\lambda, \theta, z)$  as shown by Equation 9:

$$J_{NO_3^-}(\lambda) = \int_z^0 \sigma_{NO_3^-}(\lambda, T) \phi(T, pH) I_{act}(\lambda, \theta, z) dz \quad (9)$$

where  $\theta$  is the SZA ;  $\lambda$  [nm] is the wavelength ; and  $z$  [m] is the snowpack's depth ;  $\sigma_{NO_3^-}(\lambda, T)$  is the absorption cross-section of nitrate ;  $\phi(T, pH)$  and  $I_{act}(\lambda, \theta, z)$  are nitrate photolysis quantum yield and actinic flux, respectively.

#### 4.4.1 Surface snow

From Figure 8b, one can see that  $I_{act}$  attenuates quickly with depth in the snowpack following an exponential decrease. Thus, the first few millimeters of the snow column dominate the availability of photons for photochemical reactions in the  $UV$ . Nitrate concentration measurements on surface snow were performed on a regular basis and for several years at Dome C (NITEDC and CAPOXI programs). To reduce spatial and temporal variability, average surface concentration for periods corresponding to our atmospheric observations from samples taken at different locations in the clean area sector are used. The average nitrate concentration in surface snow (few mm) is  $991 \pm 341$  ppbw (parts per billion by weight or  $ng\ g^{-1}$  of snow) (median 931 - 70 samples) in December and  $588 \pm 248$  ppbw (median 558 - 65 samples) in January, respectively. This  $\approx 40\%$  difference between December and January at the surface of the snowpack is significantly large. Considering Equation 8 with a negligible  $dz$  for surface snow samples, we estimated the  $NO_x$  fluxes [ $molecules\ cm^{-2}\ s^{-1}$ ] from the snow surface source and converted it into a production rate in  $molecules\ cm^{-3}\ h^{-1}$  using the PBL height (cm). This production was then converted into pptv  $h^{-1}$  using atmospheric pressure,  $P$  [hPa], and temperature,  $T$  [K]. Additionally, the mean surface relative  $I_{act}$  profile shows an enhancement of the actinic flux in the very first mm of snow (Fig 8b), therefore, we multiplied the results by an enhancement factor of 5. Figure 9 pictures the estimated  $P_{NO_x}$  [pptv  $h^{-1}$ ] from the surface snow for both periods. Because of the difference in nitrate in the surface snow, we estimated a mean ratio of  $1.92 \pm 0.33$  in the  $NO_x$  production between December and January (Fig. 9 - black curve on the right-hand scale). It is worth noticing that factor up to 2.6 in the surface snow  $NO_x$  production between December and January could be reached in the early morning.

**Figure 9.** Left-hand scale: Estimated  $P_{NO_x}$  [ $\text{pptv h}^{-1}$ ] in a column of  $1 \text{ cm} \times 1 \text{ cm} \times H_{PBL} \text{ cm}$  from December (red) and January (blue). Right-hand scale, their ratio  $\frac{P_{NO_x-Dec}}{P_{NO_x-Jan}}$  (unitless).

#### 4.4.2 Snowpack

An automatic snow tower experiment (Helmig et al., 2020), allows continuous year-round  $NO_x$  and  $O_3$  measurements at  
370 different snow depths and heights above the snow surface, and this monitoring has been maintained since 2015 at the same  
location as our atmospheric observations (more information in Appendix C). However, due to technical problem with the  $NO_x$   
analyzer during the 2019-2020 campaign, only the  $O_3$  monitoring instrument was running. Figure 10 shows averaged 24 h  
 $NO_x$  mixing ratios in the interstitial air at -48 cm recorded in 2016-2017 for similar periods of time.

**Figure 10.** Averaged 24 h NO<sub>x</sub> mixing ratios measured in the interstitial air at -48 cm by the automatic snow tower experiment in 2016-2017 for similar periods as our atmospheric observations.

One can see that the NO<sub>x</sub> measured at -48 cm, the bottom part of the photic zone, is  $\approx 50\%$  times higher in December 2016 than in January 2017, strengthening the theory of a strong variability in the NO<sub>x</sub> snow-source during the photolytic season, with a depleted NO<sub>x</sub> reservoir toward the end of the light season. It is worth noticing that the NO<sub>3</sub><sup>-</sup> profiles are similar between the two seasons. Additionally, calculations based on the FC results are probably underestimating the actual NO<sub>x</sub> snow-source, as mentioned in Barbero et al. (2021). Indeed, as discussed in Frey et al. (2013), the observed night time increase in wind shear at Dome C (Fig. 2) likely causes enhanced upward ventilation of NO<sub>x</sub> that temporarily accumulated in the upper snow pack during very stable conditions. This analysis is strengthening the hypothesis of an enhanced NO<sub>2</sub> snow-source in December, when the additional NO<sub>2</sub> flux seems sufficient to explain the NO<sub>2</sub> surplus.

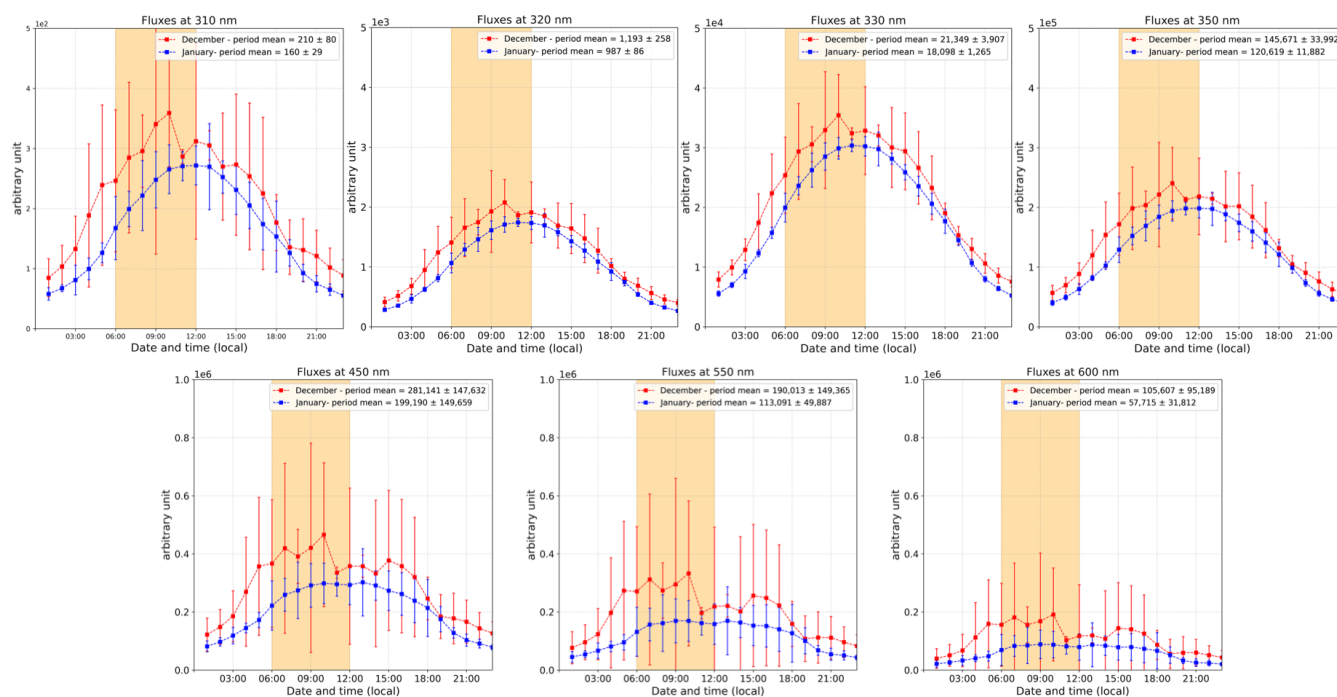

However, additional investigations on possible unidentified mechanisms or sinks of O<sub>3</sub>, are needed. Indeed, if the NO<sub>x</sub> snow-source might explain the differences between December and January in the NO<sub>x</sub> cycle, this does not support the observed O<sub>3</sub> variations. Halogenated radicals, such as iodine (IO) and bromine (BrO) probably play their part, although not significantly observed on the nitrogen oxides signal, but possibly explaining the behavior of the ozone signal. Indeed, very recently, Spolaor et al. (2021), observed a continuous decline since the 70s in the iodine concentration in ice-core samples from inner Antarctica. The study states that the enhanced UV radiation caused by the stratospheric ozone hole results in the increase of iodine re-

emissions from the snowpack. This ice-to-atmosphere iodine mass transfer could indeed explain the ozone behavior observed  
390 in the work presented here, as iodine catalytic cycles play a crucial role in the destruction of tropospheric ozone.

