## Abstract

Understanding chemical processes leading to the formation of atmospheric aerosol particles is crucial to improve our capabilities in predicting the future climate. However, those mechanisms are still inadequately characterized, especially in polar regions. In this study, we report observations of neutral and charged aerosol precursor molecules and chemical clusters composition (qualitatively and quantitatively), as well as air ions and aerosol particle number concentrations and size distributions from the Marambio research station (64°15'S - 56°38'W), located North of the Antarctic Peninsula. We conducted measurements during the austral summer, between 15 January and 25 February 2018. The scope of this study is to characterize New Particle Formation (NPF) event parameters and connect our observations of gas phase compounds with the formation of secondary aerosols to resolve the nucleation mechanisms at the molecular scale. NPF occurred on 40 % of measurement days. All NPF events were observed during days with high solar radiation, mostly with above freezing temperatures and, with low relative humidity. The averaged formation rate for 3 nm particles ( $J_3$ ) was  $0.686 \text{ cm}^{-3} \text{ s}^{-1}$  and the average particle growth rate ( $GR_{3.8-12 \text{ nm}}$ ) was  $4.2 \text{ nm h}^{-1}$ . Analysis of neutral aerosol precursor molecules showed measurable concentrations of iodic acid (IA), sulfuric acid (SA) and methane sulfonic acid (MSA) throughout the entire measurement period with significant increase of MSA and SA concentrations during NPF events. We highlight SA as a key contributor to NPF processes, while IA and MSA would likely only contribute to particle growth. Mechanistically, anion clusters containing ammonia/ dimethylamine (DMA) and SA were identified, suggesting significant concentration ammonia and DMA as well. Those species are likely contributing to NPF events since SA alone is not sufficient to explain observed nucleation rates.

61 contribution to the aerosol phase. ↓

## 63 1 Introduction

64  
65 Atmospheric aerosol particles impact the planetary energy budget and radiation balance by influencing  
66 cloud optical properties and cloud lifetime (IPCC, 2013). Even though they are crucial for regulating the cli-  
67 mate, aerosol particles remain insufficiently characterized, especially in remote regions (Schmale et al., 2019).  
68 Understanding the atmospheric processes in places where anthropogenic influence is minimal, such as polar  
69 regions, is important for characterizing the pre-industrial-like atmosphere. At the same time, polar environ-  
70 ments are significantly impacted by human-induced climate change and are warming twice as fast as the global  
71 average (Stuecker et al., 2018). Additionally, polar ecosystems and landscapes are more and more being dis-  
72 turbed by increasing average temperatures that further affect emissions of trace gases into the atmosphere.

73  
74 Aerosol particles have been observed and characterized in many places in the Arctic and Antarctica (Shaw,  
75 1979; Shaw, 1988; Asmi et al., 2010; Kerminen et al., 2018; Sipilä et al., 2016; Dall'Osto et al., 2017; Jokinen  
76 et al., 2018; Dall'Osto et al., 2018; Herenz et al., 2019; Baccarini et al., 2020; Dall'Osto et al., 2019; Beck et  
77 al., 2021; Brean et al., 2021). Antarctic primary particles, mainly originating from sea spray or blowing snow,  
78 only weakly contribute to total particle number concentration (Lachlan-Cope et al., 2020). Modelling studies  
79 have estimated that primary particles would only contribute to ~2 % of the total particle count that the ground  
80 level in Antarctica (Merikanto et al., 2009). Secondary formation of aerosol particles, on the other hand, is  
81 believed to be the principal contributor to cloud condensation nuclei (CCN), especially in the Antarctic pen-  
82 insula were models showed contributions varying from 75% up to 100 % (Jokinen et al., 2018; Kerminen et  
83 al., 2018; Merikanto et al., 2009). These secondary aerosols originate from nucleation of gas phase molecules,  
84 typically condensing oxidation products of locally or regionally emitted vapors. Once formed, neutral or  
85 charged molecular clusters can grow by condensation of gases to sizes where they can act as CCN. The process  
86 of aerosol nucleation followed by subsequent growth is called new particle formation (NPF). Only a few stud-  
87 ies have observed nucleation mode particles (sub-10 nm) from Antarctica - including oceanic, coastal, and  
88 continental areas - (Asmi et al., 2010; Virkkula et al., 2009; Järvinen et al., 2013; Kyrö et al., 2013; Weller et  
89 al., 2015; Jokinen et al., 2018; Kerminen et al., 2018; Lachlan-Cope et al., 2020; Brean et al., 2021) and only  
90 two of those report molecular clusters forming from precursor gases in coastal sites (Jokinen et al., 2018; Brean  
91 et al., 2021).

92  
93 Previously identified aerosol precursor vapors include sulfuric acid (e.g., Kulmala et al., 2013; Sipilä et al.,  
94 2010), iodic acid (Sipilä et al., 2016; Baccarini et al., 2020) and iodous acid (He et al., 2021), or highly oxy-  
95 genated organic molecules (e.g., HOMs, Ehn et al., 2014; Bianchi et al., 2019; Kirkby et al., 2016). On the  
96 other hand, nucleating ion clusters such as bisulfate ions with sulfuric acid and ammonia (e.g., Kirkby et al.,

Deleted: Our observations highlight the importance of the Antarctic Ocean, water, and ice ecosystems interacting with the land fauna – the plausible sources of the principal precursor molecules hereby investigated – for secondary aerosol formation.

105 2011; Yan et al., 2018; Jokinen et al., 2018; Beck et al., 2021), bisulfate ions and neutral sulfuric acid with  
106 dimethyl amine (DMA, Kürten et al., 2014), were previously identified to participate in aerosol formation  
107 processes.

108  
109 At Marambio, [Aboa](#), and Princess Elisabeth coastal Antarctic stations, air mass trajectories during NPF events  
110 indicated a dominant role of the Southern Ocean as a source of aerosol particles, which chemical aerosol  
111 composition analysis confirmed by the abundancy of e.g., marine-originated sulfates (Asmi et al., 2010;  
112 Herenz et al., 2019; Jokinen et al., 2018). These studies suggest that NPF is linked to sulfur-containing com-  
113 pounds originating from dimethyl sulfide ((CH<sub>3</sub>)<sub>2</sub>S, DMS). At the Antarctic coast, oceanic DMS concentra-  
114 tions are the highest during December to January (i.e., austral summer) with concentration that could exceed  
115 15 nM within the upper 10 m layer of the ocean around the Peninsula compared to a yearly average of ~5 nM  
116 (Lana et al., 2011). DMS has two well-known oxidation products formed from gas-phase reaction with OH  
117 radicals: sulfuric acid (H<sub>2</sub>SO<sub>4</sub>, SA, formed via sulfur dioxide, SO<sub>2</sub>) and methane sulfonic acid (CH<sub>3</sub>SO<sub>3</sub>H,  
118 MSA), which can then initiate particle formation and subsequent particle growth (Barnes et al., 2006;  
119 [Mardyukov and Schreiner, 2018](#)).

120  
121 Iodic acid (IA) was also found to significantly contribute to NPF in marine and polar environments (Sipilä et  
122 al., 2016; Baccarini et al., 2020; He et al., 2021). Although the chemical production of iodic acid is not fully  
123 resolved, IA results from the oxidation of reactive iodine (He et al., 2021) – in the form of I<sub>2</sub>, HIO, or inter-  
124 mediate I - itself sourcing from algae/phytoplankton emissions contained within the sea water/ice/snow and  
125 exchanged into the atmosphere (Saiz-Lopez and Von Glasow, 2012). At the Antarctic Peninsula, the Weddell  
126 Seaside – that undergoes consistent and recurrent phytoplankton bloom episodes every early spring - is a po-  
127 tential reservoir for iodic acid emissions, especially due to slower ice retreat during the [austral](#) summer and  
128 colder sea surface temperature than the Southern Ocean on the north and west-side of the peninsula ([Atkinson  
129 et al., 2012; Von Berg et al., 2020](#)).

