Abstract. Black carbon (BC) is one of the dominant absorbing aerosol species in the atmosphere. It normally has complex fractal-like structures due to the aggregation process during combustion. A wide range of aerosol-radiation interactions (ARI) of BC has been reported throughout experimental and modeling studies. One reason for the large discrepancies among multiple studies is the application of the over-simplified spherical morphology for BC in ARI estimates. Here, we employ a regional chemical transport model coupled with a radiative transfer code which utilizes the non-spherical BC optical simulations to re-evaluate the effects of particles' morphologies on BC ARI. Anthropogenic activities and wildfires are two major sources of BC emissions. Therefore, we choose four typical polluted cities in East China which are dominated by urban emissions, and three locations in the northwest US that are dominated by fire emissions in this study. Our modeling results show that spherical BC models overestimate the aerosol optical depth (AOD) at 550 nm wavelength up to 0.03 and 0.15 at typical polluted cities in East China and fire regions in the northwest US, respectively, than fractal BC models with a fractal dimension (D_f) of 1.8. Besides, spherical BC model underestimates BC aerosol absorption optical depth (AAOD) at 450 nm up to 0.016 and 0.04 at typical polluted cities in East China and fire sites in the US, respectively, than the fractal BC model. BC morphologies have relatively small impacts on the single scattering albedo (SSA) and extinction Ångström exponent (EAE), while these morphological effects on the absorption Ångström exponent (AAE) are rather significant. The spherical BC models underestimate AAE by approximately 0.17 at 450 and 850 nm wavelength pair than the fractal counterparts. Besides, BC morphologies have non-negligible impacts on the BC ARI. The calculated mean ARI using the spherical BC model is approximately 3.47 – 4.45 Wm^{-2} at typical polluted cities in China, while the values increase to approximately 3.83 – 4.92 Wm^{-2} when using the fractal aggregate model, and the relative variations are approximately 10.4% – 15.3%. The mean BC ARI increases from approximately 4.91 – 6.61 Wm^{-2} to 5.52 – 7.05 Wm^{-2} and the relative variations for BC ARI are approximately 6.2% – 6.9%

20 when we modify the BC from spheres to fractal aggregates with a D_f of 1.8 in the northwest US. Therefore, the effects of BC morphologies on the regional radiative effects should be carefully evaluated in different regions.

1 Introduction

Black carbon (BC), as the main absorbing aerosol in the atmosphere, exerts a positive radiative forcing, and lofts smoke plumes (Buseck and Buseck, 2000; Streets et al., 2006; Moosmüller et al., 2009). However, there are still large uncertainties
25 in evaluating the BC radiative effects. An important cause of the discrepancy is BC's complex morphology. BC morphologies are commonly simplified as homogeneous spheres in climate modeling. However, many studies have shown that BC particles, especially those nascent ones, have fractal-like structures. The spherical assumption for BC can lead to a large deviation from the field measurement data and non-spherical simulated results (Chakrabarty et al., 2007; Luo et al., 2018c; He et al., 2015; Liu and Mishchenko, 2005; Luo et al., 2018d; Mishchenko et al., 2016a; Luo et al., 2021b). Based on the sampled BC images,
30 researchers found that the shape of uncoated BC aggregates can be fitted well by a fractal law with monomer number (N_s), mean monomer radius (R), fractal prefactor (k_0), fractal dimension (D_f) and the radius of gyration (R_g) (Mishchenko et al., 2002; Sorensen, 2011; Luo et al., 2021a):

$$N_s = k_0 \left(\frac{R_g}{R} \right)^{D_f} \quad (1)$$

Previous studies have shown that aggregated particle models are more realistic to reproduce the optical measurement results (Bi et al., 2018; Luo et al., 2019, 2018b). Some studies have used the non-spherical BC models to investigate the radiative
35 properties of BC (Wu et al., 2015; Liu et al., 2015a; Liu and Mishchenko, 2005; Yin and Liu, 2010; Teng et al., 2019; Luo et al., 2018a; Kahnert, 2010a). However, extremely limited number of studies have evaluated the ARI of non-spherical BC in regional or global climate models. Kahnert (2010b) has made efforts to simulate the radiative properties of freshly emitted BC using the Multiple-scale Atmospheric Transport and CHemistry (MATCH) model. That study assumed a fixed solar zenith angle (SZA) and restricted the modeling region in Western Europe. However, expanding the modeling range to regions with
40 different emission characteristics is important to understand the effects of BC sources on aerosol-radiation interactions (ARI).

