22 23 24 **Abstract**

25
26 Understanding chemical processes leading to the formation of atmospheric aerosol particles is crucial
27 to improve our capabilities in predicting the future climate. However, those mechanisms are still inadequately
28 characterized, especially in polar regions, which are typically representative of the pre-industrial era in climate
29 models. In this study, we report observations of neutral and charged aerosol precursor molecules and chemical
30 clusters composition (qualitatively and quantitatively), as well as air ions and aerosol particle number
31 concentrations and size distributions from the Marambio research station (64°15'S - 56°38'W), located North
32 of the Antarctic Peninsula. We conducted measurements during the austral summer, between 15 January and
33 25 February 2018. The scope of this study is to characterize New Particle Formation (NPF) event parameters
34 and connect our observations of gas phase compounds with the formation of secondary aerosols to resolve the
35 nucleation mechanisms at the molecular scale. NPF occurred on 40 % of measurement days (i.e., 13 NPF
36 events were recorded during 35 days). All NPF events were observed during sunny days (i.e., sufficient
37 radiation), mostly with above freezing temperatures and low relative humidity ($RH < 80\%$). The averaged
38 formation rate for 3 nm particles (J_3) was $0.686 \text{ cm}^{-3} \text{ s}^{-1}$ and the average particle growth rate ($GR_{3.8-12 \text{ nm}}$) was
39 4.2 nm h^{-1} . Analysis of neutral aerosol precursor molecules showed measurable concentrations of iodic acid
40 (IA), sulfuric acid (SA) and methane sulfonic acid (MSA) throughout the entire measurement period with
41 average concentrations of 5.17×10^5 , 1.18×10^6 , $2.06 \times 10^5 \text{ molecules cm}^{-3}$, respectively. MSA and SA
42 concentrations significantly increased during NPF events. We highlight SA as a key contributor to NPF
43 processes, while IA and MSA would likely only contribute to particle growth. Mechanistically, anion clusters
44 of dimethylamine (DMA)-bisulfate (2SA) as well as numerous ammonium-(bi)sulfate clusters were identified,
45 with the latter at mass-to-charge ratios (m/z) larger than 1000 Th. All of which suggests elevated concentration
46 of both ammonia and amines in the atmosphere. Those species are likely contributing to NPF events since SA
47 alone is not sufficient to explain observed nucleation rates. Here, we provide evidence of the marine origin of
48 the measured chemical precursors and discuss their potential contribution to the aerosol phase. Our
49 observations highlight the importance of the Antarctic Ocean, water, and ice ecosystems interacting with the
50 land-fauna - the plausible sources of the principal precursor molecules hereby investigated - for secondary
51 aerosol formation.

1 Introduction

Atmospheric aerosol particles impact the planetary energy budget and radiation balance by influencing cloud optical properties and cloud lifetime (Ipcc, 2013). Even though they are crucial for regulating the climate, aerosol particles remain insufficiently characterized, especially in remote regions. Understanding the atmospheric processes in places where anthropogenic influence is minimal, such as polar regions, is important for characterizing the pre-industrial-like atmosphere. At the same time, polar environments are significantly impacted by human-induced climate change and are warming twice as fast as the global average (Stuecker et al., 2018). Additionally, polar ecosystems and landscapes are more and more being disturbed by increasing average temperatures that further affect emissions of trace gases into the atmosphere.

Aerosol particles have been observed and characterized in many places in the Arctic and Antarctica (Shaw, 1979; Shaw, 1988; Asmi et al., 2010; Kerminen et al., 2018; Sipilä et al., 2016; Dall'Osto et al., 2017; Jokinen et al., 2018; Dall'Osto et al., 2018; Herenz et al., 2019; Baccarini et al., 2020; Dall'Osto et al., 2019; Beck et al., 2021; Brean et al., 2021). Antarctic primary particles, mainly originating from sea spray or blowing snow, only weakly contribute to total particle number concentration (Lachlan-Cope et al., 2020). Secondary formation of aerosol particles, on the other hand, is believed to be the principal contributor to cloud condensation nuclei (CCN) (Jokinen et al., 2018; Kerminen et al., 2018). These secondary aerosols originate from nucleation of gas phase molecules, typically condensing oxidation products of locally or regionally emitted vapors. Once formed, neutral or charged molecular clusters can grow by condensation of gases to sizes where they can act as CCN. The process of aerosol nucleation followed by subsequent growth is called new particle formation (NPF). Only a few studies have observed nucleation mode particles (sub-10 nm) from Antarctica - including oceanic, coastal, and continental areas - (Asmi et al., 2010; Virkkula et al., 2009; Järvinen et al., 2013; Kyrö et al., 2013; Weller et al., 2015; Jokinen et al., 2018; Kerminen et al., 2018; Lachlan-Cope et al., 2020; Brean et al., 2021) and only two of those report molecular clusters forming from precursor gases in coastal sites (Jokinen et al., 2018; Brean et al., 2021).

Previously identified aerosol precursor vapors include sulfuric acid (Kulmala et al., 2013; Sipilä et al., 2010), iodic acid (Sipilä et al., 2016; Baccarini et al., 2020) and iodous acid (He et al., 2021), or highly oxygenated organic molecules (HOMs, Ehn et al., 2014; Bianchi et al., 2019; Kirkby et al., 2016). On the other hand, nucleating ion clusters such as bisulfate ions with sulfuric acid and ammonia (Kirkby et al., 2011; Yan et al., 2018; Jokinen et al., 2018; Beck et al., 2021), bisulfate ions and neutral sulfuric acid with dimethyl amine (DMA, Kürten et al., 2014), were previously identified to participate in aerosol formation processes.

At Marambio, ABOA, and Princess Elisabeth coastal Antarctic stations, air mass trajectories during NPF events indicated a dominant role of the Southern Ocean as a source of aerosol particles, which chemical aerosol composition analysis confirmed by the abundance of e.g., marine-originated sulfates (Asmi et al., 2010; Herenz et al., 2019; Jokinen et al., 2018). These studies suggest that NPF is linked to sulfur-containing compounds originating from dimethyl sulfide ((CH₃)₂S, DMS). At the Antarctic coast, oceanic DMS concentrations are the highest during December to January with concentration that could exceed 15 nM within the upper 10 m layer of the ocean around the Peninsula compared to a yearly average of ~5 nM (Lana et al., 2011). DMS has two well-known oxidation products formed from gas-phase reaction with OH radicals: sulfuric acid (H₂SO₄, SA, formed via sulfur dioxide, SO₂) and methane sulfonic acid (CH₃SO₃H, MSA), which can then initiate particle formation and subsequent particle growth.

Iodic acid (IA) was also found to significantly contribute to NPF in marine and polar environments (Sipilä et al., 2016; Baccarini et al., 2020; He et al., 2021). Although the chemical production of iodic acid is not fully resolved, IA results from the oxidation of reactive iodine (He et al., 2021) – in the form of I₂, HIO, or intermediate I - itself sourcing from algae/phytoplankton emissions contained within the sea water/ice/snow and exchanged into the atmosphere (Saiz-Lopez and Von Glasow, 2012). At the Antarctic Peninsula, the Weddell Seaside – that undergoes consistent and recurrent phytoplankton bloom episodes every early spring - is a potential reservoir for iodic acid emissions, especially due to slower ice retreat during the summer and colder sea surface temperature than the Southern Ocean on the north and west-side of the peninsula.

1 This work aims at characterizing the gas-phase aerosol precursors naturally emitted from the marine/ice
2 ecosystem and from the Antarctic continent with comprehensive gas phase and aerosol measurements
3 performed at the Marambio research station, Antarctica. We present a characterization of atmospheric NPF
4 events observed in the Antarctic Peninsula. We provide an extensive analysis of number size distributions of
5 atmospheric aerosols and naturally charged ions, from ~1 nm to 800 nm. We also report the formation rates
6 (J) and growth rates (GR) of the observed particle formation events. Our core analysis describes gas-phase
7 composition and NPF precursors by mass spectrometry measurements of the concentration of SA, MSA and
8 IA and by identifying the composition of ambient ions present during NPF events. We combine our results for
9 the chemical composition of both gas- and aerosol-phases to discuss sources of precursor vapors producing
10 secondary aerosol in the Antarctic Peninsula.