## 5 High sensitivity of the $\text{NO}_2:\text{NO}$ ratio to the sun's position

A possible reason to this productivity of the snowpack in the morning during the earlier phase of the photolysis season is  
the number of photons available, leading to higher rate of photolysis in December. Nitrate photolysis in snow occurs for  
wavelengths  $\lambda > 300$  nm (305 nm being the optimal wavelength). Measurements of solar *UV* spectral radiation have been  
395 continuously recorded at Concordia since 2007 as part of the Network for the Detection of Atmospheric Composition Change  
(NDACC). The instrument, SAOZ (Système d'Analyse par Observation Zenithal) is an *UV – Visible* (310-650 nm) diode  
array spectrometer, (1 nm resolution), looking at the scattered sunlight (Pommereau and Goutail, 1988; Kuttippurath et al.,  
2010).

**Figure 11.** 2-hour running  $\pm 1\sigma$  (error bars) of the period averaged diurnal cycles of relative radiation fluxes at different wavelengths (310, 320, 330, 350, 450, 550, and 600 nm) for both period (December and January). The yellow shaded area corresponds to the period where the  $\text{NO}_2:\text{NO}$  ratio is deviating from the steady-state equilibrium in December.

Figure 11 shows the relative radiation fluxes at different wavelengths in arbitrary unit. One can see that the relative radiation  
400 flux is systematically higher in December than in January, which could be expected as 18 days separate the first observation  
period to the summer solstice against 27 days for the second period. While this explains higher levels of  $\text{NO}_x$  due to more

photolysis activity in the snowpack in December than in January, it does not explain the early morning excess. Indeed, one can see in Figure 11 that the diurnal cycle of the radiation is somewhat symmetrical in January (in blue), while an asymmetry appears in December (in red). This is also visible while comparing the shape of the SZA for the two periods, with the difference  
405 between the two SZA cycles (black line in Figure 12), showing a bump in the morning between 06:00 and 12:00 with similar shape as the  $\text{NO}_2:\text{NO}$  deviation from equilibrium reported in Figure 7a. No different cloud cover during the two observation windows was experienced, therefore, the discontinuity in the sinusoidal shape of the radiation signal in December could be due to a smaller solar zenith angle at this latitude. Indeed, as shown in Figure 12, the difference between the SZA in January and in December,  $\Delta(\text{SZA}_{jan} - \text{SZA}_{dec})$  normalized to the December value to get percentages (black line Fig. 12), appears,  
410 indeed, higher (close to 5 %) in the morning, than during the rest of the day coinciding with the bump of  $UV$  and the  $\text{NO}_2:\text{NO}$  equilibrium deviation observed before.

**Figure 12.** (left-hand scale) 2-hour running  $\pm 1\sigma$  (error bars) of the period averaged diurnal cycles of SZA (Solar Zenith Angle) for both periods (December and January). The yellow shaded area corresponds to the period where the  $\text{NO}_2:\text{NO}$  ratio is deviating from the steady-state equilibrium in December. (right-hand scale) % difference between SZA in January and in December, normalized to the December value.

A rapid parameterization of the dependence of the  $\text{NO}_x$  production,  $P_{\text{NO}_x}$  [ $\text{pptv h}^{-1}$ ], to the position of the sun, SZA [ $^\circ$ ], has been established, taking as reference the SZA in December and keeping only the daily values (06:00 to 18:00 LT). Figure 13 shows the results of linear regressions for both periods, suggesting that it is possible to decipher the parameters linking the  
415  $\text{NO}_x$  production to the SZA. Indeed, satisfactory  $R^2$  (0.984 – December ; 0.727 - January) were found. Of course, this result

is only an approach and a thorough study of the  $\text{NO}_x$  production dependence to the sun's position would allow to improve existing models and reduce the uncertainties concerning the Antarctic nitrogen budget.

**Figure 13.** Correlations between the  $\text{NO}_x$  production and the  $\Delta(\text{SZA}_{jan} - \text{SZA}_{dec})$  normalized to the December value for both periods of atmospheric observations.

## 6 Conclusions

For the first time, direct and in-situ atmospheric measurements of  $\text{NO}_2$  were carried out in the Antarctic Plateau at Dome C. The summer variability of the  $\text{NO}_2:\text{NO}$  ratio was studied in light of this new set of observations. While the overall  $\text{NO}_2:\text{NO}$  ratio can be explained by the extended Leighton's relationship, a high  $\text{NO}_2:\text{NO}$  ratio was estimated in the morning during the early photolysis season, deviating from steady state equilibrium and not explained by the extended Leighton's relationship. The results of this study disagree with previous studies that found a systematic deviation from equilibrium, requiring around 50 pptv of halogenated radicals to explain such  $\text{NO}_2:\text{NO}$  ratio. However, the required levels of halogenated species were never observed at Dome C. While differences in atmospheric dynamics and snow cover during the different campaigns could explain the discrepancies with previous studies, it may also be due to different detection techniques being used. In our study,  $\text{NO}_2$  was measured directly for the first time at Dome C. Evaluation of the meteorological conditions and estimation of the  $\text{NO}_x$  snow-source tend to identify the  $\text{NO}_x$  snow source and the position of the sun, through SZA measurement, as the main actors of the atmospheric oxidative capacity in the Austral summer at Dome C. Indeed, it appears that a 5 % difference on the SZA

430 in the morning could lead to an excess up to 5 times the  $\text{NO}_2:\text{NO}$  ratio when at steady state. Such a high sensitivity of the  
 $\text{NO}_2:\text{NO}$  ratio to the sun position is of importance to the atmospheric chemistry models, where such a parameter can be better  
adjusted in the future. However, if the  $\text{NO}_x$  snow-source might explain the differences between December and January in the  
 $\text{NO}_x$  cycle, this does not match the observed  $\text{O}_3$  variations. Even though the depletion of the  $\text{NO}_x$  reservoir throughout the  
435 unidentified mechanisms or unidentified sinks of  $\text{O}_3$ , are needed to understand the  $\text{O}_3$  consumption. The link between the  
stratospheric ozone hole inducing an enhancement in the incident  $UV$  radiation, causing in return an increase in the ice-to-  
atmosphere iodine emissions has been established by Spolaor et al. (2021). Therefore, additional field campaigns targeting  
halogenated radicals' measurements in snow and troposphere in Antarctica are strongly needed in the near future to allow the  
scientific community to fully understand the mechanisms driving the oxidative capacity of the polar atmosphere.