130  
131 This work aims at characterizing the gas-phase aerosol precursors naturally emitted from the marine/ice ecosys-  
132 tem and from the Antarctic continent with comprehensive gas phase and aerosol measurements performed at

## 2 Methods

### 2.1 Measurement site

In-situ atmospheric gas- and particle-phase measurements were performed at the Argentinian Antarctic Station Marambio ( $64^{\circ}15'S - 56^{\circ}38'W$ ) located on the Seymour Island in the northeastern-most part of the Antarctic Peninsula. Geographically (cf. Fig. 1), the island is on the north edge of the Weddell Sea. The station is operated year-round, with extensive scientific and logistic activities during the austral summer. The campaign instrumentation was located inside a laboratory container, specifically designed for continuous atmospheric composition measurements, sufficiently away (approx. 800 m) from the station main buildings and ideally placed fore-wind from the airstrip to avoid interfering contamination signals in our measurements. Comprehensive measurements of atmospheric composition and meteorology have been carried out in this location since 2013. A description of the Marambio station surroundings, the measurement container, and some previous results can be found in earlier publications, e.g., Asmi et al. (2018).

Figure 1: Map of the Antarctic Peninsula, a), with zoom in the north sector, b), and in the Seymour Island with the Marambio station, in c). The measurement location is indicated by the red pin.

169 The austral summer campaign in 2018 for measuring the precursors contributing to NPF at the Ma-  
170 rambio station was planned for the warm season, when the probability of NPF occurrence is high (Fiebig et  
171 al., 2014; Kerminen et al., 2018). The aim was to characterize NPF events, formation, and growth parameters,  
172 and resolve the aerosol chemical precursors from their source to their chemical pathways leading to nucleation.  
173 We measured concentrations of size segregated aerosol particles (~ 1 – 800 nm diameter) from 19 January to  
174 23 February and chemical information of possible gas-phase precursors from 30 January to 20 February, con-  
175 tinuously (whenever possible).

## 176 **2.3 Instrumentation**

### 177 *Measurements of aerosols and their gas-phase precursors*

178  
179  
180  
181 We deployed a large suite of instruments, briefly described below. Instrument principles and opera-  
182 tions are given in detail in the *Supplementary Information*.

183  
184 (1) The chemical composition and concentration of neutral molecules was measured by a nitrate-based Chem-  
185 ical Ionization Atmospheric Pressure interface Time Of Flight (CI-API-TOF, ToFwerk A.G.) mass spectrom-  
186 eter (Jokinen et al., 2012). Its high-resolution analysis identifies and quantifies potential ambient gas-phase  
187 aerosol precursors, such as SA, MSA, IA, or HOMs. In some instances, we used the API-TOF to directly  
188 measure atmospheric ions (i.e., naturally charged anions or cations), allowing only atmospheric ions to enter  
189 the instruments (i.e., with no added chemical ionization) (cf. *Supplementary information*).

190  
191 (2) A nano Condensation Nucleus Counter (nCNC) combining a Particle Size Magnifier (PSM, Airmodus  
192 Ltd.) with a Condensation Particle Counter (CPC, Airmodus Ltd.) was employed to measure nano-particle  
193 concentration in the diameter range from 1 nm to 3 nm. The instrumentation and data inversions are extensively  
194 described in Vanhanen et al. (2011), Kangasluoma et al. (2016), Chan et al. (2020) and Lehtipalo et al. (2022)  
195 (cf. *Supplementary information*).

196  
197 (3) A Neutral cluster and Air Ion Spectrometer (NAIS, Airel Ltd., Mirme and Mirme, 2013) provided number  
198 size distributions of neutral particles and naturally charged atmospheric clusters in the size range from 2 to 42  
199 nm and from 0.8 to 42 nm, respectively. NAIS is well described in the literature and was operated according  
200 to the instructions of Manninen et al., 2016. (cf. *Supplementary information*).

201  
202 (4) Aerosol particle size distributions were measured with a Differential Mobility Particle Sizer (DMPS): a  
203 Vienna-type Differential Mobility Analyzer (DMA) for particle size separation (Wiedensohler et al., 2012),  
204 followed by a Condensation Particle Counter (CPC; TSI model 3772) for particle counting. The particle size  
205 distribution was measured in 25 separate size bins at a 6-minute time resolution. This measurement has been

206 carried out continuously since the year 2013 but only data measured during the summer 2018 campaign are  
207 presented here. (cf. *Supplementary information*).

208  
209 The CI-API-TOF, nCNC and NAIS were operated with individual (horizontal) inlet lines with a minimum  
210 length (1 m, 0.8 m, and 0.9 m, respectively) to minimize losses of nanoparticles. The DMPS was operated in  
211 the station's common inlet (PM10, Asmi et al., 2018) and equipped with an additional PM<sub>1</sub> cyclone to prevent  
212 super micron particles from entering the setup.

#### 213 214 *Ancillary measurements*

215  
216 Meteorological parameters were measured on the roof of the measurement container and recorded on  
217 a data logger (QML201L, Vaisala Ltd.) since 2013. Measured parameters include temperature and relative  
218 humidity (HMP155, Vaisala Ltd.), atmospheric pressure (PTB220, Vaisala Ltd.), wind speed and wind direc-  
219 tion (ultrasonic anemometer: Thies 2D, Thies Klima), and radiation (pyranometer: CMP11, Kipp&Zonen).

#### 220 221 222 *Chemical composition of the aerosol phase*

223  
224 Aerosol samples for chemical analysis were collected using a virtual impactor (VI, Loo and Cork,  
225 1988), in which particles were divided to two size fractions (fine ( $DP < 2.5 \mu\text{m}$ ) and coarse ( $2.5 \mu\text{m} < DP <$   
226  $10 \mu\text{m}$ ). Flow rate of the VI was  $16.7 \text{ L}\cdot\text{min}^{-1}$ , of which  $15 \text{ L}\cdot\text{min}^{-1}$  is used to collect the fine particles and the  
227 remaining  $1.7 \text{ L}\cdot\text{min}^{-1}$  is used for collection of the coarse particles. Particles were collected on 47-mm Teflon  
228 filters. Sampling time was one week. Collected filters were stored on petri slides and kept in a freezer ( $-18$   
229  $^{\circ}\text{C}$ ) until analysis.

230  
231 The mass concentrations of sodium ( $\text{Na}^+$ ), ammonium ( $\text{NH}_4^+$ ), potassium ( $\text{K}^+$ ), magnesium ( $\text{Mg}^{2+}$ ), calcium  
232 ( $\text{Ca}^{2+}$ ), chloride ( $\text{Cl}^-$ ), nitrate ( $\text{NO}_3^-$ ), sulphate ( $\text{SO}_4^{2-}$ ), methane sulfonic acid (MSA) and oxalate were deter-  
233 mined from the filter substrates. Cation and anion analyses were done simultaneously with two ion chroma-  
234 tography systems (Dionex ICS-2000). Filters were extracted in 10 mL of Milli-Q water with 10-min gentle  
235 rotation just before chemical analysis. The uncertainty of the IC analysis was estimated according to the anal-  
236 ysis of standards as 5 % to 10 %, depending on the ion analyzed. In this study chemical composition of the  
237 fine particles is only presented.

#### 238 239 **2.4 Characteristics of New Particle Formation events**

240  
241 NPF events were identified based on the appearance of particles in the nucleation mode (3 - 25 nm)  
242 showing signs of growth (e.g., particles reaching  $> 10 \text{ nm}$ ). A classification method was originally proposed

Deleted: )

Deleted:

245 by Dal Maso et al. (2005) based on DMPS data. In this study, we combined both DMPS and NAIS data to  
246 extend our observations to smaller sizes (Dada et al., 2018).