11 12 **2 Methods**

13 14 **2.1 Measurement site**

15
16 In-situ atmospheric gas- and particle-phase measurements were performed at the Argentinian
17 Antarctic Station Marambio (64°15'S - 56°38'W) located on the Seymour Island in the northeastern-most part
18 of the Antarctic Peninsula. Geographically, the island is on the north edge of the Weddell Sea. The station is
19 operated year-round, with extensive scientific and logistic activities during the summer. The campaign
20 instrumentation was located inside a laboratory container, specifically designed for continuous atmospheric
21 composition measurements, sufficiently away (approx. 800 m) from the station main buildings and ideally
22 placed fore-wind from the airstrip. Comprehensive measurements of atmospheric composition and
23 meteorology have been carried out in this location since 2013. A description of the Marambio station
24 surroundings, the measurement container, and some previous results can be found in earlier publications, e.g.,
25 Asmi et al. (2018).

26 27 **2.2 Austral summer campaign 2018**

28
29 The austral summer campaign in 2018 for measuring the precursors contributing to NPF at the
30 Marambio station was planned for the warm season, when the probability of NPF occurrence is high (Fiebig
31 et al., 2014; Kerminen et al., 2018). The aim was to characterize NPF events, formation, and growth
32 parameters, and resolve the aerosol chemical precursors from their source to their chemical pathways leading
33 to nucleation. We measured concentrations of size segregated aerosol particles (~ 1 – 800 nm diameter) from
34 19 January to 23 February and chemical information of possible gas-phase precursors from 30 January to 20
35 February, continuously (whenever possible).

36 37 **2.3 Instrumentation**

38 39 ***Measurements of aerosols and their gas-phase precursors***

40
41 We deployed a large suite of instruments, briefly described below. Instrument principles and
42 operations are given in detail in the *Supplementary Information*.

43
44 (1) The chemical composition and concentration of neutral molecules was measured by a nitrate-based
45 Chemical Ionization Atmospheric Pressure interface Time Of Flight (CI-API-TOF, ToFwerk A.G.) mass
46 spectrometer (Jokinen et al., 2012). Its high-resolution analysis identifies and quantifies potential ambient gas-
47 phase aerosol precursors, such as SA, MSA, IA, or HOMs. In some instances, we used the API-TOF to directly
48 measure atmospheric ions (i.e., naturally charged anions or cations), allowing only atmospheric ions to enter
49 the instruments (i.e., with no added chemical ionization) (cf. *Supplementary information*).

50
51 (2) A nano Condensation Nucleus Counter (nCNC) combining a Particle Size Magnifier (PSM, Airmodus
52 Ltd.) with a Condensation Particle Counter (CPC, Airmodus Ltd.) was employed to measure nano-particle
53 concentration in the diameter range from 1 nm to 3 nm. The instrumentation and data inversions are extensively
54 described in Vanhanen et al. (2011), Kangasluoma et al. (2016), Chan et al. (2020) and Lehtipalo et al. (2022)
55 (cf. *Supplementary information*).

1
2 (3) A Neutral cluster and Air Ion Spectrometer (NAIS, Airel Ltd., Mirme and Mirme, 2013) provided number
3 size distributions of neutral particles and naturally charged atmospheric clusters in the size range from 2 to 42
4 nm and from 0.8 to 42 nm, respectively. NAIS is well described in the literature and was operated according
5 to the instructions of Manninen et al., 2016. (cf. *Supplementary information*).

6
7 (4) Aerosol particle size distributions were measured with a Differential Mobility Particle Sizer (DMPS): a
8 Vienna-type Differential Mobility Analyzer (DMA) for particle size separation (Wiedensohler et al., 2012),
9 followed by a Condensation Particle Counter (CPC; TSI model 3772) for particle counting. The particle size
10 distribution was measured in 25 separate size bins at a 6-minute time resolution. This measurement has been
11 carried out continuously since the year 2013 but only data measured during the summer 2018 campaign are
12 presented here. (cf. *Supplementary information*).

13
14 The CI-API-TOF, nCNC and NAIS were operated with individual (horizontal) inlet lines with a minimum
15 length (1 m, 0.8 m, and 0.9 m, respectively) to minimize losses of nanoparticles. The DMPS was operated in
16 the station's common inlet (PM10, Asmi et al., 2018) and equipped with an additional PM₁ cyclone to prevent
17 super micron particles from entering the setup.

18 19 *Ancillary measurements*

20
21 Meteorological parameters were measured on the roof of the measurement container and recorded on
22 a data logger (QML201L, Vaisala Ltd.) since 2013. Measured parameters include temperature and relative
23 humidity (HMP155, Vaisala Ltd.), atmospheric pressure (PTB220, Vaisala Ltd.), wind speed and wind
24 direction (ultrasonic anemometer: Thies 2D, Thies Clima), and radiation (pyranometer: CMP11,
25 Kipp&Zonen).

26 27 *Chemical composition of the aerosol phase*

28
29 Aerosol samples for chemical analysis were collected using a virtual impactor (VI, Loo and Cork,
30 1988)), in which particles were divided to two size fractions (fine ($DP < 2.5 \mu\text{m}$) and coarse ($2.5 \mu\text{m} < DP <$
31 $10 \mu\text{m}$). Flow rate of the VI was $16.7 \text{ L}\cdot\text{min}^{-1}$, of which $15 \text{ L}\cdot\text{min}^{-1}$ is used to collect the fine particles and the
32 remaining $1.7 \text{ L}\cdot\text{min}^{-1}$ is used for collection of the coarse particles. Particles were collected on 47-mm Teflon
33 filters. Sampling time was one week. Collected filters were stored on petri slides and kept in a freezer (-18
34 $^{\circ}\text{C}$) until analysis.

35
36 The mass concentrations of sodium (Na^+), ammonium (NH_4^+), potassium (K^+), magnesium (Mg^{2+}), calcium
37 (Ca^{2+}), chloride (Cl^-), nitrate (NO_3^-), sulphate (SO_4^{2-}), methane sulfonic acid (MSA) and oxalate were
38 determined from the filter substrates. Cation and anion analyses were done simultaneously with two ion
39 chromatography systems (Dionex ICS-2000). Filters were extracted in 10 mL of Milli-Q water with 10-min
40 gentle rotation just before chemical analysis. The uncertainty of the IC analysis was estimated according to the
41 analysis of standards as 5 % to 10 %, depending on the ion analyzed. In this study chemical composition of
42 the fine particles is only presented.

43 44 **2.4 Characteristics of New Particle Formation events**

45
46 NPF events were identified based on the appearance of particles in the nucleation mode (3 - 25 nm)
47 showing signs of growth (e.g., particles reaching $> 10 \text{ nm}$). A classification method was originally proposed
48 by Dal Maso et al. (2005) based on DMPS data. In this study, we combined both DMPS and NAIS data to
49 extend our observations to smaller sizes (Dada et al., 2018).

50
51 Condensation sink (CS, s^{-1}), which is a measure of how rapid precursor vapor concentrations are lost to pre-
52 existing particles, was calculated using the particle number size distribution measured by the DMPS following
53 the method proposed by Kulmala et al. (2012).

54

1 Growth rates (GR) of particles between 3.8 nm to 12 nm were calculated using the 50 % appearance time
2 method (Lehtipalo et al., 2014; Dada et al., 2020). Formation rates ($J_{1.5}$, J_3 , J_5 , and J_{10}) were calculated using
3 the balance equation where the change in concentration of particles inside a size bin is equivalent to the sources
4 (J_{Dp}) minus the available sinks ($F_{Coag} + F_{Growth}$), as in Kulmala et al. (2012).

$$(1) J_{Dp} = \frac{dN_{Dp}}{dt} + CoagS_{Dp} \cdot N_{Dp} + \frac{GR}{\Delta Dp} \cdot N_{Dp}$$

7 where Dp represents the lower diameter of the bin, N_{Dp} is the particle number concentration inside the size bin,
8 and GR is the growth rate of particles out of the bin. ΔDp is the difference between the upper and lower ends of
9 the size bin of interest.

11 The coagulation sink ($CoagS_{Dp}$) is a measure of how rapid freshly formed particles of diameter Dp are lost to
12 pre-existing particles and is calculated as follows:

$$(2) CoagS_{Dp} = \int K(Dp, Dp') n(Dp') dDp' \cong \sum_{Dp'=Dp}^{Dp'=maxK} K(Dp, Dp') N_{Dp'}$$

16 where $K(Dp, Dp')$ is the coagulation coefficient of particle sizes Dp and Dp' , those inside the bin of J_{Dp} and
17 those of pre-existing particles, respectively. N_{Dp} is the number concentration of the pre-existing particles.

19 In this work, the formation rates of 1.5 nm particles ($J_{1.5}$) were calculated using nCNC data in the size range of
20 1.5 nm to 3 nm. Formation rates J_3 , J_5 and J_{10} were calculated using NAIS data (total particle mode – using the
21 DMA of negative voltage) at the size ranges of 3 - 7 nm, 5 - 9 nm, and 10 - 14 nm, respectively. During events
22 when the GR could not be calculated (i.e., four events in total) – due to the absence of continuous growth
23 within the size ranges -, a median growth rate calculated of all the events occurring in the same month was
24 used to estimate the formation rate as described by Kulmala et al. (2022).