The direct radiative effect (DRE) was widely used to evaluate the climate effects of aerosol (Bond et al., 2013; Saleh et al., 2015). IPCC (2014) suggested using the new terminology of ARI instead of DRE. Thus, in this work, we use the terminology of ARI to replace DRE. A global mean BC ARI of $+1.1 \text{ W m}^{-2}$ has been reported by Bond et al. (2013). However, the BC ARI values estimated based on in-situ optical measurements in some regions are much larger than the rest. BC emissions in China
45 roughly account for one-fourth of its global anthropogenic emission budget (Streets et al., 2001). East China, a typical polluted region, is dominated by anthropogenic emissions (Zhang et al., 2009; Li et al., 2017a). Therefore, BC ARI in East China has gained increasing interest.

Besides the anthropogenic sources, wildfires significantly contribute the regional BC emissions. The extremely-high BC ARI can be found in those fire sites. Recent studies have shown that BC emitted from fire sites can also loft the surrounding
50 atmospheric aerosols to the upper troposphere and lower stratosphere (Yu et al., 2019). Thus, the investigation of BC ARI in

these regions is important to understand the detailed plume dynamics and the warming effects of BC. The northwest US, as one of the most frequent wildfire regions in the world, has also been investigated in addition to East China.

In this work, we employed Weather Research and Forecasting coupled to Chemistry (WRF-Chem) to simulate the aerosol mass concentrations. Note here that WRF-Chem assumes aerosols to be spherical. Therefore, the radiative parameters of aggregated models were calculated offline using an optical module, Flexible Aerosol Optical Depth (FlexAOD). We calculated the ARI at the top of the atmosphere (TOA) using the radiative transfer model (libRadtran) after the particles' optical properties were calculated. Among all the radiative parameters, we investigated aerosol optical depth (AOD), aerosol absorption optical depth (AAOD), extinction Ångström exponent (EAE), absorption Ångström exponent (AAE), single-scattering albedo (SSA), and ARI at the TOA, which were widely used in remote sensing and climate effect evaluation.

60 2 Aerosol distribution simulation

In this work, WRF-Chem version 4.1.3 was used to simulate the transport of atmospheric species. Two areas were selected to represent the BC sources with different emission characteristics. East China, a main polluted region in the world, represented the typical polluted urban region. It consists of 115 east-west grids and 105 south-north grids centered at 112.00°E, 35.00°N with a grid resolution of 18 km. North America, one of the most frequent forest fire regions in the world, was also investigated in this work. The fire region consists of 120 east-west grids and 120 south-north grids centered at 121.48°W, 39.89°N with a grid resolution of 4 km. The schematics of the two studied regions are shown in Figure S1. Both regions have 33 vertical layers above the ground, with a top pressure of 50 hPa.

We used the Model of Emissions of Gases and Aerosols from Nature (MEGAN) to compute the biogenic emissions over two regions (Guenther et al., 1994, 2006). The anthropogenic emission inventory is vital to estimate the aerosol distributions. The anthropogenic inventory in the mainland of China was compiled by the multi-resolution emission inventory for China (MEIC) (Li et al., 2014; Liu et al., 2015b) for East China in the year 2016. We used MIX anthropogenic inventory for the region outside China (Li et al., 2017b). The Regional Acid Deposition Model version 2 (RADM2) atmospheric chemical mechanism (Stockwell et al.) and the Model Aerosol Dynamics for Europe with the Secondary Organic Aerosol Model (MADE/SORGAM) were applied in this study (Seinfeld et al., 2001; Ackermann et al., 1998). Fast-J photolysis scheme (Wild et al., 2000) was used to simulate the photolysis rates. The physical scheme options in WRF-Chem are shown in Table S1.