247  
248 Condensation sink ( $CS$ ,  $s^{-1}$ ), which is a measure of how rapid precursor vapor concentrations are lost to pre-  
249 existing particles, was calculated using the particle number size distribution measured by the DMPS following  
250 the method proposed by Kulmala et al. (2012).

251  
252 Growth rates ( $GR$ ) of particles between 3.8 nm to 12 nm were calculated using the 50 % appearance time  
253 method (Lehtipalo et al., 2014; Dada et al., 2020). Formation rates ( $J_{1.5}$ ,  $J_3$ ,  $J_5$ , and  $J_{10}$ ) were calculated using  
254 the balance equation where the change in concentration of particles inside a size bin is equivalent to the  
255 sources ( $J_{Dp}$ ) minus the available sinks ( $F_{Coag} + F_{Growth}$ ), as in Kulmala et al. (2012).

$$(1) J_{Dp} = \frac{dN_{Dp}}{dt} + CoagS_{Dp} \cdot N_{Dp} + \frac{GR}{\Delta Dp} \cdot N_{Dp}$$

258 where  $Dp$  represents the lower diameter of the bin,  $N_{Dp}$  is the particle number concentration inside the size bin,  
259 and  $GR$  is the growth rate of particles out of the bin.  $\Delta Dp$  is the difference between the upper and lower ends of  
260 the size bin of interest.

261  
262 The coagulation sink ( $CoagS_{Dp}$ ) is a measure of how rapid freshly formed particles of diameter  $Dp$  are lost to  
263 pre-existing particles **by collision or coalescence** and is calculated as follows:

$$(2) CoagS_{Dp} = \int K(Dp, Dp') n(Dp') dDp' \cong \sum_{Dp'=Dp}^{Dp'=maxK} K(Dp, Dp') N_{Dp'}$$

266  
267 where  $K(Dp, Dp')$  is the coagulation coefficient of particle sizes  $Dp$  and  $Dp'$ , those inside the bin of  $J_{Dp}$  and  
268 those of pre-existing particles, respectively.  $N_{Dp'}$  is the number concentration of the pre-existing particles.

269  
270 In this work, the formation rates of 1.5 nm particles ( $J_{1.5}$ ) were calculated using nCNC data in the size range of  
271 1.5 nm to 3 nm. Formation rates  $J_3$ ,  $J_5$  and  $J_{10}$  were calculated using NAIS data (total particle mode – using the  
272 DMA of negative voltage) at the size ranges of 3 - 7 nm, 5 - 9 nm, and 10 - 14 nm, respectively. During events  
273 when the  $GR$  could not be calculated (i.e., four events in total) – due to the absence of continuous growth  
274 within the size ranges -, a median growth rate calculated of all the events occurring in the same month was  
275 used to estimate the formation rate as described by Kulmala et al. (2022).

276  
277 In addition, the charged particle formation rates ( $J_{1.5}^+$  and  $J_{1.5}^-$ ) were calculated using ion number concentra-  
278 tion measured by NAIS in both polarities, whenever possible, to determine the contribution of ion induced  
279 nucleation to the overall formation rate, according to the following equation:

280

Deleted: .....Page Break.....

Formatted: Line spacing: 1,5 lines

Commented [QLLJ17]: RC2 >> SC3

Commented [QLLJ18]: RC1 >> C6

283 
$$(3) J_{Dp}^{\pm} = \frac{dN_{Dp}^{\pm}}{dt} + CoagS_{Dp} \cdot N_{Dp}^{\pm} + \frac{GR}{\Delta Dp} \cdot N_{Dp}^{\pm} + \alpha \cdot N_{Dp}^{\pm} \cdot N_{<Dp}^{\pm} - \chi \cdot N_{Dp} \cdot N_{<Dp}^{\pm}$$

284  
 285 where  $N_{Dp}^{\pm}$  is the concentration of ion in a given size range with a lower limit of 1.5 or 2 nm (depending on  
 286 the  $J$  associated size range) and the upper limit  $\Delta Dp$  being larger than that. The coefficient  $\alpha$  is the ion-ion  
 287 recombination coefficient and  $\chi$  is the ion-aerosol attachment coefficient.  $\alpha$  and  $\chi$  were  $1.6 \times 10^6 \text{ cm}^{-3} \cdot \text{cm}^{-1}$   
 288 and  $0.01 \times 10^6 \text{ cm}^{-3} \cdot \text{s}^{-1}$ , respectively (Kulmala et al., 2012).

289  
 290 **3 Results**

291  
 292 **3.1 Ambient conditions: Meteorological parameters**

293  
 294 Ambient meteorological conditions during the campaign are presented in Figure 2. Many sunny days  
 295 are observed, occurring with above-zero degrees Celsius ambient temperatures, high radiation, and relative  
 296 humidity below 75 %. Even though the measurement site belongs to the Antarctic continent, its position - at  
 297 relatively high latitude ( $64^{\circ}15'S$ ) - gives daily solar cycles with zero radiation during the short summer  
 298 nighttime periods (cf. Fig. 2b). During daytime, higher radiation enhances photo-active emissions from the  
 299 sea/land ecosystems and promotes atmospheric photochemistry. This is expected to lead to day-time appear-  
 300 ance of gas-phase molecules and/or molecular clusters of condensing vapors that can lead to new particle  
 301 formation and/or aerosol growth. Furthermore, since temperatures above freezing also lead to ice melting (es-  
 302 pecially in the Weddell Sea area), they are likely to enhance chemical fluxes between thinning ice, ocean, and  
 303 air (Notz, 2009). These clear sky, warm, sunny days during summertime are known to be optimal weather  
 304 conditions for NPF to occur in the mid-latitude regions (Dada et al., 2017) and in the Arctic (e.g., Beck et al.  
 305 2021) and Antarctic regions (Weller et al., 2015; Jokinen et al., 2018; Baccharini et al., 2020; Brean et al.,  
 306 2021). Analysis of winds (cf. Fig. 2e) revealed that periods of the highest temperature are seen when wind is  
 307 blowing from north, bringing warmer air across from the Southern Ocean. Predominant winds were seen from  
 308 North-Northwest and South-Southwest sectors. The strongest winds were recorded from the South ( $180^{\circ}$ ), also  
 309 driving primarily cold air from the continental plateau, agreeing with Asmi et al. (2018).

### 3.2 Observation & Characterization of NPF events

A total of 13 NPF events (occurring on 12 days) were observed during the 35-day summer campaign. Figure 3a shows the continuous size distribution series over the total measurement period from NAIS measurement (size range: 1.8 – 42 nm) and Figure 3b combined the data from nCNC (size shown: 1.2 – 2.7 nm), the NAIS (2.7 nm - 12 nm), and the DMPS (12 nm – 800 nm). Daily number size distribution plots are shown for the 12 event days separately in the *Supplementary Information* (Fig. S3) as well as continuous size distribution series for ion mode (Fig. S4).

**Figure 3:** a) Number size distribution from NAIS measurement from 1.8 nm to 42 nm over the whole measurement campaign and b) combined size distribution of aerosol particle from 1.2 nm to 800 nm for 3-7 February 2018. The last surface plot combines data from nCNC (1.2 - 2.7 nm), NAIS (particle mode, 2.7 - 12 nm) and DMPS (12-800 nm), whenever the data were available and according to DMPS data flag (only unpolluted data are shown from the DMPS measurements).