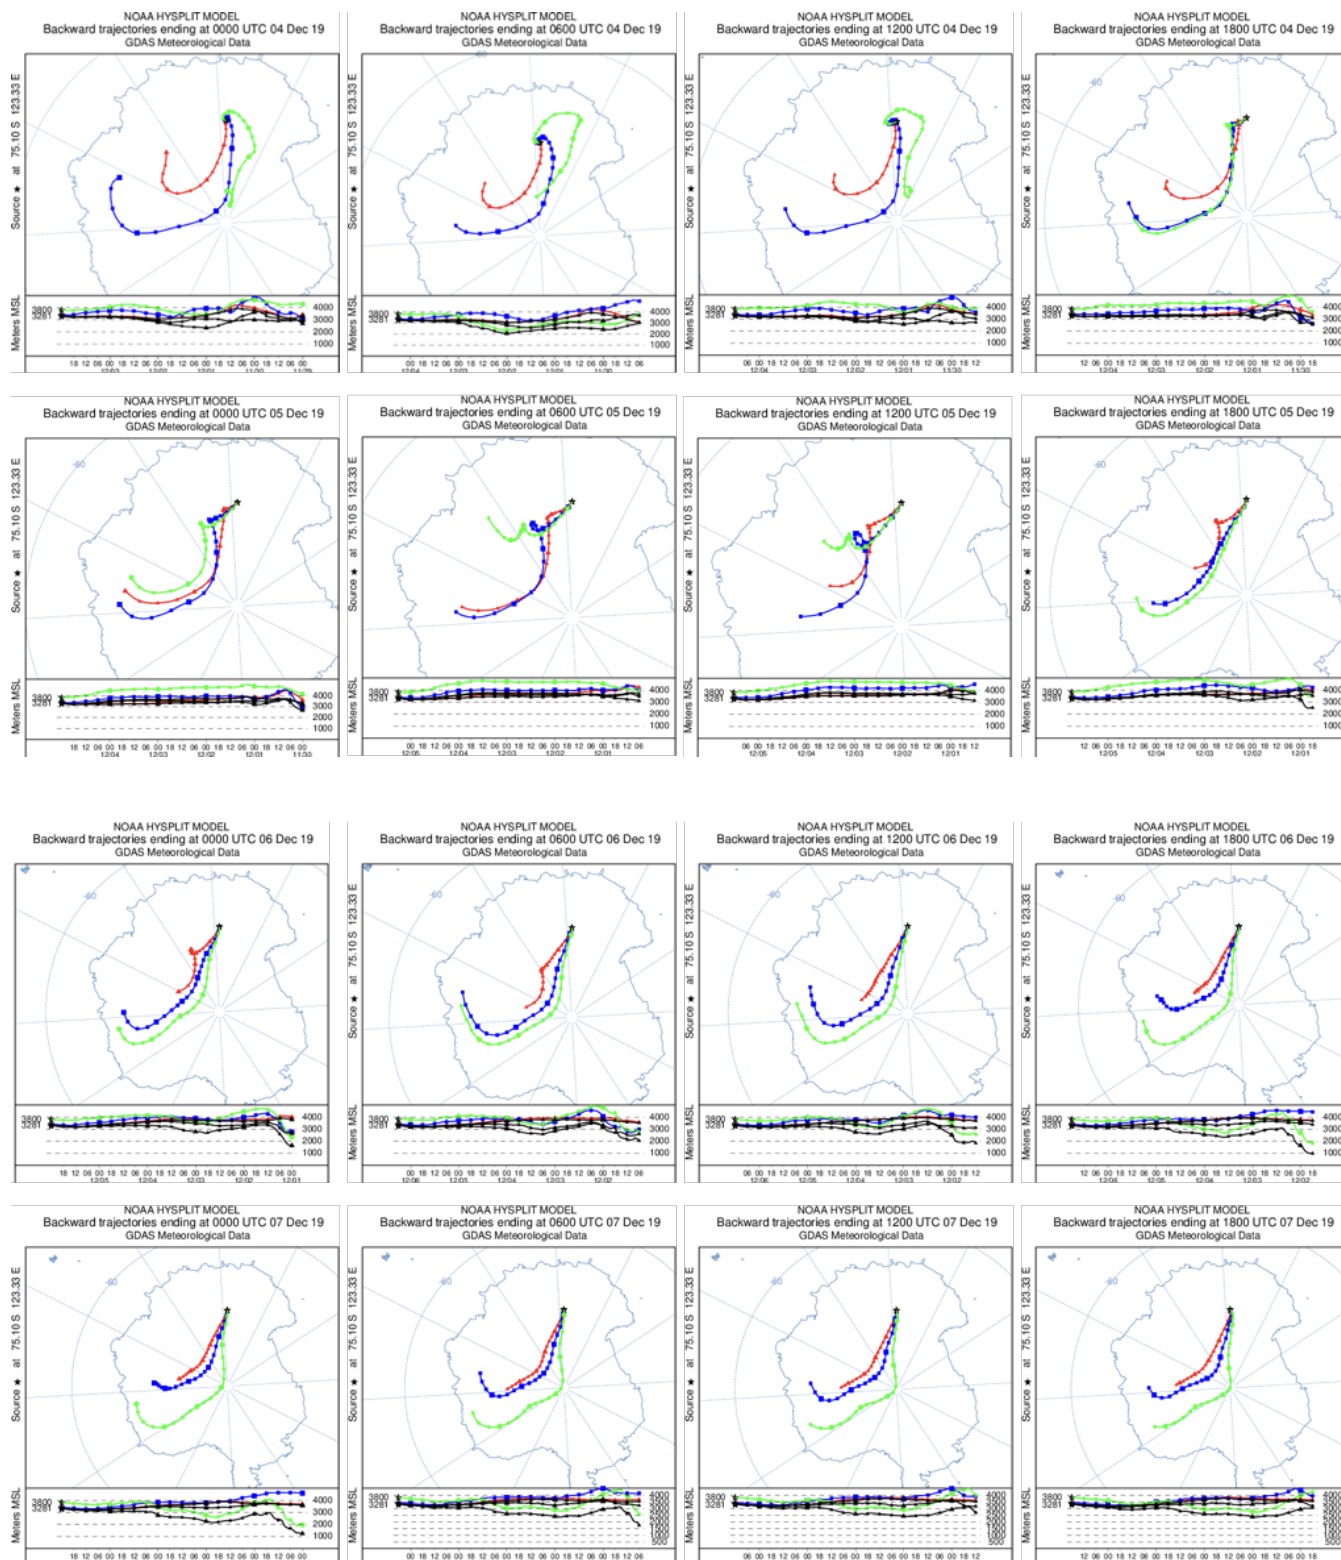

#### 440 **Appendix A: NOAA HYSPLIT backward trajectories reconstruction for the observation periods (Dome C is represented by the black star)**

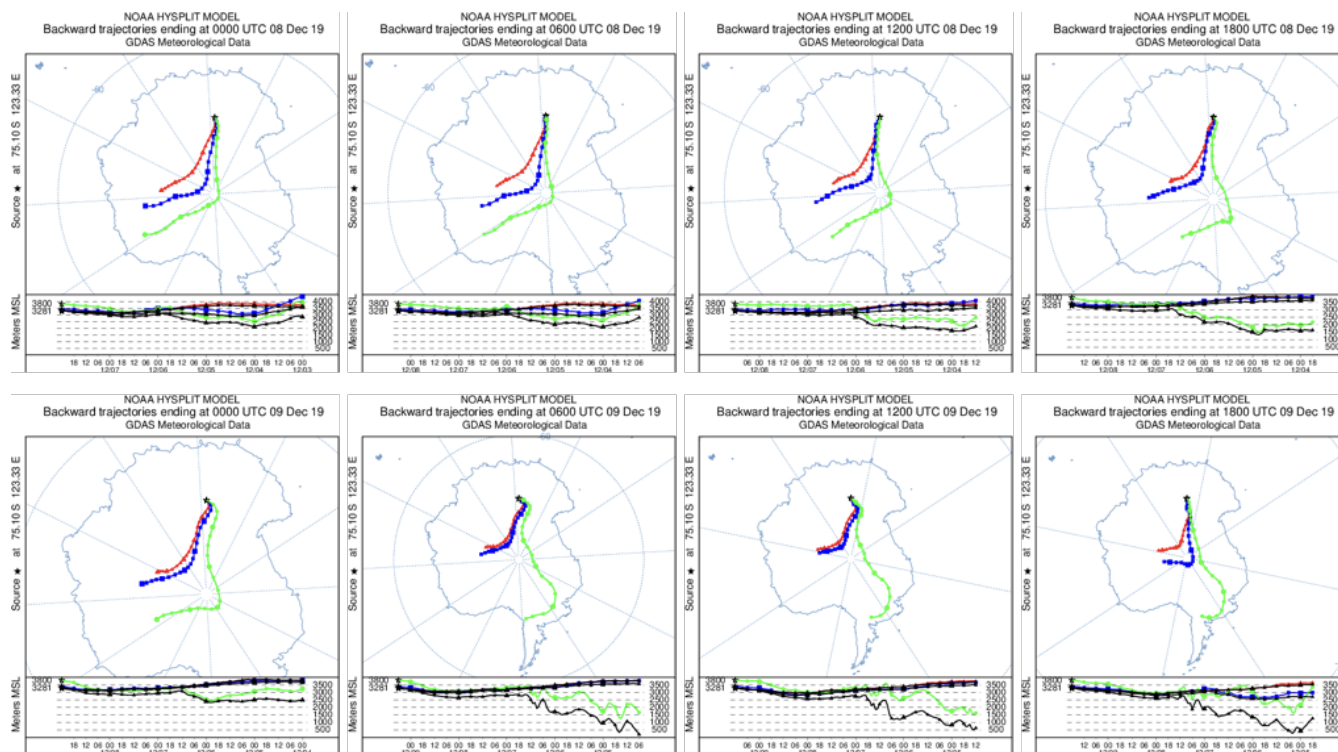

Using the HYSPLIT model, 5 days (120 hours) backward trajectories were conducted. For each, day of observation, 4 runs at  
different times (UTC): 00:00, 06:00, 12:00 and 18:00, therefore corresponding to 08:00, 14:00, 20:00 and 02:00 (day+1) local  
time (LT), at different altitudes: 3,200 a.m.s.l (above mean sea level); 3,400 a.m.s.l and 3,800 a.m.s.l.