The EDGAR-HTAP anthropogenic inventory for 2010 was used in the North American region. MOSAIC aerosol scheme (Zaveri and Peters, 1999; Zaveri et al., 2008) and CBM-Z (carbon bond mechanism) photochemical mechanism (Zaveri and Peters, 1999) was used in forest fire region simulation. The Fire emission was provided by the Fire INventory from NCAR (FINN) (Wiedinmyer et al., 2011). Note here EDGAR-HTAP anthropogenic inventory and FINN were provided for the MOZART chemical mechanism, so we manually mapped the emission for the MOZART chemical mechanism to the CBM-Z chemical mechanism based on the study of Emmons et al. (2010). The National Center for Environmental Prediction (NCEP) Global Forecast System's final gridded analysis data set was used to provide the meteorological initial and boundary conditions. The chemical initial and boundary conditions were obtained from the Model for Ozone and Related Tracer, version 4 (MOZART-4).

3 Calculating the ARI of BC

85 3.1 The morphology of BC

In this work, we only consider externally mixed BC aerosols, which is commonly represented by fractal structures. D_f is a key parameter to describe the compactness of fractal BC (Wang et al., 2017; Yuan et al., 2019), and the BC morphology can vary from a chain-like structure to a spherical structure if D_f increase from approximately 1.8 to 3. The freshly emitted BC generally exhibits a fluffy structure with a D_f of approximately 1.8 (Heinson et al., 2010, 2017). The laboratory measurements
90 also showed that the freshly emitted BC generally presents a small D_f . Chakrabarty et al. (2006) have shown that D_f of BC emitted from wildland fuels generally exhibits a range of 1.67 – 1.83. A D_f range of 1.6 – 1.9 was observed for BC produced from diesel combustion (Wentzel et al., 2003). China et al. (2013) indicated that the BC freshly emitted from wildfire generally exhibits a D_f range of 1.74 – 1.92. However, a more compact structure was commonly observed for BC in the atmosphere with the particle aging (Li et al., 2003; Adachi et al., 2014; Chen et al., 2016; Adachi et al., 2007). A D_f range of 2.2 – 2.4
95 was observed in the study of Adachi et al. (2007). The fractal structures with a larger are widely used to describe the BC with more compact structures (Adachi et al., 2007). Chakrabarty et al. (2006) further showed that the D_f of aged BC can reach up to 2.6. To represent both fluffy and compact BC, D_f s of 1.8, 2.2, and 2.6 were considered. Even though k_0 was also measured in a wide range in the atmosphere, its impact was relatively small, so we assumed a fixed k_0 of 1.2 in this work. The typical morphologies of fractal BC are shown in Figure 1.

100 The volume-mean particle radius was commonly used to describe the size of non-spherical BC. N_s and R are two important parameters to describe the volume-mean particle radius of BC. Previous studies have observed a range of approximately 8 – 57 nm for BC monomer radius (Eggersdorfer and Pratsinis, 2012; Mikhailov et al., 2006; KOylU and Faeth, 1992; Lee et al., 2002), while Kahnert and Kanngießner (2020) further showed that the typical range is approximately 10 – 25 nm. In this work, we assumed a fixed monomer radius of 20 nm. We considered an N_s range 1 – 1000 to represent BC with different sizes. The
105 volume-mean particle radius (r_p) can be calculated using:

$$r_p = RN_s^{1/3} \quad (2)$$

We must clarify that BC can internally mix with other compositions, and the morphology can become more complex (Wang et al., 2021, 2017). However, we mainly focus on the freshly emitted BC, and only consider externally mixed BC. Further investigations would be performed for more complex internally mixed BC in the future.