During each of the NPF events observed during the campaign, high population of sub-3 nm aerosol particles were seen with concentration larger than  $10^4 \text{ cm}^{-3}$ . The particles were observed to grow to Aitken mode size range (25 - 100 nm) but rarely reached the accumulation mode sizes (i.e., > 100 nm) (cf. Fig. 3b). Strong NPF events were identified before midday - local time - (66 % of events), lasting longer than events occurring later in the afternoon. Afternoon events (33 % of the total events) never lasted longer than 2.5 hours. NPF events

354 did vary from day to day: On certain days, growth of the particles was interrupted by abrupt changes in wind  
355 direction - resulting in an inability to retrieve a growth or a formation rate within reasonable uncertainty (e.g.,  
356 28 January) -; on other days multiple NPF events were observed (e.g., 16 February); or NPF events appeared  
357 to have a bumped shape – appearing sporadically - resembling those observed in the Arctic by Beck et al.  
358 (2021) as the events observed on 28 January and 6 February.

359  
360 Formation rates were calculated for particle sizes of 1.5, 2, 3, 5 and 10 nm particles, as summarized in Table  
361 1. These formation rates were calculated for the smallest possible particles but also for bigger sizes to ease the  
362 comparison with the literature.

364 Formation rates of 1.5 nm particles (i.e.,  $J_{1.5}$ ) were surprisingly high, reaching the maximum rates of 9.2, 10.0,  
365 or even  $19 \text{ cm}^{-3} \text{ s}^{-1}$ , on Feb. 11<sup>th</sup>, 10<sup>th</sup>. and 3<sup>rd</sup>, respectively. These significantly high values are comparable to  
366 those calculated for highly vegetated rural location or even urban areas (e.g., Deng et al., 2020; Kontkanen et  
367 al., 2016; Yu et al., 2014), which is surprising due to the remote nature of the environment at our measurement  
368 site. For example, formation rates for 1.5 nm particle on the order of  $0.030 - 0.013 \text{ cm}^{-3} \text{ s}^{-1}$  were estimated for  
369 the Aboa research station on the other side of the Weddell Sea in East Antarctica (Jokinen et al. 2018). A recent  
370 study observing nucleation phenomena at the peninsula close by our measurement location (Brean et al., 2021)  
371 found a remarkably high  $J_{1.7}$  value reaching up to  $3.07 \text{ cm}^{-3} \text{ s}^{-1}$  but still lower than our observed values. Alt-  
372 hough the formation rates at 1.5 nm are higher than those reported previously, the rates for larger particles  
373 (i.e.,  $J_3, J_5, J_{10}$ ) are comparable with the previously reported studies. This discrepancy between formations rates  
374 of 1.5 nm particles and of bigger particles could be attributed to favorable nucleation conditions (i.e., sufficient  
375 nucleating vapors) but a lack of condensable vapors contributing to particle growth which, in all, reduces the  
376 probability of particle survival.

378 The nucleation rates for 3 nm particles in our study ranged from  $0.13 \text{ cm}^{-3} \text{ s}^{-1}$  to  $3 \text{ cm}^{-3} \text{ s}^{-1}$ , which were, on  
379 average, also significantly higher than  $0.03 \text{ cm}^{-3} \text{ s}^{-1} < J_3 < 0.14 \text{ cm}^{-3} \text{ s}^{-1}$  reported from Jokinen et al. (2018)  
380 study or from Kecorius et al. (2019) who showed  $J_3$  values from  $0.080 \text{ cm}^{-3} \text{ s}^{-1}$  to  $0.319 \text{ cm}^{-3} \text{ s}^{-1}$  during a polar  
381 cruise in the Arctic. On the other hand, our observation agrees with the  $J_{10}$  reported by Kyrö et al. (2013)  
382 ranging from  $0.003$  to  $0.3 \text{ cm}^{-3} \text{ s}^{-1}$ , with  $0.006 \text{ cm}^{-3} \text{ s}^{-1} < J_{10} < 0.37 \text{ cm}^{-3} \text{ s}^{-1}$  in our case.

384 Additionally, to account for ion induced nucleation, we calculated the formation rates for charged ions of 1.5  
385 nm ( $J_{1.5}^{\pm}$ ) separately using the ion concentrations measured with the (N)AIS in ion mode. The formation rates  
386 for positive 1.5 ions,  $J_{1.5}^+$ , ranged from  $3.6 \times 10^{-4}$  to  $8.3 \times 10^{-2} \text{ cm}^{-3} \text{ s}^{-1}$  and  $J_{1.5}^-$  was from  $2.2 \times 10^{-3}$  to  $5.4 \times 10^{-2}$   
387  $\text{cm}^{-3} \text{ s}^{-1}$ . Our results are significantly lower than the maximum  $J_{1.5}$  of  $0.33 \text{ cm}^{-3} \text{ s}^{-1}$  reported in Beck et al.  
388 (2021) or from Kyrö et al. (2013) who showed  $0.02 \text{ cm}^{-3} \text{ s}^{-1} < J_{1.6} < 4.2 \text{ cm}^{-3} \text{ s}^{-1}$  - in two coastal Antarctic sites,  
389 but in the range reported from the Arctic ocean by Kecorius et al. (2019, e.g.,  $0.026 \text{ cm}^{-3} \text{ s}^{-1} < J_{1.6} < 0.060 \text{ cm}^{-3}$   
390  $\text{ s}^{-1}$ ). In comparison to 1.5 nm-neutral particle formation rates, the ion formation rates do not represent a major

Deleted: This could be attributed to sufficient precursor vapors favoring nucleation, while insufficient ones required for fast growth to larger sizes.

400 contribution (ratio  $J_{neutral}/J_{ion} \sim 10^3$ ), implying that the relatively high neutral nucleation rates are not primarily  
401 due to ion-mediated nucleation.

402  
403 Particle growth rates were calculated for 3.8 nm to 12 nm diameter size or alternatively up to 11 nm and 8 nm  
404 for event #1 and event #13, respectively, whenever the shape of the number size distribution was continuously  
405 increasing. Averages for each event are also presented in Table 1. Similarly to formation rates of the smallest  
406 particles, the growth rates were remarkably higher ( $1.2 \text{ nm h}^{-1} < GR < 10.9 \text{ nm h}^{-1}$ ) than previously reported  
407 for other Antarctic sites. In comparison, Weller et al. (2015) reported growth rates from 3 to 25 nm particles  
408 ranging from 0.06 to 0.9  $\text{nm h}^{-1}$  at Neumayer III station, Jokinen et al. (2018) showed  $0.26 \text{ nm h}^{-1} < GR < 1.30$   
409  $\text{nm h}^{-1}$  at Aboa and Brean et al. (2021) published growth rates for 4.5 - 10 nm particles of 0.41  $\text{nm h}^{-1}$  to 0.58  
410  $\text{nm h}^{-1}$  measured at the Peninsula. Additionally, Kerminen et al. (2018) reviewed aerosol characterization from  
411 many different field studies and indicated an upper growth rate estimation of 5.5  $\text{nm h}^{-1}$  (as 95<sup>th</sup> percentile) in  
412 Antarctic sites versus 4.1  $\text{nm h}^{-1}$  in Arctic environments. Recent Arctic studies by Kecorius et al. (2019)  
413 reported  $0.62 \text{ nm h}^{-1} < GR_{(3-7 \text{ nm})} < 4.25 \text{ nm h}^{-1}$  while Collins et al. (2017) reported averaged growth rates of  
414  $4.3 \pm 4.1 \text{ nm h}^{-1}$ .