#### 445 **A1 December**

As mentioned in Section 2.1 of the manuscript, the meteorological conditions and air masses origins in December were favor-  
able for atmospheric measurements for the purpose of our study. Indeed, one can see on Figure A1 that the air masses were  
originating from the Plateau during the observation period. The 9<sup>th</sup> of December at 14:00 LT, i.e., 06:00 UTC, air masses at  
3,800 a.m.s.l was simulated to be originating from the Antarctic Peninsula, but this had no impact on our observations as we  
450 stopped them around 10:00 LT.

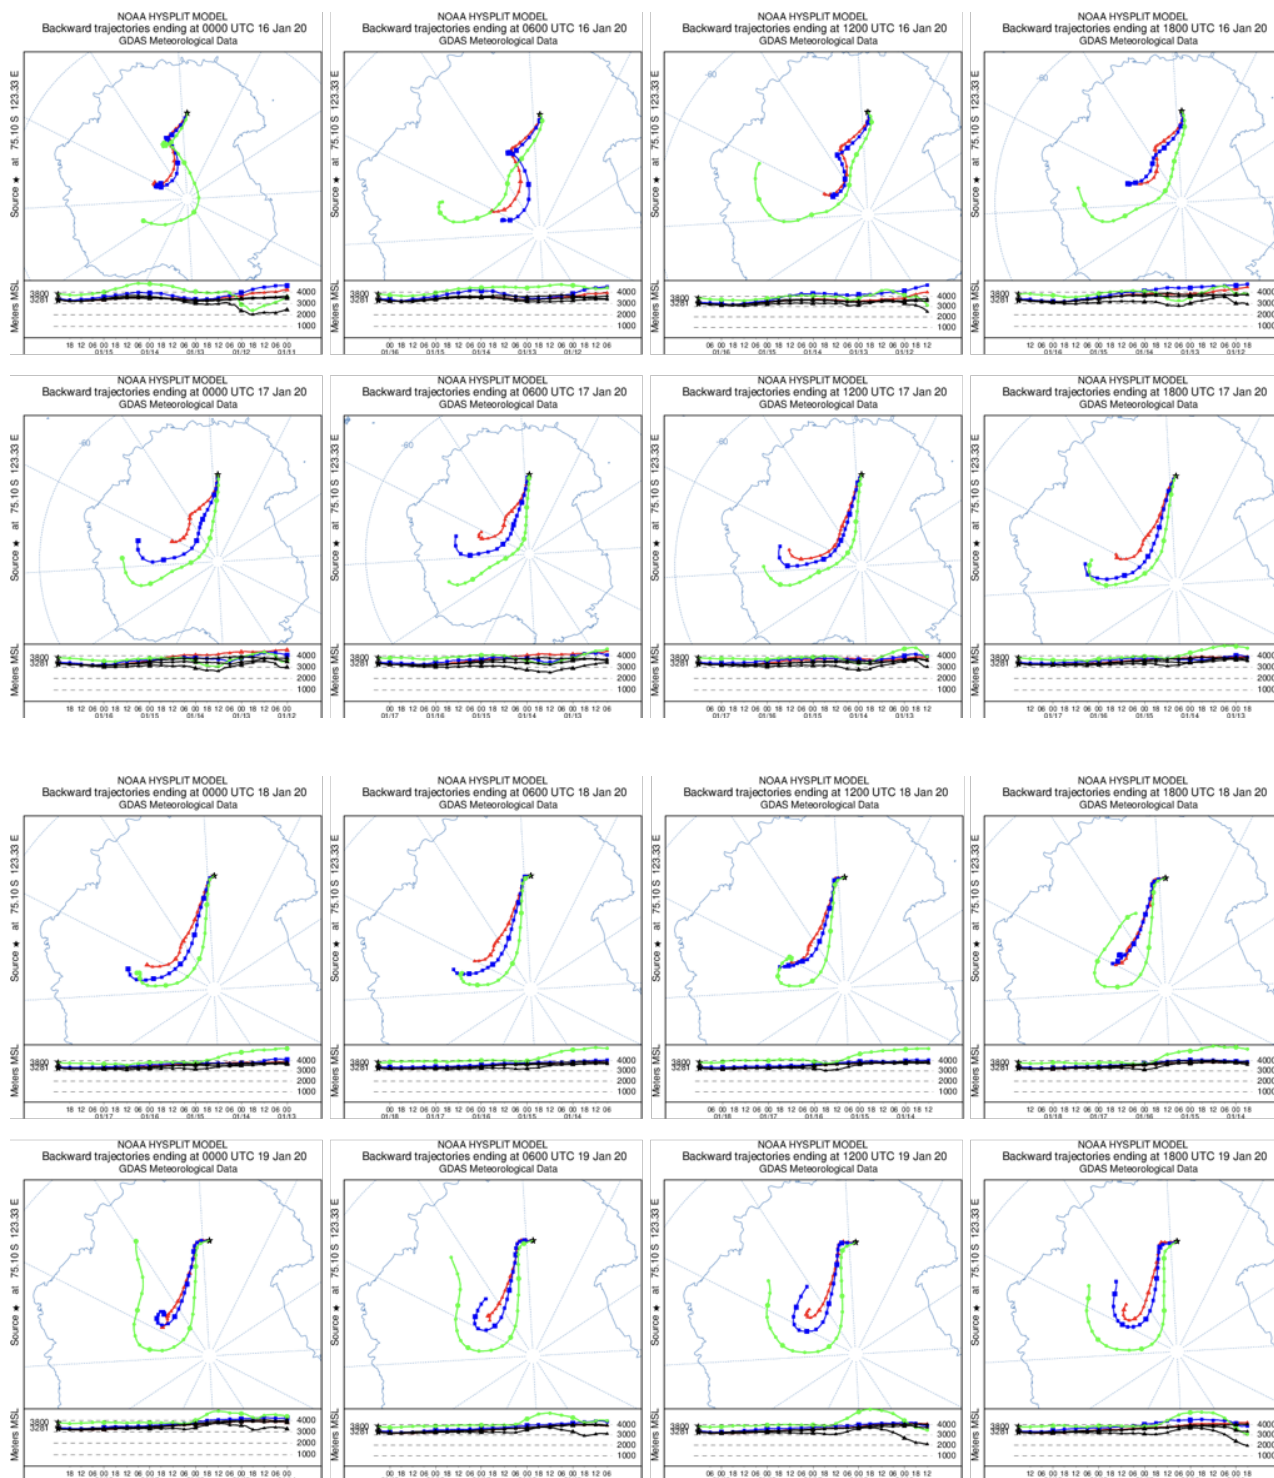