26 In addition, the charged particle formation rates ($J_{1.5}^{\pm}$ and J_2^{\pm}) were calculated using ion number
27 concentration measured by NAIS in both polarities, whenever possible, to determine the contribution of ion
28 induced nucleation to the overall formation rate, according to the following equation:

$$(3) J_{Dp}^{\pm} = \frac{dN_{Dp}^{\pm}}{dt} + CoagS_{Dp} \cdot N_{Dp}^{\pm} + \frac{GR}{\Delta Dp} \cdot N_{Dp}^{\pm} + \alpha \cdot N_{Dp}^{\pm} \cdot N_{<Dp}^{\pm} - \chi \cdot N_{Dp} \cdot N_{<Dp}^{\pm}$$

32 where N_{Dp}^{\pm} is the concentration of ion in a given size range with a lower limit of 1.5 or 2 nm
33 (depending on the J associated size range) and the upper limit ΔDp being larger than that. The
34 coefficient α is the ion-ion recombination coefficient and χ is the ion-aerosol attachment coefficient. α
35 and χ were $1.6 \times 10^6 \text{ cm}^{-3} \cdot \text{cm}^{-1}$ and $0.01 \times 10^6 \text{ cm}^{-3} \text{ s}^{-1}$, respectively (Kulmala et al., 2012).

3 Results

3.1 Ambient conditions: Meteorological parameters

41 Ambient meteorological conditions during the campaign are presented in Figure 1. Many sunny days
42 are observed, occurring with above-zero degrees Celsius ambient temperatures, high radiation, and relative
43 humidity below 75 %. Even though the measurement site belongs to the Antarctic continent, its position - at
44 relatively high latitude ($64^{\circ}15'S$) - gives daily solar cycles with zero radiation during the short summer
45 nighttime periods (cf. Fig. 1b). During daytime, higher radiation enhances photo-active emissions from the
46 sea/land ecosystems and promotes atmospheric photochemistry. This is expected to lead to day-time
47 appearance of gas-phase molecules and/or molecular clusters of condensing vapors that can lead to new
48 particle formation and/or aerosol growth. Furthermore, since temperatures above freezing also lead to ice
49 melting (especially in the Weddell Sea area), they are likely to enhance chemical fluxes between thinning ice,
50 ocean, and air (Notz, 2009). These clear sky, warm, sunny days during summertime are known to be optimal
51 weather conditions for NPF to occur in the mid-latitude regions (Dada et al., 2017) and in the Arctic (e.g.,
52 Beck et al. 2021) and Antarctic regions (Weller et al., 2015; Jokinen et al., 2018; Baccarini et al., 2020; Brea

1 et al., 2021). Analysis of winds (cf. Fig. 1e) revealed that periods of the highest temperature are seen when
2 wind is blowing from north, bringing warmer air across from the Southern Ocean. Predominant winds were
3 seen from North-Northwest and South-Southwest sectors. The strongest winds were recorded from the South
4 (180°), also driving primarily cold air from the continental plateau, agreeing with Asmi et al. (2018).
5

6
7 **Figure 1:** Time series of meteorological parameters: (a) temperature (dark blue), dew point (light blue), (b) global radiation (orange),
8 (c) relative humidity (light green), (d) atmospheric pressure (blue green), (e) wind direction (dark blue bars) and wind speed (medium
9 blue line). The data are presented with a 10-min resolution and reference time set as local standard, UTC-3.

3.2 Observation & Characterization of NPF events

A total of 13 NPF events (occurring on 12 days) were observed during the 35-day summer campaign. Figure 2a shows the continuous size distribution series over the total measurement period from NAIS measurement (size range: 1.8 – 42 nm) and Figure 2b combined the data from nCNC (size shown: 1.2 – 2.7 nm), the NAIS (2.7 nm - 12 nm), and the DMPS (12 nm – 800 nm). Daily number size distribution plots are shown for the 12 event days separately in supplementary (Fig. S3) as well as continuous size distribution series for ion mode (Fig. S4).

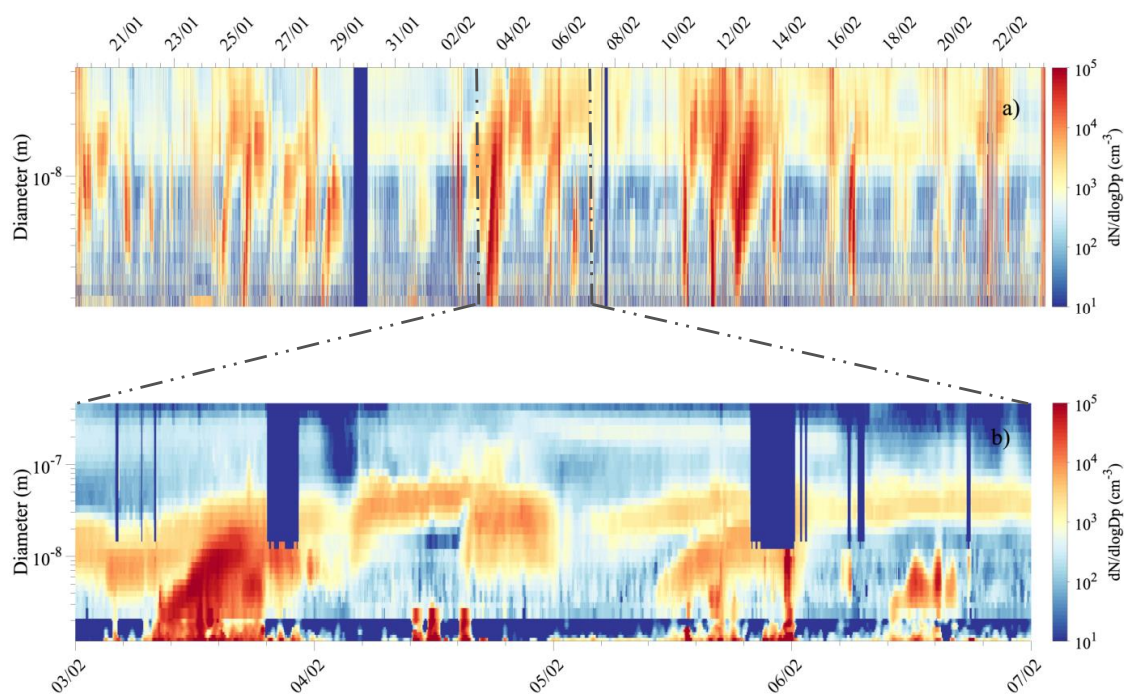

Figure 2: a) Number size distribution from NAIS measurement from 1.8 nm to 42 nm over the whole measurement campaign and b) combined size distribution of aerosol particle from 1.2 nm to 800 nm for 3-7 February 2018. The last surface plot combines data from nCNC (1.2 - 2.7 nm), NAIS (particle mode, 2.7 - 12 nm) and DMPS (12-800 nm), whenever the data were available and according to DMPS data flag (only unpolluted data are shown from the DMPS measurements).

During each of the NPF events observed during the campaign, high population of sub-3 nm aerosol particles were seen with concentration larger than 10^4 cm^{-3} . The particles were observed to grow to Aitken mode size range (25 - 100 nm) but rarely reached the accumulation mode sizes (i.e., > 100 nm) (cf. Fig. 2b).

Strong NPF events were identified before midday - local time - (66 % of events), lasting longer than events occurring later in the afternoon. Afternoon events (33 % of the total events) never lasted longer than 2.5 hours. NPF events did vary from day to day: On certain days, growth of the particles was interrupted by abrupt changed in wind direction - resulting in an inability to retrieve a growth or a formation rate within reasonable uncertainty (e.g., 28 January) -; on other days multiple NPF events were observed (e.g., 16 February); or NPF events appear to have a bumped shape – appearing sporadically - resembling those observed in the Arctic by Beck et al. (2021) as the events observed on 28 January and 6 February.

Formation rates were calculated for particle sizes of 1.5, 2, 3, 5 and 10 nm particles, as summarized in Table 1.