110 3.2 The refractive index and size distribution of BC

BC refractive index shows a little spectral dependence (Chang and Charalampopoulos, 1990), while it doesn't vary largely with wavelengths in the short wavelength range, and the absorption Ångström exponent is approximately 1 (Liu et al., 2018; Lack and Cappa, 2010). Therefore, BC refractive index is commonly assumed to be spectrally invariant (Bond and Bergstrom, 2006). The suggested BC refractive index values by Bond and Bergstrom (2006) were commonly used. In this work, the median
115 value of $1.85 + 0.71i$ was used, as it was widely used in many regional and global climate models (e.g. WRF-Chem). The size

distribution of BC and OC also suffers large uncertainties from different fuels and conditions. The size distribution of BC is commonly fitted by a lognormal size distribution with a geometric mean radius (r_g), and a geometric standard deviation (σ_g) (Schwarz et al., 2008; Mishchenko et al., 2016b):

$$n(r_p) = \frac{N_0}{\sqrt{2\pi}r_p \ln(\sigma_g)} \exp \left[- \left(\frac{\ln(r_p) - \ln(r_g)}{\sqrt{2} \ln(\sigma_g)} \right)^2 \right] \quad (3)$$

120 where r_p is the aerosol radius, N_0 is the total number concentration calculated by the mass concentration obtained from WRF-Chem by assuming BC mass density, r_g , and σ_g . The details about the calculation of N_0 are shown in Curci (2012). Firstly, by assuming $N_0 = 1$, we created a look-up table for different r_g and σ_g , and then the optical properties were obtained by plugging in the tested BC's r_g and σ_g .

125 BC geometric mean radius of 0.05 – 0.06 μm is frequently observed by instruments and widely assumed in numerical studies (Alexander et al., 2008; Coz and Leck, 2011; Reddington et al., 2013; Liu et al., 2018). In this work, BC geometric mean radius was assumed to be 0.05 μm . σ_g was assumed to be a fixed value of 1.6. We used the volume-equivalent radius of non-spherical BC to characterize the BC size. The density of BC was assumed to be 1.8 gm^{-3} based on the suggested values by Bond and Bergstrom (2006).

3.3 BC radiative properties

130 In this work, BC radiative properties were calculated using the multiple sphere T-matrix method (MSTM) (Mackowski and Mishchenko, 2011, 1996). Using MSTM, the extinction efficiency (Q_{ext}), scattering efficiency (Q_{sca}), and phase function (P) can be directly calculated. Then, extinction cross-section (C_{ext}) and scattering cross-section (C_{sca}) were obtained using:

$$C_{ext} = Q_{ext} \pi r_p^2 \quad (4)$$

$$C_{sca} = Q_{sca} \pi r_p^2 \quad (5)$$

135 where r_p represents the volume-equivalent radius of non-spherical BC. In this work, we have calculated the optical properties of BC with a N_s range of 1 – 1000. Bulk extinction cross-section ($\langle C_{ext} \rangle$), scattering cross-section ($\langle C_{sca} \rangle$) and phase function $\langle P \rangle$ were calculated using the following equations:

$$\langle C_{ext} \rangle = \int_{r_{min}}^{r_{max}} C_{ext}(r_p) n(r_p) dr \quad (6)$$

$$\langle C_{sca} \rangle = \int_{r_{min}}^{r_{max}} C_{sca}(r_p) n(r_p) dr \quad (7)$$

$$\langle P(\theta) \rangle = \frac{\int_{r_{min}}^{r_{max}} C_{sca}(r_p) P(\theta, r_p) n(r_p) dr}{\langle C_{sca} \rangle} \quad (8)$$

140 In climate modeling, instead of using the phase function, the Legendre expansion coefficients were commonly used:

$$\langle P(\theta) \rangle = \sum_{S=1}^{S_{max}} \alpha_S P_S(\cos\theta) \quad (9)$$

where θ is the scattering angle, P_S are generalized spherical functions, α_S are the expansion coefficients, and S_{max} is the order of truncation of the expansion. In this work, we used the pmom code in the Libradtran software to calculate the Legendre expansion coefficients. The asymmetry parameter (g) was calculated using:

$$145 \quad g = \int_0^\pi \cos\theta \langle P(\theta) \rangle \sin\theta d\theta \quad (10)$$