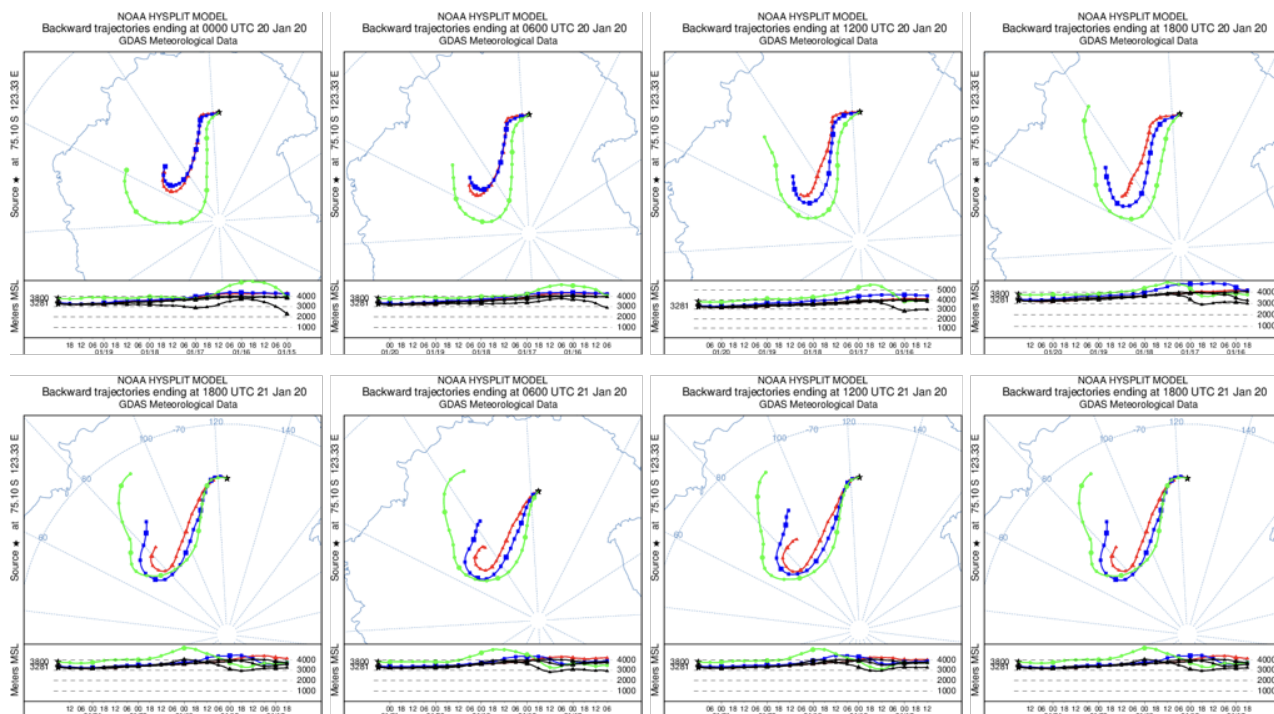

**Figure A1.** HYSPLIT 5 days backward trajectories from the 4<sup>th</sup> to the 9<sup>th</sup> of December 2019. The model was run every 6 hours for each day and at 3 different altitudes: 3,800 a.m.s.l (green), 3,400 a.m.s.l (blue) and 3,200 a.m.s.l (red).

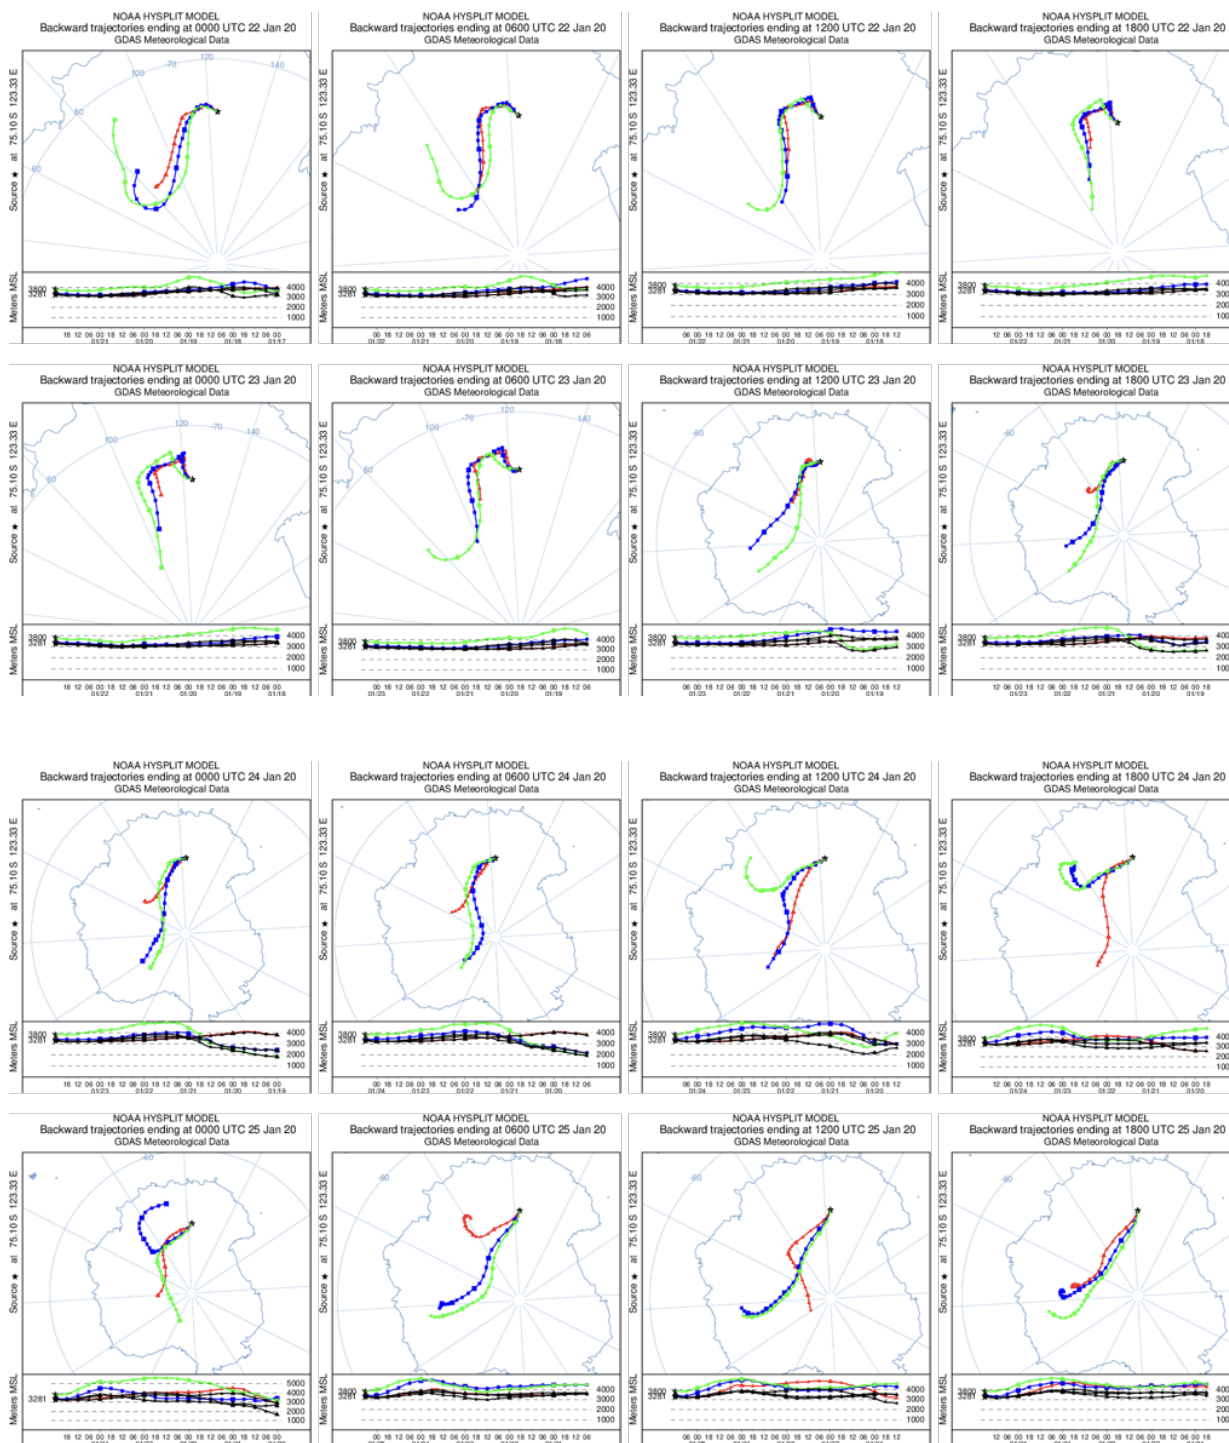

## A2 January

**Figure A2.** HYSPLIT 5 days backward trajectories from the 16<sup>th</sup> to the 21<sup>st</sup> of January 2020. The model was run every 6 hours for each day and at 3 different altitudes: 3,800 a.m.s.l (green), 3,400 a.m.s.l (blue) and 3,200 a.m.s.l (red).