1 Formation rates of 1.5 nm particles (i.e., $J_{1.5}$) were surprisingly high, reaching the maximum rates of 9.2, 10.0,
2 or even 19 $\text{cm}^{-3} \text{s}^{-1}$, on Feb. 11th, 10th, and 3rd, respectively. These significantly high values are comparable to
3 those calculated for highly vegetated rural location or even urban areas (e.g., Deng et al., 2020; Kontkanen et
4 al., 2016; Yu et al., 2014), which is surprising due to the remote nature of the environment at our measurement
5 site. For example, formation rates for 1.5 nm particle on the order of 0.030 - 0.013 $\text{cm}^{-3} \text{s}^{-1}$ were estimated for
6 the ABOA research station on the other side of the Weddell Sea in East Antarctica (Jokinen et al. 2018). A
7 recent study observing nucleation phenomena at the peninsula close by our measurement location (Brean et
8 al., 2021) found a remarkably high $J_{1.7}$ value reaching up to 3.07 $\text{cm}^{-3} \text{s}^{-1}$ but still lower than our observed
9 values. Although the formation rates at 1.5 nm are higher than those reported previously, the rates for larger
10 particles are comparable owing to the low survival probability of the particles. This could be attributed to
11 sufficient precursor vapors favoring nucleation, while insufficient ones required for fast growth to larger sizes.
12

13 The nucleation rates for 3 nm particles in our study ranged from 0.13 $\text{cm}^{-3} \text{s}^{-1}$ to 3 $\text{cm}^{-3} \text{s}^{-1}$, which were, on
14 average, also significantly higher than 0.03 $\text{cm}^{-3} \text{s}^{-1} < J_3 < 0.14 \text{ cm}^{-3} \text{s}^{-1}$ reported from Jokinen et al. (2018)
15 study or from Kecorius et al. (2019) who showed J_3 values from 0.080 $\text{cm}^{-3} \text{s}^{-1}$ to 0.319 $\text{cm}^{-3} \text{s}^{-1}$ during a polar
16 cruise in the Arctic. On the other hand, our observation agrees with the J_{10} reported by Kyrö et al. (2013)
17 ranging from 0.003 to 0.3 $\text{cm}^{-3} \text{s}^{-1}$, with 0.006 $\text{cm}^{-3} \text{s}^{-1} < J_{10} < 0.37 \text{ cm}^{-3} \text{s}^{-1}$ in our case.
18

19 Additionally, to account for ion induced nucleation, we calculated the formation rates for charged ions of 1.5
20 nm ($J^{+/-}_{1.5}$) separately using the ion concentrations measured with the (N)AIS in ion mode. The formation rates
21 for positive 1.5 ions, $J^{+}_{1.5}$, ranged from 3.6×10^{-4} to $8.3 \times 10^{-2} \text{ cm}^{-3} \text{s}^{-1}$ and $J_{1.5}$ was from 2.2×10^{-3} to 5.4×10^{-2}
22 $\text{cm}^{-3} \text{s}^{-1}$. Our results are significantly lower than the maximum $J_{1.5}$ of 0.33 $\text{cm}^{-3} \text{s}^{-1}$ reported in Beck et al.
23 (2021) or from Kyrö et al. (2013) who showed $0.02 \text{ cm}^{-3} \text{s}^{-1} < J_{1.6} < 4.2 \text{ cm}^{-3} \text{s}^{-1}$ - in two coastal Antarctic sites,
24 but in the range reported from the Arctic ocean by Kecorius et al. (2019, e.g., $0.026 \text{ cm}^{-3} \text{s}^{-1} < J_{1.6} < 0.060 \text{ cm}^{-3}$
25 s^{-1}). In comparison to 1.5 nm-neutral particle formation rates, the ion formation rates do not represent a major
26 contribution (ratio $J_{neutral}/J_{ion} \sim 10^3$), implying that the relatively high neutral nucleation rates are not primarily
27 due to ion-mediated nucleation.
28

29 Particle growth rates were calculated for 3.8 nm to 12 nm diameter size or alternatively up to 11 nm and 8 nm
30 for event #1 and event #13, respectively, whenever the shape of the number size distribution was continuously
31 increasing. Averages for each event are also presented in Table 1. Similarly to formation rates of the smallest
32 particles, the growth rates were remarkably higher ($1.2 \text{ nm h}^{-1} < GR < 10.9 \text{ nm h}^{-1}$) than previously reported
33 for other Antarctic sites. In comparison, Weller et al. (2015) reported growth rates from 3 to 25 nm particle
34 ranging from 0.06 to 0.9 nm h^{-1} at Neumayer III station, Jokinen et al. (2018) showed $0.26 \text{ nm h}^{-1} < GR < 1.30$
35 nm h^{-1} at ABOA and Brean et al. (2021) published growth rates for 4.5 - 10 nm particles of 0.41 nm h^{-1} to 0.58
36 nm h^{-1} measured at the Peninsula. Additionally, Kerminen et al. (2018) reviewed aerosol characterization from
37 many different field studies and indicated an upper growth rate estimation of 5.5 nm h^{-1} (as 95th percentile) in
38 Antarctic sites versus 4.1 nm h^{-1} in Arctic environments. Recent Arctic studies by Kecorius et al. (2019)
39 reported $0.62 \text{ nm h}^{-1} < GR_{(3-7 \text{ nm})} < 4.25 \text{ nm h}^{-1}$ while Collins et al. (2017) reported averaged growth rates of
40 $4.3 \pm 4.1 \text{ nm h}^{-1}$.
41

Table 1: Summary of NPF event classification, formation and growth parameters calculated during the Marambio austral summer campaign. The pollution flag is determined based on DMPS data according to NILU/EBAS format classification at the start time of the event (when data available, 000: clean data, 189: data coming from a possibly polluted sector (e.g., station main buildings), 599: suspected pollution from unknown source). All formation rates are averaged between the start and end of the characterized events.

#	Date (dd/mm)	Start Time (SLT*, hh:mm)	Duration (hh:mm)	Flag (DMPS)	Formation Rates (J_{top} , $\text{cm}^{-3}\text{s}^{-1}$)				Condensation Sink (s^{-1})	Growth Rates ($Gr_{3.8-12}^{**}$, $\text{nm}\cdot\text{h}^{-1}$)
					$J_{1.5}$ ($J_{1.5}^{\text{a}}/J_{1.5}^{\text{b}}$)	$(\phi_2/\phi_1)^*$	J_3	J_5

* Standard local time, UTC -3

** Growth rates were calculated ideally from 3.8 nm to 12 nm. If the growth on that range cannot be determined in that range, the specific range is indicated in subscript as $Gr_{X,Y}^{**}$.

3.3 Chemical composition of the gas-phase precursor molecules

3.3.1 Gas-phase contribution to NPF

Measurements utilizing nitrate based chemical ionization mass spectrometry (CI-API-TOF) detected gas-phase molecules and molecular clusters that have affinity for proton transfer with nitrate reagent ion. These included SA, MSA, and IA, detected as HSO_4^- and $\text{HNO}_3\text{HSO}_4^-$ (m/z 96.9601 Th and 159.9557 Th), CH_3SO_3^- and $\text{HNO}_3\text{CH}_3\text{SO}_3^-$ (m/z 94.9808 Th and 157.9765 Th), IO_3^- and $\text{HNO}_3\text{IO}_3^-$ (m/z 174.8898 Th and 237.8854 Th), respectively. Concentrations were calculated from high resolution peak fitting and reported below. The time series of those compounds during the whole campaign, according to the data availability of the CI operation, are shown in Figure 3.

The measured gas-phase concentrations of the species of interest showed maxima of $\sim 2.6 \times 10^7$ molecules cm^{-3} , $\sim 2.3 \times 10^7$ molecules cm^{-3} and $\sim 3.6 \times 10^6$ molecules cm^{-3} for the total SA, MSA, and IA concentrations, respectively. The three gas-phase compounds seemed to evolve with roughly similar behavior, likely due to favorable weather conditions promoting atmospheric chemical reactions and especially by enhancing photochemical oxidation reactions within a stable boundary layer. A significant and simultaneous increase in SA, MSA, IA concentrations was observed during peaking radiation time at noon and prior to many NPF events, though to a smaller extent for IA. This clearly demonstrates the diurnal nature of the emission of those species, and their transport – especially for SA and IA – as shown in Figure 4. Additionally, it is worth mentioning that even though the MSA concentrations were on average higher than those of SA, event days correlated strongly with peaking SA concentration (then becoming higher than MSA concentration) while IA – whose concentration remained unchanged independently of NPF occurrence – was significantly lower than SA or MSA concentrations.