### 3.3 Chemical composition of the gas-phase precursor molecules

#### 3.3.1 Gas-phase contribution to NPF

Measurements utilizing nitrate based chemical ionization mass spectrometry (CI-APi-TOF) detected gas-phase molecules and molecular clusters that have affinity for proton transfer with nitrate reagent ion. These included SA, MSA, and IA, detected as  $\text{HSO}_4^-$  and  $\text{HNO}_3\text{HSO}_4^-$  (m/z 96.9601 Th and 159.9557 Th),  $\text{CH}_3\text{SO}_3^-$  and  $\text{HNO}_3\text{CH}_3\text{SO}_3^-$  (m/z 94.9808 Th and 157.9765 Th),  $\text{IO}_3^-$  and  $\text{HNO}_3\text{IO}_3^-$  (m/z 174.8898 Th and 237.8854 Th), respectively. Concentrations were calculated from high resolution peak fitting and reported below. The time series of those compounds during the whole campaign, according to the data availability of the CI operation, are shown in Figure 4.

The measured gas-phase concentrations of the species of interest showed maxima of  $\sim 2.6 \times 10^7$  molecules  $\text{cm}^{-3}$ ,  $\sim 2.3 \times 10^7$  molecules  $\text{cm}^{-3}$  and  $\sim 3.6 \times 10^6$  molecules  $\text{cm}^{-3}$  for the total SA, MSA, and IA concentrations, respectively. The three gas-phase compounds seemed to evolve with roughly similar behavior, likely due to favorable weather conditions promoting atmospheric chemical reactions and especially by enhancing photochemical oxidation reactions within a stable boundary layer. A significant and simultaneous increase in SA, MSA, IA concentrations was observed during peaking radiation time ~~close to noon-time – coinciding with local zenith time, i.e., solar noon that is slightly later than midday~~ and prior to many NPF events, though to a smaller extent for IA. This clearly demonstrates the diurnal nature of the emission of those species, and their transport – especially for SA and IA – as shown in Figure 5. Additionally, it is worth mentioning that even though the MSA concentrations were on average higher than those of SA, event days correlated strongly with peaking SA concentration (then becoming higher than MSA concentration) while IA – whose concentration remained unchanged independently of NPF occurrence - was significantly lower than SA or MSA concentrations.

476 with He et al. (2021). Earlier studies have shown that IA is even anticorrelated with (still omnipresent) solar  
477 radiation in more continental Antarctica (Jokinen et al., 2018). It is likely that even very low levels of solar  
478 radiation would be sufficient to saturate the iodic acid production (Beck et al., 2021). Distinctively, a clear  
479 difference in the statistical series can be seen between event and non-event days, with more than doubled SA  
480 concentration at zenith-time (factor of 2.25). MSA concentrations are only slightly higher in the morning and  
481 afternoon – with an apparent drop occurring from 14:00 to 16:00 – although the starting concentration at  
482 sunrise and sunset are also smaller, depicting strong concentration variability as compared to non-event days.  
483 On the other hand, IA is on average lower during event-days – e.g., from  $\sim 4.5 \times 10^5$  molecules  $\text{cm}^{-3}$  vs  $\sim 3 \times$   
484  $10^5$  molecules  $\text{cm}^{-3}$ , with a factor of 1.5 smaller at zenith-time. This last observation indicates that IA is likely  
485 not a key contributor to particle formation, while the duo SA-MSA could influence the aerosol phase as already  
486 suggested by Beck et al. (2021), Hodshire et al. (2019) and Willis et al. (2016).

523 increasing (Fig. 6d). MSA increased by almost a factor of 10 by 13:00 ( $[MSA]_{t=13.00} = 1.3 \times 10^6$  molecules  $cm^{-3}$ )  
524  $^3$ ) and by more than 2 orders of magnitude at 16:00 ( $[MSA]_{t=17.30} = 9.6 \times 10^6$  molecules  $cm^{-3}$ ) as compared by  
525 the minimum baseline of  $\sim 2 \times 10^5$  molecules  $cm^{-3}$  for both MSA and SA. SA maximum concentration was  
526  $6.5 \times 10^6$  molecules  $cm^{-3}$ , also observed at 13:00.

527 IA concentrations were fluctuating throughout the day with maximum concentrations of  $\sim 2.05 \times 10^5$  molecules  
528  $cm^{-3}$  and  $\sim 2.35 \times 10^5$  molecules  $cm^{-3}$ , respectively around 05:30 – 06:30 and shortly after 13:00. The net  
529 increase of all these gas-phase species occurred quasi-simultaneously as the increase of formation rate of the  
530 smallest particles and ions (Fig. 6c), occurring around noon. Interestingly, several sudden, short-lasting in-  
531 creases for all SA, MSA, and IA concentrations were seen even before 13:00, matching bumps in nucleation  
532 mode particles around 09:00 and 11:00 and one to two orders of magnitudes increase of cluster mode particles  
533 at 11:00. The high concentrations of SA, MSA (and possibly IA) likely trigger the observed aerosol processes  
534 (i.e., nucleation and/or growth of particles).

535  
536 We investigated the mass spectrum further and show a complementary mass spectrum in Figure S2. Any highly  
537 oxygenated organic molecules, HOMs (Bianchi et al., 2019; Ehn et al., 2014) could be reliably resolved from  
538 the mass spectra analysis. We estimate that the total oxidized organic contribution, possibly condensable  
539 HOM, did not exceed  $5.5 \times 10^6$  molecules  $cm^{-3}$ , between 16:30 and 17:30; assuming mass spectral peaks found  
540 above 200 Th with positive mass defect could be HOMs (*cf. Supplementary*). However, the actual HOM con-  
541 tribution is likely to be only a fraction of this estimation. Therefore, it is unlikely that HOM significantly  
542 contributed to nucleation or growth of newly formed particles.

543  
544 Specifically for this event, we complemented the CI-APi-TOF measurement with negative APi-TOF ambient  
545 measurement mode, from 14:52 to 15:53, as reported in Table S1. By showing the divergence of the exact  
546 molecular mass of a detected ion in high resolution from its integer mass (i.e., defined as mass defect), a mass  
547 defect plot illustrates the mass defect of selected ions (in y-axis) over a studied mass range (in x-axis). Com-  
548 pared to a typical mass spectrum this has the advantage to show the most significant ion population at once,  
549 rather independently of signal intensity which is then scaled by the marker size, easing the identification of  
550 e.g., clustering mechanisms as further discussed. There, each point of the mass defect plot corresponds to a  
551 unique atomic composition. An example of such representation is shown in Figure 6, for the study case of 16  
552 February.

**Deleted:** noise to signal

560 The API-TOF ion mode showed TIC maximum values around 50 ions  $s^{-1}$ , detecting only ions that are naturally  
 561 charged. The highest signals (i.e., intensity shown by marker sizes, cf. Fig. 7) are bisulfate and its multimers  
 562  $(H_2SO_4)_{0-4}HSO_4^-$ , respectively at  $m/z = 96.9601$ ,  $m/z = 194.9275$ ,  $m/z = 292.8949$  and  $m/z = 390.8622$ . Along  
 563 with SA multimers, successive addition of sulfuric acid and ammonia  $NH_3$  formed clusters represented with  
 564 the light-blue dots, within the mass range 400 – 1250 Th. These sulfuric acid (bisulfate) - ammonia clusters  
 565 were found with up to 10 additions of  $H_2SO_4$  and 9  $NH_3$  on top of the  $HSO_4^-$  core ion. In line with previous field  
 566 observations (e.g., Schobesberger et al., 2015; Bianchi et al., 2016; Jokinen et al., 2018; Yan et al., 2018; Beck  
 567 et al., 2021; Sipilä et al., 2021) and laboratory studies (e.g., Kirkby et al., 2011; Schobesberger et al., 2015)  
 568 showed that ammonia is detected only in clusters with 3 or more  $H_2SO_4$  molecules around the  $HSO_4^-$  core.