As mentioned in Section 2.1, the meteorological conditions and air masses origins in January were favorable for atmospheric measurements from the 17<sup>th</sup> to the 20<sup>th</sup> of January (Fig. A2). However, the 10 ppbv drop of O<sub>3</sub> observed at the end of the observation period is suspected to be caused by oceanic inputs as suggested by Legrand et al. (2009). On Figure A3, a drastic change in the origin of the air masses is observed the 23<sup>rd</sup> between 06:00 (UTC) and 12:00 (UTC), or 14:00 and 20:00 LT, corresponding to the sudden drop in O<sub>3</sub> mixing ratio around 17:00-18:00 LT.

**Figure A3.** HYSPLIT 5 days backward trajectories from the 22<sup>nd</sup> to the 25<sup>th</sup> of January 2020. The model was run every 6 hours for each day and at 3 different altitudes: 3,800 a.m.s.l (green), 3,400 a.m.s.l (blue) and 3,200 a.m.s.l (red).

Figure A4 shows the HYSPLIT 10 days back trajectory estimation for the 23<sup>rd</sup> of January ending at 20:00 LT at Dome C. One can see that for the 3,400 a.m.s.l, the model predicts air masses coming from the east coast of Antarctica, strengthening our conclusions of an air mass influenced by the ocean reaching the Antarctic Plateau, leading to the 10 ppbv O<sub>3</sub> drop observed in the early evening of the 23<sup>rd</sup> of January 2020.

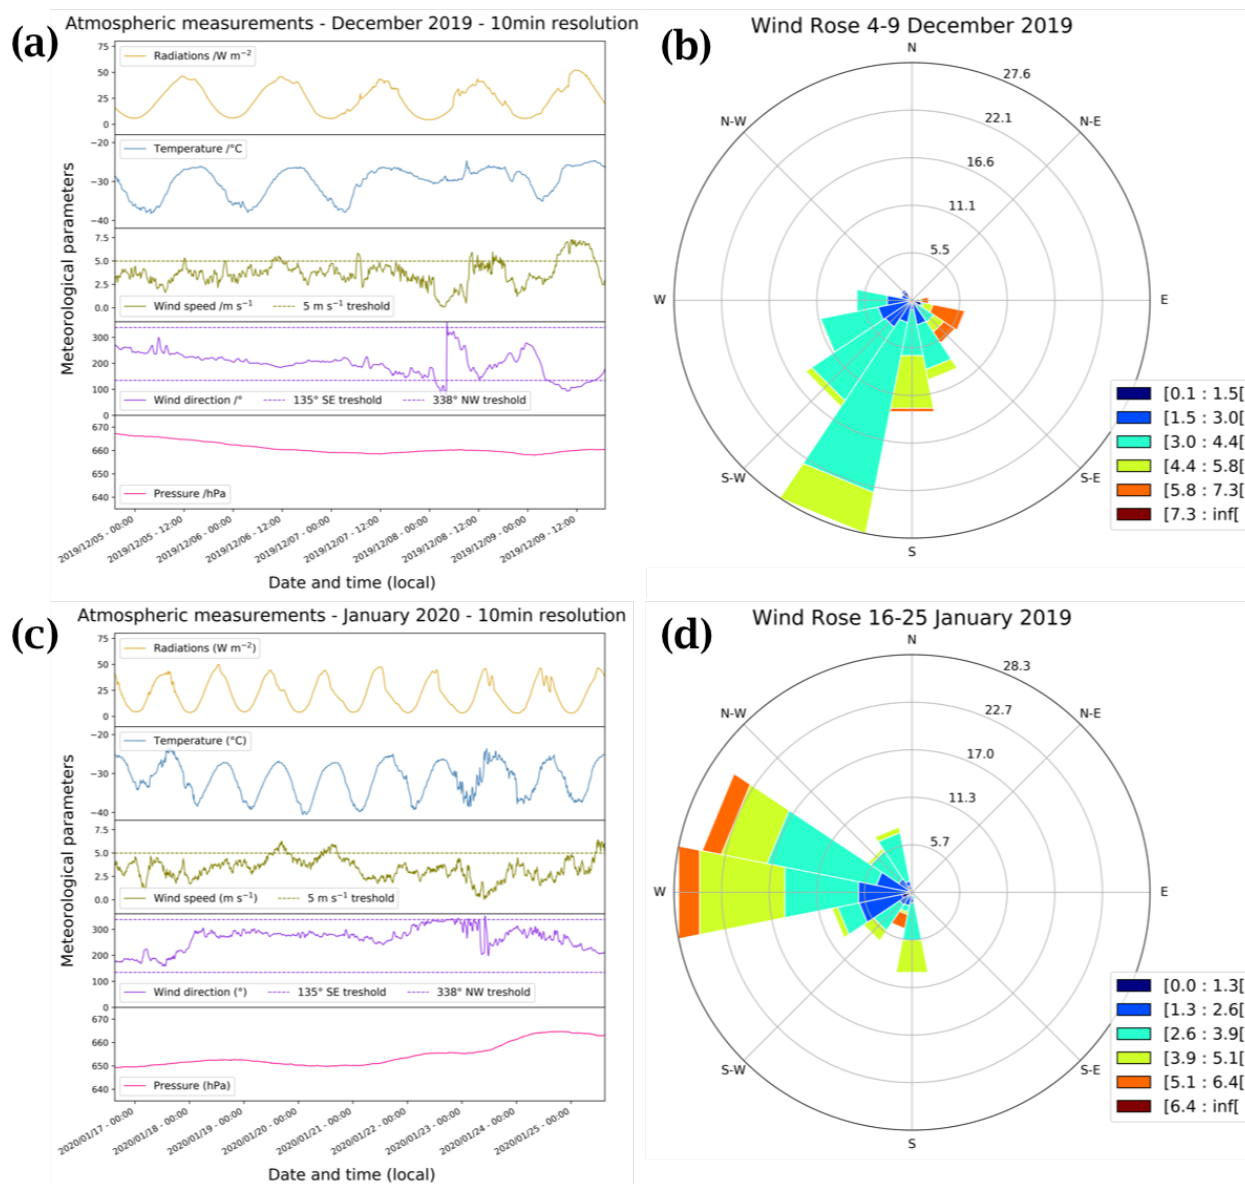

**Figure A4.** HYSPLIT 10 days backward trajectories of the 23<sup>rd</sup> ending at 12:00 UTC (20:00 LT) at 3 different altitudes: 3,800 a.m.s.l (green), 3,400 a.m.s.l (blue) and 3,200 a.m.s.l (red).

## Appendix B: Meteorological conditions during two periods of observations

The wind rose of the January period (Fig. B1d) shows strong wind from the West/North-West direction. Looking at Figure B1c, this event occurred in late January, around the 23<sup>rd</sup>, strengthening our hypothesis of ocean air masses that might have reached Dome C at the end of January.

**Figure B1.** (a) and (c) Local meteorological conditions (2-m observations) encountered during the periods of atmospheric observations measured by the local automatic weather station (AWS– Vaisala Milos 520) completed with a broadband  $UV$  radiometer, spectral range 305–385 nm. (b) and (d) The corresponding wind rose in  $m s^{-1}$  at Dome C.

## 465 Appendix C: Snow-Tower experiment

Figure C1 shows the schematic of the snow-tower device, along with a photograph of one of the snow towers. We can see the two partially buried snow towers at the ends of the diagram, as well as the fully exposed atmospheric mast in the middle.

Figure C1. Snow-Tower installation at Dome C.