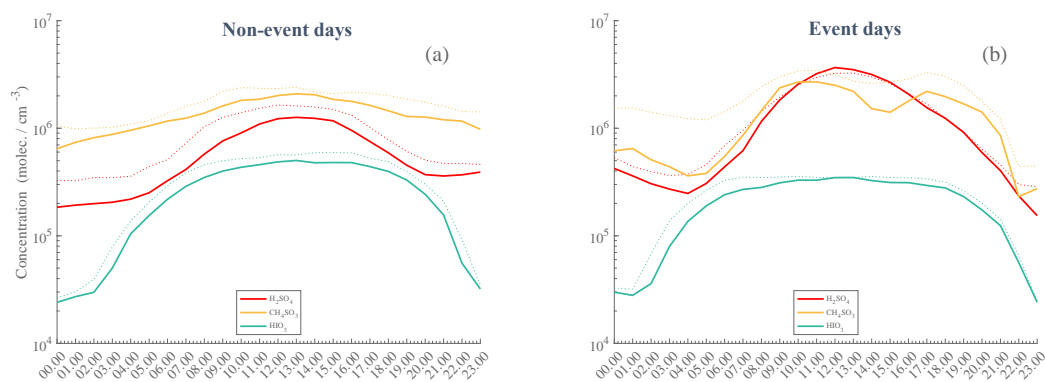

Figure 3: High resolution time series of H_2SO_4 (SA, red), CH_3SO_3 (MSA, orange), HIO_3 (IA, green). Numbers specified on the top of the figure refer to the event number as introduced in the NPF analysis (Cf. Table 1). The data are averaged to 10 min with local time (UTC -3). Note that the missing points are due to switch of the measurement mode and / or data availability.

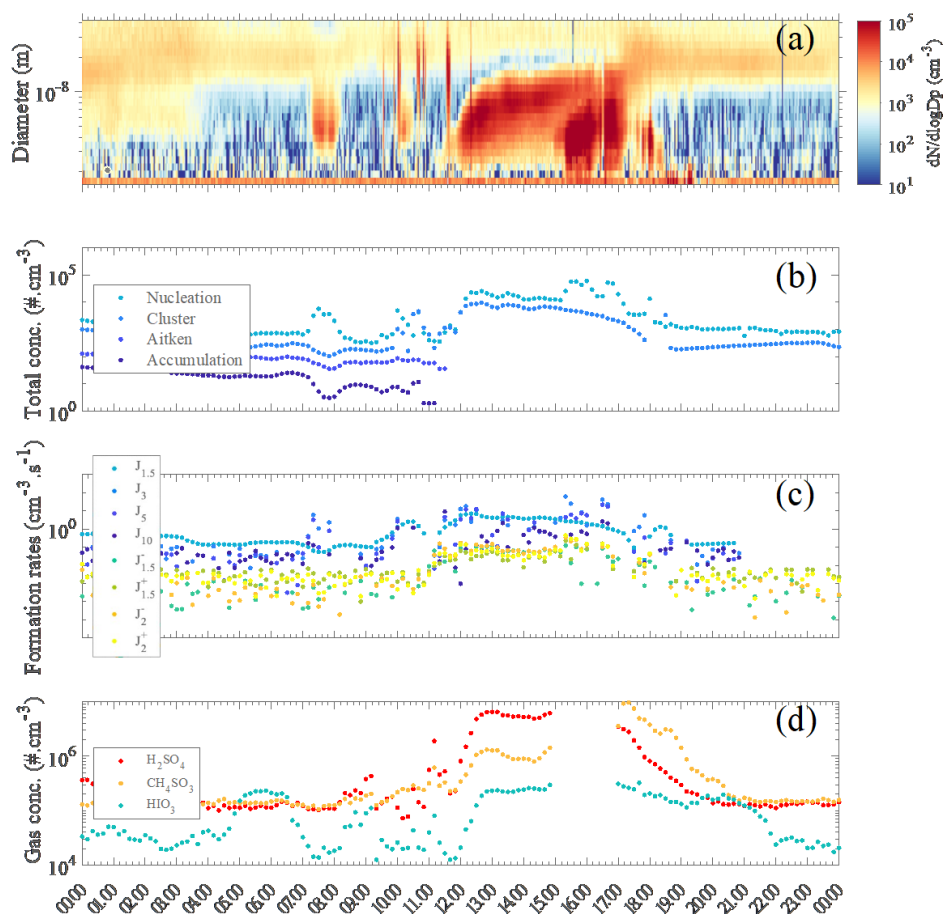

29
30
31 **Figure 4:** Statistical diurnal time series of H₂SO₄ (SA, red), CH₄SO₃ (MSA, orange), HIO₃ (IA, green) observed during non-event days
32 (a) and event days (b). The solid lines represent the median hourly average concentrations, the dotted lines are the concentration means
33 and the colored shaded areas show data points within the 25th and the 75th percentiles. Nighttime is represented by the gray-shaded area
34 with median theoretical sunsets and sunrises occurring during the campaign. The actual sunset and sunrise values could vary approx.
35 +/- 1.25 hours from the beginning to the end of the campaign.

36
37 Figure 4 shows the diurnal variations of SA, MSA and IA for event (b) and non-event days (a), separately. In
38 both figures, we could see a clear rise in concentrations of SA, MSA and IA throughout the day, with maxima
39 observed at midday. While both MSA and SA concentration are on average increasing after sunrise, IA
40 concentration started to increase already during nighttime, shortly after 01:00 SLT, suggesting that strong
41 photochemistry conditions (i.e., direct solar radiation) might not be necessary to produce the observed IA
42 agreeing with He et al. (2021). Earlier studies have shown that IA even anticorrelated with (still omnipresent)
43 solar radiation in more continental Antarctica (Jokinen et al., 2018). It is likely that even very low levels of
44 solar radiation would be sufficient to saturate the iodic acid production (Beck et al., 2021). Distinctively, a
45 clear difference in the statistical series can be seen between event and non-event days, with more than doubled
46 SA concentration at zenith-time (factor of 2.25). MSA concentrations are only slightly higher in the morning
47 and afternoon – with an apparent drop occurring from 14.00 to 16.00 – although the starting concentration at
48 sunrise and sunset are also smaller, depicting strong concentration variability as compared to non-event days.
49 On the other hand, IA is on average lower during event-days – e.g., from $\sim 4.5 \times 10^5$ molecules cm⁻³ vs $\sim 3 \times$
50 10^5 molecules cm⁻³, with a factor of 1.5 smaller at zenith-time. This last observation indicates that IA is likely
51 not a key contributor to particle formation, while the duo SA-MSA could influence the aerosol phase as already
52 suggested by Beck et al. (2021), Hodshire et al. (2019) and Willis et al. (2016).

3.3.2 Molecular characterization of aerosol / ion precursors: Study case of Feb 16th

53
54
55
56
57 The aerosol event observed on 16 February was particularly interesting due to the occurrence of two
58 consecutive NPF events within the same day. An overview of both aerosol concentration / parameters and
59 reactive trace gases concentration for 16 February is shown in Figure 5 with (a) the particle number size
60 distribution series from NAIS measurement, (b) time series of total particle concentration within several size
61 modes (i.e., cluster, nucleation, Aitken and accumulation), (c) estimated *J* rates for 1.5, 3, 5 and 10 nm particle
62 and (d) time series for SA, MSA and IA.

63
64 **Figure 5:** Overview of Aerosol formation event on February 16th, 2018: (a) Number size distribution from NAIS measurements
65 (Particle mode). (b) Concentrations of particles modes (cluster: sub- 3 nm – medium light blue, nucleation: 3 – 25 nm – light blue,
66 Aitken: 25 – 100 nm – medium dark blue, accumulation: 100 – 1000 nm – dark blue). Note that the missing points for Aitken and
67 Accumulation mode are due to data filtering from suspected pollution from the DMPS data set. (c) Formation rate estimation for J_{1.5}
68 (neutral – light blue, (-) – blue green, (+) – green), J₂ ((-) – orange, (+) – yellow), J₃ (medium light blue), J₅ (medium dark blue) and J₁₀
69 (dark blue). Note that the formation rate calculation depends on the condensation/coagulation sinks calculated from the DMPS data.
70 (d) High resolution time series of H₂SO₄ (red), CH₃SO₃ (orange), HIO₃ (green). Note that the data gap is due to ion mode of API-
71 measurement. All data are averaged / estimated with a 10 min time resolution, with standard local time (UTC -3) as clock reference.

72
73 A clear NPF episode occurred from about 11:15 in the morning until sunset with a net increase of cluster and
74 nucleation mode particle concentrations. Close to noontime all trace gases of interest were significantly
75 increasing (Fig. 5d). MSA increased by almost a factor of 10 by 13:00 ($[MSA]_{t=13.00} = 1.3 \times 10^6$ molecules cm⁻³)
76 and by more than 2 orders of magnitude at 16:00 ($[MSA]_{t=17.30} = 9.6 \times 10^6$ molecules cm⁻³) as compared by
77 the minimum baseline of $\sim 2 \times 10^5$ molecules cm⁻³ for both MSA and SA. SA maximum concentration was
78 6.5×10^6 molecules cm⁻³, also observed at 13:00. IA concentrations were fluctuating throughout the day with
79 maximum concentrations of $\sim 2.05 \times 10^5$ molecules cm⁻³ and $\sim 2.35 \times 10^5$ molecules cm⁻³, respectively around
80 05:30 – 06:30 and shortly after 13:00. The net increase of all these gas-phase species occurred quasi-
81 simultaneously as the increase of formation rate of the smallest particles and ions (Fig. 5c), occurring around

82 noon. Interestingly, several sudden, short-lasting increases for all SA, MSA, and IA concentrations were seen
83 even before 13:00, matching bumps in nucleation mode particles around 09:00 and 11:00 and one to two orders
84 of magnitudes increase of cluster mode particles at 11:00. The high concentrations of SA, MSA (and possibly
85 IA) likely trigger the observed aerosol processes (i.e., nucleation and/or growth of particles).