**Deleted:** 6

569  
 570 **The numerous clusters containing both sulfuric acid and ammonia, as well as the high intensity of the respec-**  
 571 **ative cluster signal (depicted by the marker size in Figure 6) suggest a high concentration of such ion group in**  
 572 **the gas-phase which also could indicate an ion induced nucleation, driven by the ternary system SA-ammonia(-**  
 573 **water) – similar to observations made by Jokinen et al. (2018) in East Antarctica as well as measured in multiple**  
 574 other locations around the globe (e.g., Bianchi et al., 2016; Yan et al., 2018; Beck et al., 2021; Sipilä et al.,  
 575 2021).  
 576

**Deleted:** The observed presence of ammonia with sulfuric acid in the measured gas-phase ions with relatively high intensity, suggests that the

590 Additional clusters containing SA and dimethyl amine ((CH<sub>3</sub>)<sub>2</sub>NH, DMA), principally as  
591 (H<sub>2</sub>SO<sub>4</sub>)<sub>2</sub>·(CH<sub>3</sub>)<sub>2</sub>NH.HSO<sub>4</sub><sup>-</sup> (m/z = 337.9527) and as (H<sub>2</sub>SO<sub>4</sub>)<sub>3</sub>·(CH<sub>3</sub>)<sub>2</sub>NH.HSO<sub>4</sub><sup>-</sup> (m/z = 435.9210) but also one  
592 larger cluster, (H<sub>2</sub>SO<sub>4</sub>)<sub>7</sub>·(CH<sub>3</sub>)<sub>2</sub>NH.HSO<sub>4</sub><sup>-</sup> (m/z = 827.7893) was identified. Similarly to the finding of Brean et  
593 al. (2021) who detected various SA-amine clusters around the peninsula, SA-DMA-H<sub>2</sub>O driven nucleation  
594 could also occur leading to formation rates significantly higher than those observed in the SA-NH<sub>3</sub>-H<sub>2</sub>O system  
595 (Kürten et al., 2014; Almeida et al., 2013). In fact, as shown in laboratory studies, (negative) ion composition  
596 from API-TOF analysis likely matches the cluster composition of the neutral clusters in NPF (Schobesberger  
597 et al., 2013). The appearance of DMA in the SA dimer and trimer suggests sufficient DMA to trigger nuclea-  
598 tion; while the NH<sub>3</sub> in larger clusters is consistent with much higher NH<sub>3</sub> gas concentrations that then dominate  
599 nano-particle growth. This highlights that DMA is 1000 times more effective than NH<sub>3</sub> for nucleation; so that  
600 sub-ppt DMA and 100 – 1000 ppt levels (and above) of NH<sub>3</sub> could explain the ion cluster distribution observed  
601 in Figure 7.

Commented [QLLJ38]: RC2>> TC16

Deleted: 6

602  
603 Individual MSA-related ions can be identified (cf. Fig. 7, orange dots) at m/z = 94.9808 and m/z = 192.9482,  
604 respectively. Several studies have shown the possible role of MSA in aerosol processes, including nucleation  
605 (Hodshire et al., 2019) - especially with involvement on SA-DMA clusters (Bork et al., 2014). However, in  
606 our case, MSA was only found as CH<sub>3</sub>SO<sub>3</sub><sup>-</sup> and as CH<sub>3</sub>SO<sub>3</sub>H.HSO<sub>4</sub><sup>-</sup>. MSA was not observed in larger clusters  
607 solely composed of SA, NH<sub>3</sub> and DMA and therefore likely does not contribute to the nucleation observed on  
608 that day (at least not through to negative ion pathway).

Commented [QLLJ39]: RC2 >> SC9

Commented [QLLJ40]: RC2>>TC17

609  
610 Finally, we identified the presence of halogen compounds, (cf. Fig. 7, yellow and green dots), such as Br<sup>-</sup> (m/z  
611 = 78.9189), I<sup>-</sup> (m/z = 126.9050), IO<sub>3</sub><sup>-</sup> (m/z = 174.8898), HIO<sub>3</sub>NO<sub>3</sub><sup>-</sup> (m/z = 237.8854), HIO<sub>3</sub>HSO<sub>4</sub><sup>-</sup> (m/z =  
612 272.8571). The presence of halogenated species as natural ions could also indicate that these compounds con-  
613 tribute to aerosol processes. However, these ions were only identified as small halogen clusters of low molec-  
614 ular weight and with only low signal intensity. Considering previous observations in the arctic and coastal  
615 environment (Sipilä et al., 2016) only shows iodine-related nucleation as successive addition of multiple iodic  
616 acid and water group, it is unlikely that IA promotes nucleation either through neutral or ion-induced mecha-  
617 nism at this Antarctic site.

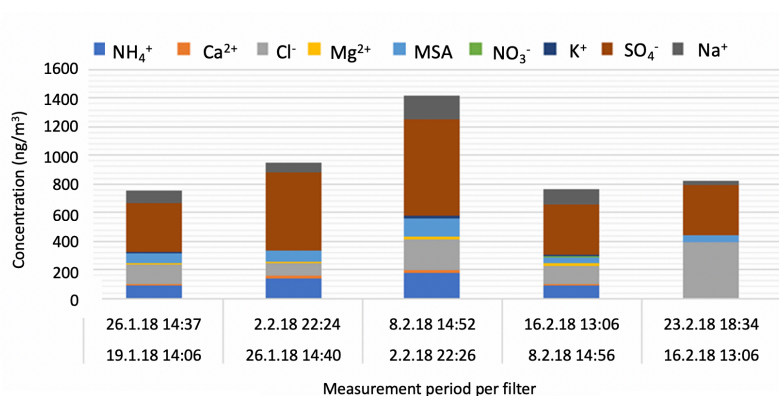

Commented [QLLJ41]: RC2 >> SC10

Deleted: represented by

Commented [QLLJ42]: RC2 >> SC11

Deleted: because only small halogen clusters (e.g., with ni-  
trate or sulfuric acid) were found at low mass range and in  
relatively small abundance added to the fact that no further  
clustering was seen as IA/water addition as observed in the  
Arctic and coastal environments by Sipilä et al. (2016), it is  
unlikely that IA significantly promoted nucleation either  
through neutral or ion-induced mechanism at this site.

### 3.3.3 Chemical composition of the aerosol phase

Formatted: Justified, Indent: Left: 1,27 cm, First line: 1,27 cm, Line spacing: 1,5 lines  
Formatted: Centred, Line spacing: 1,5 lines

Figure 8: Chemical composition of water-soluble ions from weekly fine aerosol samples (PM2.5).

Asmi et al. (2018) reported aerosol chemical composition from weekly filter analysis containing marine-originated sea salt aerosols and the presence of ammonium, sulfate, nitrate and mesylate (CH<sub>3</sub>SO<sub>3</sub><sup>-</sup>). Here, we performed the identical analysis, which agrees with the previously reported results.

Until February 16<sup>th</sup>, the fine aerosol composition remains rather constant with high amounts of non-sea salt sulphate (nss-sulphate, i.e., sulphate - 0.246 × sodium - in mass concentration, Brewer (1975)) which is partly neutralized by ammonia and a significant contribution from secondary marine MSA. The presence of Na<sup>+</sup>, Cl<sup>-</sup> and Ca<sup>2+</sup> ions also indicates contribution from primary marine sea salt and continental soil minerals. Aerosol composition and mass concentrations are very similar to those found in Asmi et al. (2018) for Marambio summer aerosol. The highest concentrations of ions are measured during the active nucleation period in the beginning of February. By the end of the month, the concentrations of MSA, ammonium and calcium ions decrease. No indications of anthropogenic contamination is found in the samples.

The bulk aerosol chemical composition (Fig. 8) reflects rather well the observed cycle of the secondary particle formation and provides further evidence of the important role of sulphate/sulfuric acid, methane sulfonate, and ammonia in the production and especially in the growth of Antarctic secondary aerosol. The qualitative agreement of gas-phase and particle-phase compositions indicates that it is likely possible that these compounds originate from similar marine/coastal sources.