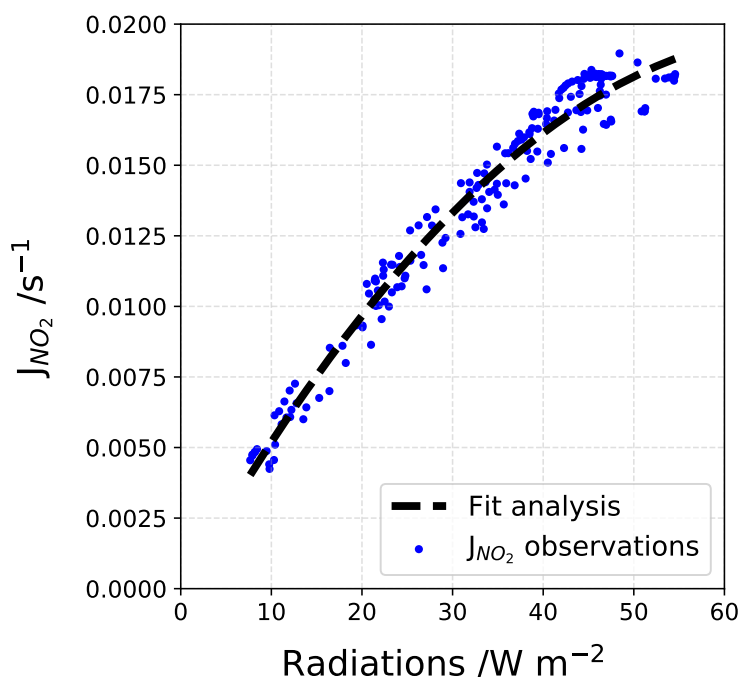

#### Appendix D: NO<sub>2</sub> and O<sup>1</sup>D photolysis rate constant reconstruction: $J_{NO_2-recons}$ and $J_{O^1D-recons}$

The  $J_{NO_2-recons}$  [s<sup>-1</sup>] is reconstructed using a correlation fit analysis between the *UV* radiations signal and the sparse  $J_{NO_2}$  measurements obtained with the MetCon 2π spectral radiometer (Fig. D1). A two degrees polynomial function, Equation D1, was found to be the best correlation fit (dashed black line in Fig. D1).

$$J_{NO_2-recons} = a + b \times UV + c \times UV^2 \quad (D1)$$

with  $J_{NO_2-recons}$ , the reconstructed photolysis rate coefficient; *a*, *b* and *c*, the regression fits parameters; and *UV*, the measured *UV* radiations.

**Figure D1.** Fit analysis for the reconstruction of the  $J_{NO_2}$  signal.

475 Table D1 gives the values of *a*, *b* and *c* parameters for the photolysis rate constant at both periods.

**Table D1.** Polynomial regression fit parameters from Equation D1 applied to reconstruct the photolysis rate coefficient signal.

$J_{NO_2-recons} = a + b \times UV + c \times UV^2$			
	<i>a</i>	<i>b</i>	<i>c</i>
December 4 <sup>th</sup> to 9 <sup>th</sup>	0.0	$5.722 \times 10^{-04}$	$-4.141 \times 10^{-06}$
January 16 <sup>th</sup> to 25 <sup>th</sup>	0.0	$7.029 \times 10^{-04}$	$-7.868 \times 10^{-06}$

Figure D2 represents the comparison between the reconstructed signal and the actual observations, on the bottom panel, the residual  $\Delta J_{NO_2-recons}$  is represented showing a good agreement between the reconstructed signal and the original observations.

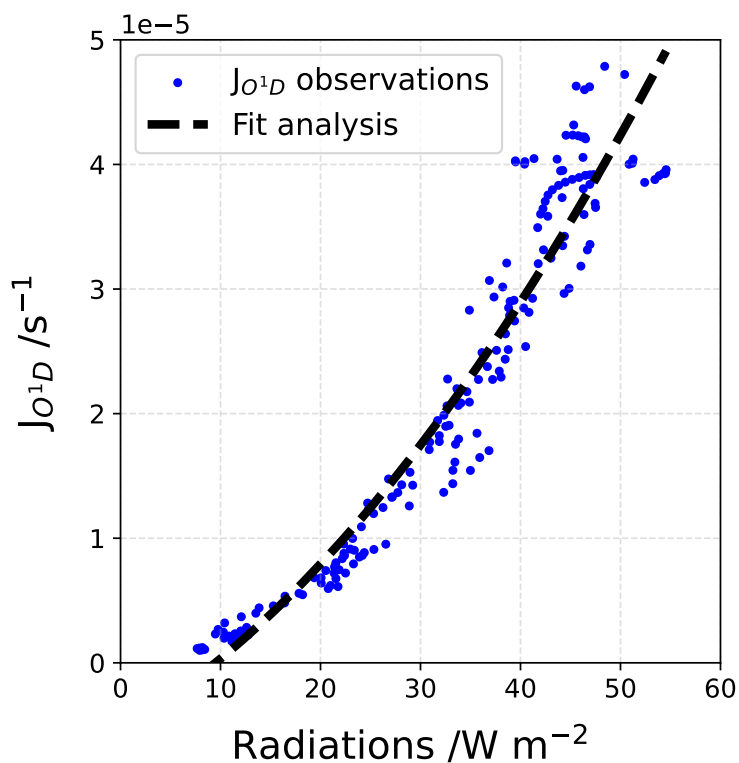

**Figure D2.** (top) Comparison between reconstructed and measured signal and (bottom) residual.

The  $J_{O^1D-recons}$  [ $s^{-1}$ ] is reconstructed using a correlation fit analysis between the  $UV$  radiations signal and the sparse  $J_{O^1D}$  measurements obtained with the MetCon  $2\pi$  spectral radiometer (Fig. D3). A two degrees polynomial function, Equation D2, was found to be the best correlation fit (dashed black line in Fig. D3).

$$J_{O^1D-recons} = a + b \times UV + c \times UV^2 \quad (D2)$$

with  $J_{O^1D-recons}$ , the reconstructed photolysis rate coefficient;  $a$ ,  $b$  and  $c$ , the regression fits parameters; and  $UV$ , the measured  $UV$  radiations.

**Figure D3.** Fit analysis for the reconstruction of the  $J_{O^1D-recons}$  signal.

485 Table D2 gives the values of  $a$ ,  $b$  and  $c$  parameters for the photolysis rate constant at both periods.

**Table D2.** Polynomial regression fit parameters from Equation D2 applied to reconstruct the photolysis rate coefficient signal.

	$J_{O^1D-recons} = a + b \times UV + c \times UV^2$		
	$a$	$b$	$c$
December 4 <sup>th</sup> to 9 <sup>th</sup>	0.0	$4.702 \times 10^{-07}$	$9.674 \times 10^{-09}$
January 16 <sup>th</sup> to 25 <sup>th</sup>	0.0	$6.251 \times 10^{-07}$	$1.279 \times 10^{-09}$

Figure D4 represents the comparison between the reconstructed signal and the actual observations, on the bottom panel, the residual  $\Delta J_{O^1D-recons}$  is represented showing a good agreement between the reconstructed signal and the original observations.