86

87 We investigated the mass spectrum further and show a complementary mass spectrum in Figure S2. Any highly
88 oxygenated organic molecules, HOMs (Bianchi et al., 2019; Ehn et al., 2014) could be reliably resolved from
89 the mass spectra analysis. We estimate that the total oxidized organic contribution, possibly condensable
90 HOM, did not exceed 5.5×10^6 molecules cm^{-3} , between 16:30 and 17:30; assuming mass spectral peaks found
91 above 200 Th with positive mass defect could be HOMs (cf. Supplementary). However, the actual HOM
92 contribution is likely to be only a fraction of this estimation. Therefore, it is unlikely that HOM significantly
93 contributed to nucleation or growth of newly formed particles.

94

95 Specifically for this event, we complemented the CI-API-TOF measurement with negative API-TOF ambient
96 measurement mode, from 14:52 to 15:53, as reported in Table S1. A mass defect (i.e., divergence of ion exact
97 mass-to-charge from the unit resolution to the mass-to-charge ratio of this same ion - determined by the sum
98 of atomic masses of individual atoms contained in the charged molecular cluster) plot from the measurement
99 is depicted in Figure 6.

100

101 **Figure 6:** Mass defect plot for (a) (-) API-TOF measurements, on 16 February from 14.52 to 15.52. The figure type represents the
102 deviation of high resolution fitted peaks normalized to the unit mass detected for each peak y-axis - e.g. $\text{Br}^{\text{exact mass}} = 78.9189$, $\text{Br}^{\text{unit mass}} = 79$, $\text{Br}^{\text{mass defect}} = -0.0811$ - while the x-axis represents the mass range (m/z). Data average is 1 hour for each spectrum to improve
103 the noise to signal ratio and the peak shape statistics.
104

105 The API-TOF ion mode showed TIC maximum values around 50 ions s^{-1} , detecting only ions that are naturally
106 charged. The highest signals (i.e., intensity shown by marker sizes, cf. Fig. 6) are bisulfate and its multimers
107 (H_2SO_4) $_0\text{-}_4\text{HSO}_4^-$, respectively at $m/z = 96.9601$, $m/z = 194.9275$, $m/z = 292.8949$ and $m/z = 390.8622$. Along
108 with SA multimers, successive addition of sulfuric acid and ammonia NH_3 formed clusters represented with
109 the light-blue dots, within the mass range 400 – 1250 Th. These sulfuric acid (bisulfate) - ammonia clusters
110 were found with up to 10 additions of H_2SO_4 and 9 NH_3 on top of the HSO_4^- core ion. In line with previous field
111 observations (e.g., Schobesberger et al., 2015; Bianchi et al., 2016; Jokinen et al., 2018; Yan et al., 2018; Beck
112 et al., 2021; Sipilä et al., 2021) and laboratory studies (e.g., Kirkby et al., 2011; Schobesberger et al., 2015)
113 showed that ammonia is detected only in clusters with 3 or more H_2SO_4 molecules around the HSO_4^- core.
114

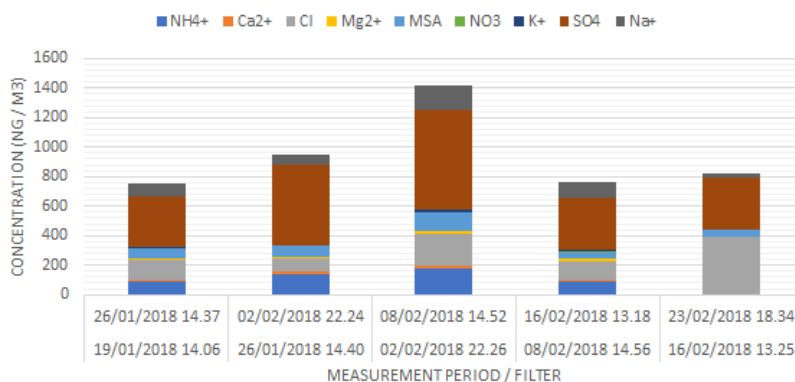

115 The observed presence of ammonia with sulfuric acid in the measured gas-phase ions with relatively high
116 intensity, suggests that the ion induced nucleation was driven by the ternary system SA-ammonia(-water)
117 similar to observations made by Jokinen et al. (2018) in East Antarctica as well as measured in multiple other
118 locations around the globe (e.g., Bianchi et al., 2016; Yan et al., 2018; Beck et al., 2021; Sipilä et al., 2021).

119
120 Additional clusters containing SA and dimethyl amine ((CH₃)₂NH, DMA), principally as
121 (H₂SO₄)₂.(CH₃)₂NH.HSO₄⁻ (m/z = 337.9527) and as (H₂SO₄)₃.(CH₃)₂NH.HSO₄⁻ (m/z = 435.9210) but also one
122 larger cluster, (H₂SO₄)₇.(CH₃)₂NH.HSO₄⁻ (m/z = 827.7893) was identified. Similarly to the finding of Breañ et
123 al. (2021) who detected various SA-amine clusters around the peninsula, SA-DMA-H₂O driven nucleation
124 could also occur leading to formation rate significantly higher than those observed in the SA-NH₃-H₂O system
125 (Kürten et al., 2014; Almeida et al., 2013). In fact, as shown in laboratory studies, (negative) ion composition
126 from APi-TOF analysis likely matches the cluster composition of the neutral clusters in NPF (Schobesberger
127 et al., 2013). The appearance of DMA in the SA dimer and trimer suggests sufficient DMA to trigger
128 nucleation; while the NH₃ in larger clusters is consistent with much higher NH₃ gas concentrations that then
129 dominate nano-particle growth. This highlights that DMA is 1000 times more effective than NH₃ for
130 nucleation; so that sub-ppt DMA and 100 – 1000 ppt levels (and above) of NH₃ could explain the ion cluster
131 distribution observed in Figure 6.

132
133 Individual MSA-related ions can be identified (orange dots) at m/z = 94.9808 and m/z = 192.9482,
134 respectively. Several studies have shown possible role of MSA in aerosol processes, including nucleation
135 (Hodshire et al., 2019) - especially with involvement on SA-DMA clusters (Bork et al., 2014). However, in
136 our case, MSA was only found as CH₃SO₃⁻ and as CH₃SO₃H.HSO₄⁻. MSA was not observed in larger clusters
137 solely composed of SA, NH₃ and DMA and therefore likely does not contribute to the nucleation observed on
138 that day (at least not through to negative ion pathway).

139
140 Finally, we identified the presence of halogen compounds, represented by yellow and green dots, such as Br⁻
141 (m/z = 78.9189), I⁻ (m/z = 126.9050), IO₃⁻ (m/z = 174.8898), HIO₃NO₃⁻ (m/z = 237.8854), HIO₃HSO₄⁻ (m/z =
142 272.8571). The presence of halogenated species as natural ions could also indicate that these compounds
143 contribute to aerosol processes. However, because only small halogen clusters (e.g., with nitrate or sulfuric
144 acid) were found at low mass range and in relatively small abundance added to the fact that no further clustering
145 was seen as IA/water addition as observed in the Arctic and coastal environments by Sipilä et al. (2016), it is
146 unlikely that IA significantly promoted nucleation either through neutral or ion-induced mechanism at this
147 site.