661 Backward trajectories from sampled air masses (Fig. 9) were analyzed and seen to originate mostly  
662 from the West sector passing through the Southern Ocean before surrounding the Peninsula from its Northwest  
663 side - coinciding with the observed wind directions. The observed trajectories could explain the low concen-  
664 tration of IA, whose variability was independent of NPF occurrence due to (1) the absence of travel over the  
665 Weddell littoral seaside prior to the NPF or (2) because the algae bloom on the melting sea ice – possibly  
666 responsible for an increase reactive iodine of organic origin- has already occurred earlier in the season. On the  
667 other hand, the air is clearly enriched in MSA and SA when passing over the ocean that has the highest DMS  
668 concentration over the Dec-Feb months (Lana et al., 2011). In some instances, air mass trajectories are seen to  
669 turn over the north of the peninsula, which can indicate a possible enrichment of gas produced by the fauna on  
670 the land or at the shore (e.g., local source of ammonia and amines from penguin colony established at approx.  
671 8 km South of the sampling site during summertime). With a majority of trajectories originating from the  
672 Bellingshausen sea, NH<sub>3</sub> and various type of amines likeley originate from the (melting) ocean as discussed  
673 in Dall'Osto et al. (2017).

674 ↓  
675 Figure 9c also shows altitudes of the air mass trajectories. While (Kerminen et al., 2018) reviewed that Ant-  
676 arctic NPF would easily take place within the free troposphere, both the number size distribution and the  
677 indicated altitude flight path point toward nucleation processes occurring at the surface layer considering the  
678 lifetime ( $\lambda$ ) of key gas-phase precursors (e.g.,  $\lambda_{SA} < 0.5$  h, Fiedler et al. (2005)). Similar back trajectories were  
679 calculated for non-event days, separately for days with high SA concentration (i.e., [SA] > 2 × 10<sup>6</sup> molecules  
680 cm<sup>-3</sup>) and for days with lower SA (Fig. S5a-c and Fig. 5a'-c', respectively). The result of the analysis as well  
681 as the model characteristics are shown in the Supplementary Information.

Local wind analysis (Fig. S6) was performed to determine possible local emission sources. In essence, no prevalent wind direction was found specifically for NPF days. However, in some instances, moderate to strong winds were seen to originate from the South/South-West sector where strong emission from the fauna is likely to occur by the shore at this season. Those days, 25 January (event # 3), 10 February (event # 9), and 11 Feb (event # 10), were among the highest growth ( $GR_{3,8-12} = 10 \text{ nm h}^{-1}$ ) and the highest formation rates ( $J_{1,5} = 10 \text{ cm}^{-3} \text{ s}^{-1}$  and  $J_{1,5} = 9.2 \text{ cm}^{-3} \text{ s}^{-1}$ ), respectively, which agree with our hypothesis attributing high emissions of e.g., ammonia / amines to the bird colony. On the other hand, Event #12 has a different trajectory and prevalent wind direction against the South sector. Given the fact that the anion mass defect (Fig.7) suggests significant presence of ammonia and possibly DMA on this event, specifically, nitrogen-containing base compounds origin can be explain by bio-mechanism from the zoo/phytoplankton in the Antarctic ocean.

714 **4 Discussion**

715  
716 We observed the presence of many chemical constituents with significant, measurable concentrations,  
717 especially during aerosol formation events:

718  
719 (1) IA daily maximum concentrations showed low variability, independent of NPF occurrence. Its  
720 concentration - only rarely over  $10^6$  molecules  $\text{cm}^{-3}$ - was unlikely sufficient to initiate NPF alone  
721 as compared with previously reported concentrations of  $10^8$  molecules  $\text{cm}^{-3}$  and  $(>) 8 \times 10^6$  mol-  
722 ecules  $\text{cm}^{-3}$  for Arctic and coastal studies (Sipilä et al., 2016; Baccarini et al., 2020; Beck et al.,  
723 2021). Iodine emissions have been connected to sea-ice conditions and photolabile iodine com-  
724 pounds that are rapidly oxidized (Saiz-Lopez et al., 2015; He et al., 2021). The colder Weddell  
725 Sea provides high potential for the emission of iodine and thus iodic acid in the atmosphere. How-  
726 ever, the temporality is a key factor governing such emissions. In fact, many studies have shown  
727 that IA concentration in polar-marine environment are usually peaking in early spring - already  
728 before the sea ice melt onset - (Saiz-Lopez et al., 2007) and during the refreezing transition period  
729 (Baccarini et al., 2020), strongly linking Iodic acid emissions with the sea ice state. This alterna-  
730 tively implies that our measurement period was then not optimum to catch iodine-related vapors  
731 maxima since the neighboring sea ice – key surface emission medium - was already melted around  
732 the Seymour Island. We do not exclude the possibility that IA would contribute to NPF in other  
733 seasons, but our data set show that during the summer period, from mid-January until the end of  
734 February, IA is likely not substantial.

735  
736 The high concentrations of SA suggest that SA plays a key role in nucleation similarly to earlier  
737 observations from Antarctica (Jokinen et al., 2018) and from the Arctic (Beck et al., 2021). The  
738 significantly higher nucleation rates, with similar concentrations of SA, contrast with those studies  
739 that concluded that sulfuric acid – ammonia ion induced nucleation was the primary pathway to  
740 new particle formation. The reported new particle formation rates were systematically below  $1$   
741  $\text{cm}^{-3} \text{s}^{-1}$ , typically ca. 2 orders of magnitude lower than observed in our study despite comparable  
742 air temperatures.

743  
744 Taking the case study of 16 February as an example, we found sulfuric acid – ammonia complexes  
745 with high abundance from the analysis of natural ion chemical composition (Fig. 7). That would  
746 indicate that at least negative ion-induced nucleation pathway proceeds with sequential addition  
747 of SA and  $\text{NH}_3$ . However, the total nucleation rate was  $3.6 \text{ cm}^{-3} \text{ s}^{-1}$  on this day, much larger than  
748 the negative ion induced nucleation rate of  $0.06 \text{ cm}^{-3} \text{ s}^{-1}$ . This would lead to the conclusion that a  
749 neutral nucleation mechanism could dominate the process in our case.

756 Outside the case study, nucleation rates are still remarkably high, often exceeding the ion-induced  
757 nucleation rate limit set by ion-production rate of ca. 2 ion pairs  $\text{cm}^{-3} \text{s}^{-1}$  by galactic cosmic radi-  
758 ation. While the exact nature of neutral mechanism is not directly detected, the parameterization  
759 experiments performed in the CERN CLOUD-chamber (Dunne et al., 2016; Kürten, 2019) indi-  
760 cate that very high concentrations of ammonia would be needed to explain the observed nucleation  
761 rates – above ppb levels, under assumption that the ternary SA-NH<sub>3</sub>-H<sub>2</sub>O mechanism was solely  
762 responsible for initial nucleation.

- (2) Another possibility is that dimethyl amine – as detected in negative ion spectra (cf. Fig. 7) - effi-  
763 ciently nucleates with sulfuric acid and could be primarily responsible for neutral new particle  
764 SA-H<sub>2</sub>O-DMA formation pathway, as discussed in several studies (Kürten et al., 2014; Brean et  
765 al., 2021). Unfortunately, the deployed instrumentation does not allow the determination of DMA  
766 concentrations to assess the exact contribution of DMA on nucleation. Yet, our observation shows  
767 significantly higher nucleation rates than the reported values of both studies and, considering the  
768 range of measured SA concentrations, this conjecture is not likely to happen alone but rather as a  
769 possible synergetic effect of both amines and ammonia in the nucleation with sulfuric acid and  
770 water at the encountered temperatures.