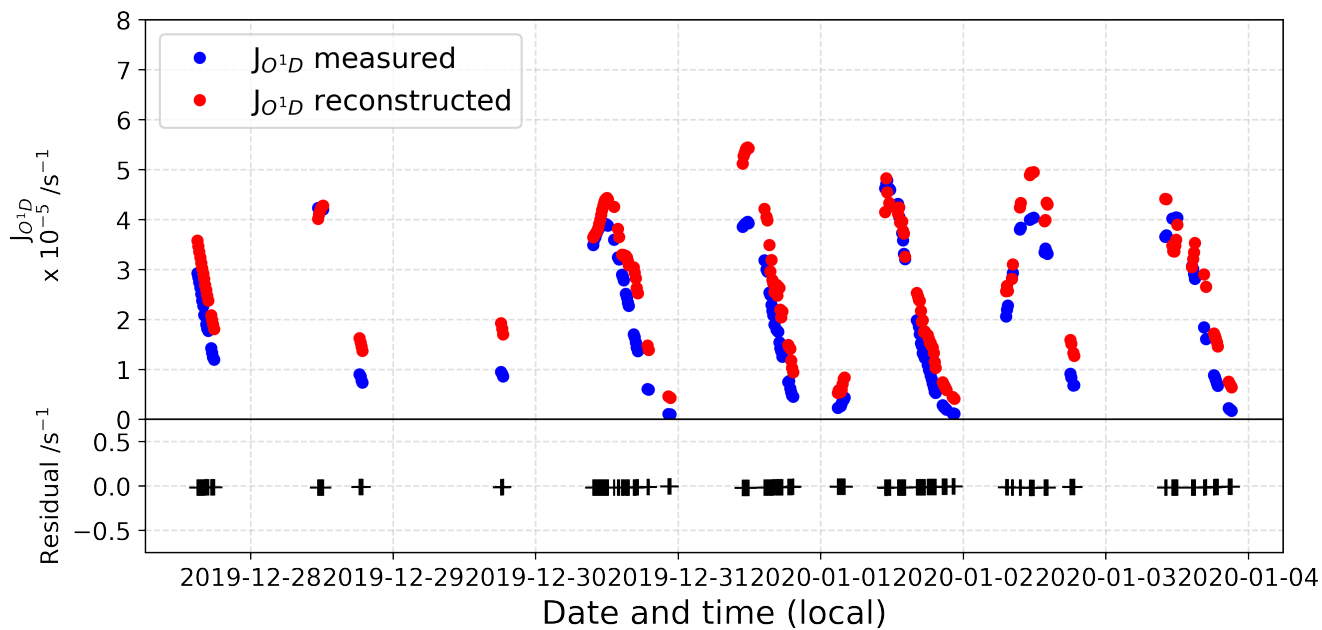

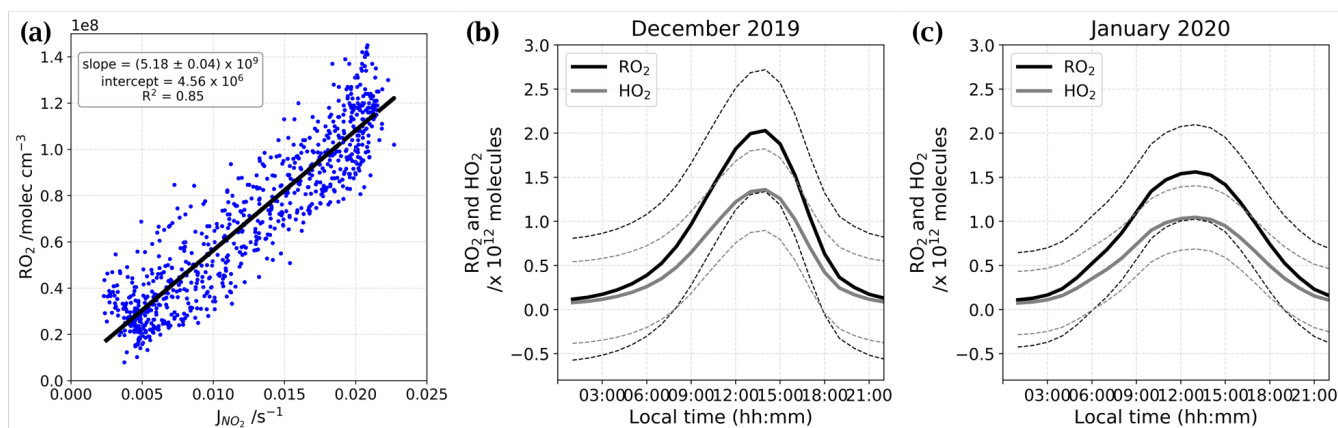

Figure D4. (top) Comparison between reconstructed and measured signal and (bottom) residual.

### Appendix E: $RO_x$ estimation from $J_{NO_2}$

490 Using the linear correlation between  $RO_2$  and  $J_{NO_2}$  given by Kukui et al. (2014) (Fig. E1a); the  $RO_2$  data from OPALE campaign (Kukui et al., 2014); and the reconstructed  $J_{NO_2}$  signal, we were able to estimate the  $RO_2$  and  $HO_2$  total number of molecules in the atmospheric boundary layer at Dome C during our periods of observation (Fig. E1b and E1c).

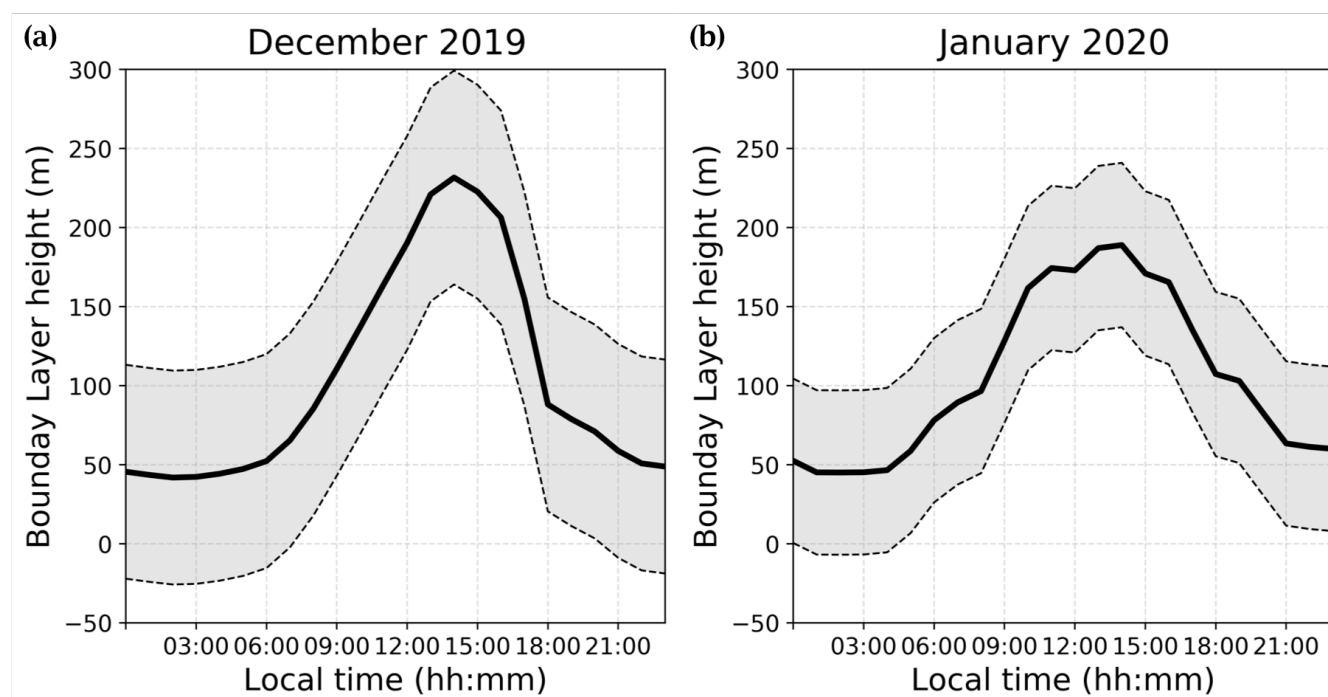

**Figure E1.** (a) linear correlation between  $RO_2$  and  $J_{NO_2}$  taken from Kukui et al. (2014). (b) and (c) total number of molecules of  $RO_2$  (black) and  $HO_2$  (grey) estimated for both periods of observations residual.

## Appendix F: Polar boundary layer height $H_{PBL}$

The regional climate model MAR, which has been applied extensively for studying the polar regions, e.g., Agosta et al. (2019); Gallée et al. (2015b); Gallée and Gorodetskaya (2010), was used in its latest Antarctic configuration: version 3.11 (Kittel et al., 2021), including drifting-snow physics (Amory et al., 2021) at 35 km resolution and forced by ERA5 reanalysis (<https://www.ecmwf.int/en/forecasts>) to generate the Boundary layer height extracted every hour to match the timestamp of our observations. Boundary layer height at Dome C during both periods of observations extracted from the regional model MAR are presented in Figure F1.

**Figure F1.** Atmospheric boundary layer height (PBL) (solid lines)  $\pm 1\sigma$  (dashed lines) estimated for both periods by the MAR regional model.

## 500 Appendix G: Reactions and their chemical rates

The list of reactions at stakes in Dome C troposphere with the associated daily average chemical rates based on their expression given by Atkinson (1998, 2003); Atkinson et al. (2004, 2007),  $J_{NO_2}$  measurements and  $J_{NO_3^-}$  estimation from Barbero et al. (2021), for Dome C conditions.

### 505 O<sub>x</sub> reaction

### HO<sub>x</sub> reaction

### NO<sub>x</sub> reaction

### ClO<sub>x</sub> reaction

### BrO<sub>x</sub> reaction

### IO<sub>x</sub> reaction

525 From the list above, one can see that the chemical sources of NO<sub>2</sub> and sinks from RO<sub>x</sub> and XO have similar rates.

*Author contributions.* Grants obtained by JS and RG funded the project. The IBBCEAS instruments were designed, developed and validated by CB and AB under the supervision of RG. JS, RG, NC, MMF and DH contributed with their knowledge in atmospheric sciences. NC provided technical and engineering support during the 2019-2020 Antarctic campaign. The paper was written by AB, with contributions from all authors.

530 *Data availability.* The data used in this study "will be available at PDI-30390: Data submission 2021-12-07T09:55:41Z" with license "CC-BY: Creative Commons Attribution 4.0 International".