3.3.3 Chemical composition of the aerosol phase

151
152
153 **Figure 7:** Chemical composition of water-soluble ions from weekly fine aerosol samples (PM_{2.5})

154

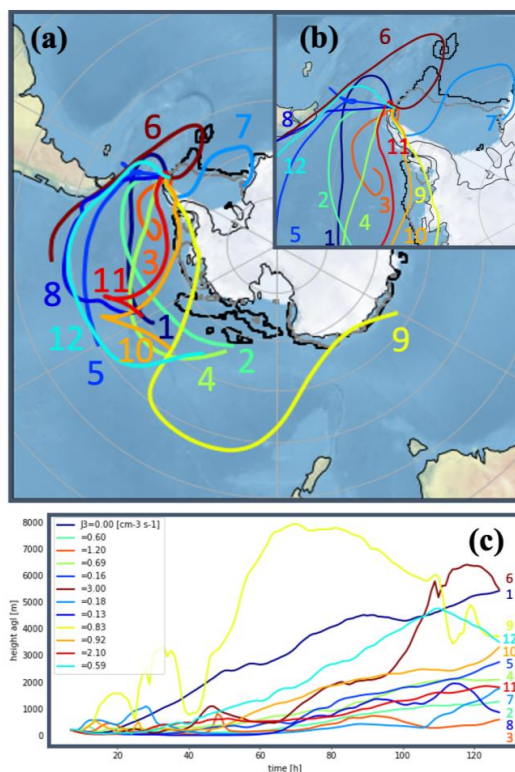

155 Asmi et al. (2018) reported aerosol chemical composition from weekly filter analysis containing
156 marine-originated sea salt and the presence of ammonium, sulfate, nitrate and mesylate (CH_3SO_3^-). Here, we
157 performed the identical analysis, which agrees with the previously reported results.

158
159 Until February 16th, the fine aerosol composition remains rather constant with high amounts of non-sea salt
160 sulphate (nss-sulphate, i.e., sulphate - $0.246 \times$ sodium - in mass concentration, Brewer (1975)) which is partly
161 neutralized by ammonia and a significant contribution from secondary marine MSA. The presence of Na, Cl
162 and Ca ions also indicate contribution from primary marine sea salt and continental soil minerals. Aerosol
163 composition and mass concentrations are very similar to those found in Asmi et al. (2018) for Marambio
164 summer aerosol. The highest concentrations of ions are measured during the active nucleation period in the
165 beginning of February. By the end of the month, the concentrations of MSA, ammonium and calcium ions
166 decrease. No indications of anthropogenic contamination are found in the samples.

167
168 The bulk aerosol chemical composition (Fig. 7) reflects rather well the observed cycle of the secondary particle
169 formation and provides further evidence of the important role of sulphate/sulfuric acid, methane sulfonate, and
170 ammonia in the production and especially in the growth of Antarctic secondary aerosol. The qualitative
171 agreement of gas-phase and particle-phase compositions indicates that it is likely possible that these
172 compounds originate from similar marine/coastal sources.

173 174 **3.3.4 Source of gas-phase precursors**

175
176 Backward trajectories from sampled air masses (Fig. 8) were analyzed and seen to originate mostly
177 from the West sector passing through the Southern Ocean before surrounding the Peninsula from its Northwest
178 side - coinciding with the observed wind directions. The observed trajectories could explain the low
179 concentration of IA, whose variability was independent of NPF occurrence due to (1) the absence of travel
180 over the Weddell littoral seaside proceeding the NPF or (2) because the algae bloom on the melting sea ice –
181 possibly responsible for an increase reactive iodine of organic origin- has already occurred earlier in the season.
182 On the other hand, the air is clearly enriched in MSA and SA when passing over the ocean that has the highest
183 DMS concentration over the Dec-Feb months (Lana et al., 2011). In some instances, air mass trajectories were
184 seen to turn over the north of the peninsula, which can indicate an enrichment of gas produced by the fauna on
185 the land or at the shore (e.g., local source of ammonia and amines from penguin colony established at approx.
186 8 km South of the sampling site during summertime). Figure 8c also shows altitudes of the air mass
187 trajectories. While (Kerminen et al., 2018) reviewed that Antarctic NPF would easily take place within the free
188 troposphere, both the number size distribution and the indicated altitude flight path point toward nucleation
189 processes occurring at the surface layer considering the lifetime (λ) of key gas-phase precursors (e.g., $\lambda_{\text{SA}} < 0.5$
190 h, Fiedler et al. (2005)). Similar back trajectories were calculated for non-event days, separately for days with
191 high SA concentration (i.e., $[\text{SA}] > 2 \times 10^6$ molecules cm^{-3}) and for days with lower SA (Fig. S5a-c and Fig.
192 5a'-c', respectively). The result of the analysis as well as the model characteristics are shown in *Supplementary*
193 *Information*.

194
195 **Figure 8:** Backward trajectories for recorder NPF events (a) (numbering according to classification Table 1). (b) shows a zoom-in over
196 the Antarctic Peninsula and (c) shows the trajectory altitudes colored by formation rates J_3 values. In panel (a) and (b) the black and
197 grey lines delimit the sea ice extent as average for January and February 2018, respectively. Sea ice data are from:
198 <http://sjdads.colorado.edu/DATASETS/NOAA/G02135/south/monthly/> (Fetterer et al., 2017).

199 Local wind analysis (Fig. S6) was performed to determine possible local emission sources. In essence, no
200 prevalent wind direction was found specifically for NPF days. However, in some instances, moderate to strong
201 winds were seen to originate from the South/South-West sector where strong emission from the fauna is likely
202 to occur by the shore at this season. Those days, 25 January (event # 3), 10 February (event # 9), and 11 Feb
203 (event # 10), were among the highest growth ($GR_{3,8-12} = 10 \text{ nm h}^{-1}$) and the highest formation rates ($J_{1.5} = 10$
204 $\text{cm}^{-3} \text{s}^{-1}$ and $J_{1.5} = 9.2 \text{ cm}^{-3} \text{s}^{-1}$), respectively.

205 206 **4 Discussion**

207
208 We observed the presence of many chemical constituents with significant, measurable concentrations,
209 especially during aerosol formation events:

- 210
211 (1) IA daily maximum concentrations showed low variability, independent of NPF occurrence. Its
212 concentration - only rarely over $10^6 \text{ molecules cm}^{-3}$ - was unlikely sufficient to initiate NPF alone
213 as compared with previously reported concentration of $10^8 \text{ molecules cm}^{-3}$ and ($>$) 8×10^6
214 molecules cm^{-3} for Arctic and coastal studies (Sipilä et al., 2016; Baccharini et al., 2020; Beck et
215 al., 2021). Iodine emissions have been connected to sea-ice conditions and photolabile iodine
216 compounds that are rapidly oxidized (Saiz-Lopez et al., 2015; He et al., 2021). The colder Weddell
217 Sea provides high potential for the emission of iodine and thus iodic acid in the atmosphere.
218 However, the temporality is a key factor governing such emissions. In fact, many studies have
219 shown that IA concentration in polar-marine environment are usually peaking in early spring -
220 already before the sea ice melt onset - (Saiz-Lopez et al., 2007) and during the refreezing transition

221 period (Baccarini et al., 2020), strongly linking Iodic acid emission with the sea ice state. This
222 alternatively implies that our measurement period was then not optimum to catch iodine-related
223 vapors maxima since the neighboring sea ice – key surface emission medium - was already melted
224 around the Seymour Island. We do not exclude the possibility that IA would contribute to NPF in
225 other season, but our data set show that during the summer period, from mid-January until the end
226 of February, IA is likely not substantial.

227
228 The high concentrations of SA suggest that SA plays a key role in nucleation similarly to earlier
229 observations from Antarctica (Jokinen et al., 2018) and from the Arctic (Beck et al., 2021). The
230 significantly higher nucleation rates, with similar concentrations of SA, contrast with those studies
231 that concluded that sulfuric acid – ammonia ion induced nucleation was the primary pathway to
232 new particle formation. The reported new particle formation rates were systematically below 1
233 $\text{cm}^{-3} \text{s}^{-1}$, typically ca. 2 orders of magnitude lower than observed in our study despite comparable
234 air temperatures.

235
236 Taking the study case of 16 February as an example, we found sulfuric acid – ammonia complexes
237 with high abundancy from the analysis of natural ion chemical composition (Fig. 6). That would
238 indicate that at least negative ion-induced nucleation pathway proceeds with sequential addition
239 of SA and NH_3 . However, the total nucleation rate was $3.6 \text{ cm}^{-3} \text{ s}^{-1}$ on this day, much larger than
240 negative ion induced nucleation rate of $0.06 \text{ cm}^{-3} \text{ s}^{-1}$. This would lead to the conclusion that a
241 neutral nucleation mechanism should dominate the process in our case.

242
243 Outside the case study, nucleation rates are still remarkably high, often exceeding the ion-induced
244 nucleation rate limit set by ion-production rate of ca. 2 ion pairs $\text{cm}^{-3} \text{ s}^{-1}$ by galactic cosmic
245 radiation. While the exact nature of neutral mechanism is not directly detected, the
246 parameterization experiments performed in CLOUD-chamber CERN (Dunne et al., 2016; Kürten,
247 2019) indicate very high concentration of ammonia would be needed to explain the observed
248 nucleation rates – above ppb levels, under assumption that ternary sulfuric acid – ammonia – water
249 mechanism was solely responsible for initial nucleation.