The radiative properties of fractal BC and BC spheres were calculated at 300 nm – 4000 nm wavelengths. The step size of $\Delta\lambda = 50$ nm was chosen when λ is less than 1000 nm, while $\Delta\lambda = 200$ nm was selected for $1000 \text{ nm} \leq \lambda \leq 2000$ nm, and $\Delta\lambda = 400$ nm when $\lambda \geq 2000$ nm. We created look-up tables for $\langle C_{abs} \rangle$, $\langle C_{sca} \rangle$, and the Legendre expansion coefficients of phase functions for each σ_g and r_g . Thus, the optical properties of BC can be obtained by interpolating the look-up tables.

150 3.4 Flexible Aerosol Optical Depth (FlexAOD)

The aerosol mass concentrations from WRF-Chem were inputted into an optical software FlexAOD (Flexible Aerosol Optical Depth) (Curci, 2012; Curci et al., 2015) for the calculation of the aerosol radiative properties. FlexAOD is an optical post-processing tool for the chemistry-transport model, and it started as a tool for the Geos-Chem model. We have made some modifications on FlexAOD to make it accommodate the WRF-Chem outputs. We firstly mapped the aerosols from WRF-Chem
155 into 5 categories: BC, organic carbon(OC), inorganic salt (INS), sea salt (SA), and dust (DST). The mapping details are shown in Tables S2 – S3. After the WRF-Chem species were mapped, the size distribution, refractive indices, and hygroscopic growth factors were then assigned.

The FleAOD firstly reads the aerosol mass concentrations from WRF-Chem, then transforms to aerosol volume concentrations based on the assigned mass densities. Based on the assigned normalized size distributions, we can calculate the number
160 concentration (N_0) of each aerosol. FlexAOD pre-calculates the optical properties of each aerosol by assuming $N_0 = 1$ with the assumed size distributions. The total scattering/extinction coefficients can be obtained by multiplying the pre-calculated scattering/extinction cross-sections with the number concentrations. The total phase function is identical to the pre-calculated phase function by assuming $N_0 = 1$. In FlexAOD, aerosol shapes were assumed to be spherical and the corresponding optical properties of each aerosol species were calculated using the Mie code provided by Mishchenko et al. (1999), and the bulk
165 optical properties were then calculated by combining an assembly of aerosols.

FlexAOD assumed that the BC shape was spherical. To consider the non-spherical structures, BC optical properties were overwritten using the look-up tables created in Section 3.3. As described in Section 3.3, we have created look-up tables for

non-spherical BC for different size distributions. Thus, if the size distribution of BC is assigned, the optical properties of BC with a normalized size distribution can be determined by interpolating the look-up tables. Once the number concentration is calculated, we can determine the total optical properties.

Apart from BC, the physical properties of other chemical species were also specified. We used the OC refractive indices suggested by Highwood (2009). The density of OC varies from different conditions. The density of the oxidized organic aerosol was reported to be approximately 1.3 g cm^{-3} (Cross et al., 2007), while Nakao et al. (2013) reported that the density of OC with lower oxidation was approximately $1 - 1.2 \text{ g cm}^{-3}$. For freshly formed OC, $0.9 - 1.1 \text{ g cm}^{-3}$ was used by Liu et al. (2017). In this work, the density of OC was assumed to be 1.2 g m^{-3} . OC size is also commonly fitted by a lognormal size distribution. In the study of He et al. (2016) and Dentener et al. (2006), $r_g = 0.03 \mu\text{m}$ and $r_g = 0.075 \mu\text{m}$ were assumed for hydrophobic and hydrophilic OC, respectively. In this study, all OC was assumed to be hydrophilic, and we assumed a r_g of $0.075 \mu\text{m}$ and a σ_g of 1.6. The refractive indices of dust were identical to those used in the GOCART Model (Chin et al., 2002), and the refractive indices of other chemical species were adapted from the OPAC package (Hess et al., 1998). The physical properties are displayed in Table S4. Similar to the study of Curci et al. (2019), the hygroscopic growth factors of different aerosols were taken from the OPAC package (Hess et al., 1998). For dust, the gamma distribution was assumed: (Martin et al., 2003; Curci, 2012):