- (3) In addition to the high quantity of SA and MSA measured in CI mode, MSA was observed in ion-  
771 cluster in form of  $\text{CH}_3\text{SO}_3^-$  and MSA clusters with bisulfate ion but not in any larger nucleating  
772 cluster. Its contribution to a possible ion-induced nucleation mechanism is therefore unlikely in  
773 our case. However, we still cannot exclude the possibility that MSA would be weakly bounded to  
774 ion clusters and then evaporated inside the mass spectrometer vacuum chambers and lost in semi-  
775 energetic collisions within the electric fields used to focus ions inside the system. Additionally,  
776 mesylate (i.e., the MSA fragments -  $\text{CH}_3\text{SO}_3^-$ ) were observed in significant fraction in the chemi-  
777 cal speciation of the aerosol phase, which indicates its involvement in particle growth.

- (4) The missing link is the (high) concentration of ammonia and amines required to follow the pro-  
782 posed SA-(NH<sub>3</sub>/DMA)-H<sub>2</sub>O nucleation scheme, likely on the order of ppb for ammonia and ppt  
783 levels for DMA. Without direct measurement of neither NH<sub>3</sub> nor DMA, we can only speculate  
784 that our observations point toward a strong source, possibly land-based (e.g., from high penguin  
785 population during summertime) or marine-based (e.g., emissions from plankton biological activ-  
786 ity from the (melting) ocean). In fact, predominant wind possibly passing over a penguin colony  
787 at shore was seen from the wind roses proposed in Figure S6 for event 3, 4, 7, 9, and 10 and  
788 confirmed by the air mass trajectory analysis (Fig. 9). Yet, for our case study (event 12) - proving  
789 significant contribution of ammonia / DMA to detected in ion clusters - , nor the wind analysis nor  
790 the backward trajectory analysis point toward emission sourcing from the bird colony. We do not

805  
806 (5) MSA, together with DMA, NH<sub>3</sub> and SA, could potentially nucleate via a neutral, yet unidentified  
807 mechanism. However, this potential mechanism does not manifest itself in chemical composition  
808 of negative ion clusters, and potentially would only occur as neutral. It is also important to consider  
809 that our measurement relies on clusters that are stable enough to be analyzed in the very low-  
810 pressure chamber of the TOF, and thus might not be detectable with all species or molecular cluster  
811 possibly present in the real atmosphere. Further investigations of nucleation potential of MSA  
812 including the aforementioned compounds as mixture are required before MSA can be attributed  
813 to be responsible for our observed high nucleation rates that we observe at Marambio.

814  
815 (6) To this remains the question of organics; our data set do not show substantial presence of HOMs  
816 (as characterized in forest environments), and possible detected compounds entering in our estimation – yet unidentified chemically, and which can also represent instrumental chemical background – could be low-volatility organic compounds originating from marine environment that may contribute to the growth to some extent (Weller et al., 2015; Kecorius et al., 2019).

820  
821 (7) A possible explanation for our observations of higher-than-expected nucleation and growth rates  
822 is that particle formation and growth could occur primarily at colder temperatures at higher altitudes, which would enhance both SA-NH<sub>3</sub> and SA-DMA nucleation. Nucleated particles would then be transported to lower altitudes resulting in apparently higher nucleation and growth rates.  
823  
824 This in turn, suggest more regional emission sources rather than local emissions of SA, NH<sub>3</sub> or  
825 DMA as our analysis points toward. However, further investigations on vertical mixing would  
826 have been needed to confirm vertical distribution of nucleation and growth rates.

## 828 5 Conclusion

829  
830  
831 The Austral summer campaign 2018 at the Marambio Antarctic research station revealed very active  
832 aerosol processes and a frequency of new particle formation events of ~ 40 %. Out of 35 days of active measurement, a total of 13 NPF events were identified and characterized. In Marambio, NPF was promoted by key  
833 meteorological factors: high radiation (clear sky conditions), low humidity conditions (incl. the absence of  
834 precipitation), and high temperature – close to zero or above. We retrieved formation and growth rates for neutral and charged particles measured within 1.5 nm up to 800 nm size range - combining nCNC, NAIS and  
835  
836

Commented [QLLJ62]: RC2>>TC29

Deleted: well known

840 DMPS instrumentation. As a reference, the formation rate of 3-nm (neutral) particles ( $J_3$ ) during NPF was on  
841 average  $0.6863 \text{ cm}^{-3} \text{ s}^{-1}$  and the growth rate ( $GR_{4-12 \text{ nm}}$ ) was on average  $4.2 \text{ nm.h}^{-1}$ . Those values are particularly  
842 high in comparison with the literature, the comparison remains even more surprising considering the most  
843 active NPF day where  $J_{1,5}$  reached  $19 \text{ cm}^{-3} \text{ s}^{-1}$  and  $GR_{4-12 \text{ nm}}$  was  $10.9 \text{ nm.h}^{-1}$ . The chemical analysis of gas-  
844 phase aerosol precursors with CI-API-TOF showed high concentrations of SA and MSA - on average  $5.17 \times$   
845  $10^5 \text{ molecules cm}^{-3}$  and  $1.18 \times 10^6 \text{ molecules cm}^{-3}$ , respectively – but quite low concentration of IA (on average  
846  $2.06 \times 10^5 \text{ molecules cm}^{-3}$ ). All chemical species reached their maxima during mid-day (e.g., with maximum  
847 concentration of  $2.56 \times 10^7$ ,  $2.32 \times 10^7 \text{ molecules.cm}^{-3}$ , respectively for SA and MSA during aerosol formation  
848 events). The ubiquitously high SA concentration (peaking at almost  $10^7 \text{ molecules cm}^{-3}$  during many events)  
849 and the high abundancy of SA-associated ion clusters makes no doubt on its involvement on NPF. The speci-  
850 cation of negative ion spectra revealed clusters of dimethylamine – sulfuric acid – bisulfate-ions, as well as  
851 various clusters of sulfuric acid - ammonia- bisulfate-ion - consistent with previously reported studies. How-  
852 ever, the systematically high formation / growth rates cannot be quantitatively explained by SA-(DMA/  $\text{NH}_3$ )-  
853  $\text{H}_2\text{O}$  NPF pathways without direct measurement of DMA and  $\text{NH}_3$  gas phase concentrations. Additionally,  
854 consistently high concentrations of MSA during daytime suggests a possible role of MSA in the growth, along  
855 with SA and ammonia - as confirmed by the bulk aerosol chemical composition. Herein, the mechanism of  
856 forming secondary aerosol in the peninsula involves a combination of SA, DMA,  $\text{NH}_3$  and MSA (and only  
857 relatively low contribution of IA, at least at this time of the year). Better understanding the synergetic effect  
858 of DMA/ $\text{NH}_3$  at these temperatures and environments require more field measurements and simulated exper-  
859 iments, specifically including direct measurement of DMA and  $\text{NH}_3$  concentrations.

877 **Author's Contribution**

878  
879 **EA** and **MS** supervised the project. **EA** initiated the measurement container deployment and is responsible for  
880 the large size aerosol and auxiliary measurements data from the measurement container. **LLJQ** co-organized  
881 the project, prepared, set up and performed the measurements, analyzed the data, and wrote the manuscript.  
882 **LLJQ** operated the instrumentation with the help of **EA**, **JEF** and **GEC**. **EA**, **MS** and **TJ** supervised the  
883 analysis and contributed to the scientific discussion in collaboration with **DW**. **LLJQ** analyzed the gas-phase  
884 measurements and produced most figures. **LD** processed, analyzed, and discussed the aerosol phase data, pre-  
885 pared by **TC**, **JL**, **GPF** and **EA**. **LB** and **MA** analyzed the chemical composition of bulk aerosols. **EA** per-  
886 formed the backward trajectory analysis and its relevant figures. All co-authors contributed to the scientific  
887 discussion, commenting and the revision of the manuscript.