250
251 (2) Another possibility is that dimethyl amine – as detected in negative ion spectra (cf. Fig. 6) -
252 efficiently nucleates with sulfuric acid and could be primarily responsible for neutral new particle
253 SA- H_2O -DMA formation pathway, as discussed in several studies (Kürten et al., 2014; Brean
254 et al., 2021). Unfortunately, the deployed instrumentation does not allow the determination of DMA
255 concentrations to assess the exact contribution of DMA on nucleation. Yet, our observation shows
256 significantly higher nucleation rates than the reported values of both studies and considering the
257 range of measured SA concentrations this conjecture is not likely to happen alone but rather as a
258 possible synergetic effect of both amines and ammonia in the nucleation with sulfuric acid and
259 water at the encountered temperatures.

260
261 (3) In addition to the high quantity of SA and MSA measured in CI mode, MSA was observed in ion
262 cluster in form of CH_3SO_3^- and MSA clusters with bisulfate ion but not in any larger nucleating
263 cluster. Its contribution to a possible ion-induced nucleation mechanism is therefore unlikely in
264 our case. However, we still cannot exclude the possibility that MSA would be weakly bounded to
265 ion clusters and then evaporated inside the mass spectrometer vacuum chambers and lost in semi-
266 energetic collisions within the electric fields used to focus ions inside the system. Additionally,
267 mesylate (i.e., the MSA fragments - CH_3SO_3^-) were observed in significant fraction in the
268 chemical speciation of the aerosol phase, which indicates its involvement in particle growth.

269
270 (4) The missing link is the (high) concentration of ammonia and amines required to follow the
271 proposed SA-(NH_3 /DMA)- H_2O nucleation scheme, likely on the order of ppb for ammonia and
272 ppt levels for DMA. Without direct measurement of neither ammonia nor DMA, we can only
273 speculate that our observations point toward a strong source, possibly land-based (e.g., from high
274 penguin population during summertime). In fact, predominant wind possibly passing over a
275 penguin colony at shore was seen from the wind roses proposed in Figure S6 for event 3, 4, 7, 9,

- 276 and 10 and confirmed by the air mass trajectory analysis (Fig. 8). Ammonia and amine
277 concentrations are key parameters that need to be assessed to fully understand the nucleation
278 mechanism that our analysis suggests.
279
- 280 (5) MSA, together with DMA, NH₃ and SA, could potentially nucleate via a neutral, yet unidentified
281 mechanism. However, this potential mechanism does not manifest itself in chemical composition
282 of negative ion clusters, and potentially would only occur as neutral. It is also important to consider
283 that our measurement relies on clusters that are stable enough to be analyzed in the very low-
284 pressure chamber of the TOF, and thus might not be detectable with all species or molecular cluster
285 possibly present in the real atmosphere. Further investigations of nucleation potential of MSA
286 including the aforementioned compounds as mixture are required before MSA can be attributed
287 to be responsible for our observed high nucleation rates that we observe at Marambio.
288
- 289 (6) To this remains the question of organics; our data set do not show substantial presence of HOMs
290 (as characterized in forest environments), and possible detected compounds entering in our
291 estimation – yet unidentified chemically, and which can also represent instrumental chemical
292 background – could be low-volatility organic compounds originating from marine environment
293 that may contribute to the growth to some extent (Weller et al., 2015; Kecorius et al., 2019).
294
- 295 (7) A possible explanation for our observations of higher-than-expected nucleation and growth rates
296 is that particle formation and growth could occur primarily at colder temperatures at higher
297 altitudes, which would enhance both SA-NH₃ and SA-DMA nucleation. Nucleated particles would
298 then be transported to lower altitudes resulting in apparently higher nucleation and growth rates.
299 This in turns suggest more regional emission source rather than local emissions of SA, NH₃ or
300 DMA as our analysis points toward. However, further investigations on vertical mixing would
301 have been needed to confirm vertical distribution of nucleation and growth rates.
302

303 5 Conclusion

304
305 The Austral summer campaign 2018 at the Marambio Antarctic research station revealed very active
306 aerosol processes and a frequency of new particle formation events of ~ 40 %. Out of 35 days of active
307 measurement, a total of 13 NPF events were identified and characterized. In Marambio, NPF was promoted
308 by key well known meteorological factors: high radiation (clear sky conditions), low humidity conditions (incl.
309 the absence of precipitation), and high temperature – close to zero or above. We retrieved formation and growth
310 rates for neutral and charged particles measured within 1.5 nm up to 800 nm size range - combining nCNC,
311 NAIS and DMPS instrumentation. As a reference, the formation rate of 3-nm (neutral) particles (J_3) during
312 NPF was on average $0.6863 \text{ cm}^{-3} \text{ s}^{-1}$ and the growth rate ($GR_{4-12 \text{ nm}}$) was on average 4.2 nm.h^{-1} . Those values
313 are particularly high in comparison with the literature, the comparison remains even more surprising
314 considering the most active NPF day where $J_{1.5}$ reached $19 \text{ cm}^{-3} \text{ s}^{-1}$ and $GR_{4-12 \text{ nm}}$ was 10.9 nm.h^{-1} . The chemical
315 analysis of gas-phase aerosol precursors with CI-API-TOF showed high concentrations of SA and MSA - on
316 average $5.17 \times 10^5 \text{ molecules cm}^{-3}$ and $1.18 \times 10^6 \text{ molecules cm}^{-3}$, respectively – but quite low concentration
317 of IA (on average $2.06 \times 10^5 \text{ molecules cm}^{-3}$). All chemical species reached their maxima during mid-day (e.g.,
318 with maximum concentration of 2.56×10^7 , $2.32 \times 10^7 \text{ molecules.cm}^{-3}$, respectively for SA and MSA during
319 aerosol formation events). The ubiquitously high SA concentration (peaking at almost $10^7 \text{ molecules cm}^{-3}$
320 during many events) and the high abundancy of SA-associated ion clusters makes no doubt on its involvement
321 on NPF. The speciation of negative ion spectra revealed clusters of dimethylamine – sulfuric acid – bisulfate-
322 ions, as well as various clusters of sulfuric acid - ammonia- bisulfate-ion - consistent with previously reported
323 studies. However, the systematically high formation / growth rates cannot be quantitatively explained by SA-
324 (DMA/ NH₃)-H₂O NPF pathways without direct measurement of DMA and NH₃ gas phase concentrations.
325 Additionally, consistently high concentrations of MSA during daytime suggests a possible role of MSA in the
326 growth, along with SA and ammonia - as confirmed by the bulk aerosol chemical composition. Herein, the
327 mechanism of forming secondary aerosol in the peninsula involves a combination of SA, DMA, NH₃ and MSA
328 (and only relatively low contribution of IA, at least at this time of the year). Better understanding the synergetic
329 effect of DMA/NH₃ at these temperatures and environments require more field measurements and simulated
330 experiments, specifically including direct measurement of DMA and NH₃ concentrations.

339 (GASPARCON – grant n° 714621 & COALA – grant n° 638703) and EMME-CARE (grant n° 856612). We
340 acknowledge the support from the Academy of Finland (projects n° 296628 and n° 328290), the Center of
341 Excellence program (project n° 307331, 334514, 3282290), and Finnish Academy ACFA (project n° 335845
342 and ACCC Flagship funding (337552). We thank the generous help from the Servicio Meteorológico Nacional
343 - SMN, the Fuerza Aerea Argentina - FAA, and the FINNish Antarctic Research Program – FINNARP. We
344 are thankful for the technical personnel of the Marambio base for their support in cooperation, logistics and
345 measurements. We thank Toftools for providing mass spectrometry analysis tool package for MATLAB.

346

347 **Author's Contribution**

348

349 **EA** and **MS** supervised the project. **EA** initiated the measurement container deployment and is responsible for
350 the large size aerosol and auxiliary measurements data from the measurement container. **LLJQ** co-organized
351 the project, prepared, set up and performed the measurements, analyzed the data, and wrote the manuscript.
352 **LLJQ** operated the instrumentation with the help of **EA**, **JEF** and **GEC**. **EA**, **MS** and **TJ** supervised the
353 analysis and contributed to the scientific discussion in collaboration with **DW**. **LLJQ** analyzed the gas-phase
354 measurements and produced most figures. **LD** processed, analyzed, and discussed the aerosol phase data,
355 prepared by **TC**, **JL**, **GPF** and **EA**. **LB** and **MA** analyzed the chemical composition of bulk aerosols. **EA**
356 performed the backward trajectory analysis and its relevant figures. All co-authors contributed to the scientific
357 discussion, commenting and the revision of the manuscript.