$$n(r) = N_0 r_p^{(1-3b)/b} \exp\left(-\frac{r_p}{ab}\right) \quad (11)$$

where a and b are two parameters for the distribution, and b is in the range of $0 - 0.5$.

We must clarify that many internally mixed particles exist in the atmosphere, while in this study we mainly aim to study the morphological effects of freshly emitted particles, and more complex particles may be investigated in the future. Effective refractive indices were calculated using the volume mixing method for hydrophilic particles.

The total column SSA and AOD were calculated by FlexAOD, and AAOD was calculated by:

$$\text{AAOD} = \text{AOD}(1 - \text{SSA}) \quad (12)$$

AAE and EAE were calculated by:

$$\text{AAE} = -\frac{\ln(\text{AAOD}_1) - \ln(\text{AAOD}_2)}{\ln(\lambda_1) - \ln(\lambda_2)} \quad (13)$$

$$\text{EAE} = -\frac{\ln(\text{AOD}_1) - \ln(\text{AOD}_2)}{\ln(\lambda_1) - \ln(\lambda_2)} \quad (14)$$

here λ_1 and λ_2 represent two reference wavelengths; AAOD_1 and AAOD_2 represent the AAOD at corresponding wavelengths; AOD_1 and AOD_2 represent the AOD at corresponding wavelengths.

3.5 ARI modeling

The optical properties (Extinction coefficient, SSA, Asymmetric factor (ASY)) calculated using FlexAOD at each WRF-Chem grid were inputted into a radiative transfer model, libRadtran (Mayer and Kylling, 2005), to calculate the radiative fluxes at

the top-of-the-atmosphere (TOA). The radiative transfer equation was solved by DISORT radiative transfer equation solver
200 (Stamnes et al., 1988; Buras et al., 2011). Based on the longitude, latitude, and UTC time, libRadtran can select a standard at-
mosphere background and determine the solar zenith angle (SZA).. The albedo information was obtained from NASA EARTH
OBSERVATIONS (NEO). Besides, we filled the missing values with the albedo provided by WRF-Chem. In this work, we
just considered the ARI for clear-sky. The radiative transfer calculations were performed for each hour and then were averaged
over one day. In this work, the direct radiative effects (ARI) of BC aerosol were calculated using following equations:

$$205 \quad \text{ARI} = \text{FLUX}_{\text{With BC}} - \text{FLUX}_{\text{Without BC}} \quad (15)$$

$$\text{FLUX} = F^{\downarrow} - F^{\uparrow} \quad (16)$$

where F^{\downarrow} represents downward radiative flux and F^{\uparrow} represents upward radiative flux. In this work, we just considered the ARI
at the TOA.

210 4 Results

4.1 Impacts of BC morphology on AOD and AAOD

To verify the modeling performance for the aerosol concentrations, we compared the simulated PM_{2.5} concentrations with
observations at some monitoring sites, and the results are shown in Figure 2. In the figures, the left column represents the
typical cities in China, and the right column represents the sites in North America. As shown in Figure 2, the calculated PM_{2.5}
215 concentrations in China are generally consistent with the observations. Even though the simulated PM_{2.5} concentrations in
the fire region are a little higher than the observations, the deviations are not large, and the general trends are consistent.
Therefore, it is reasonable to represent the atmospheric aerosol concentrations using WRF-Chem modeling. We just compare
the calculated AOD and AAOD in Beijing with observations from AEROSOL ROBOTIC NETWORK (AERONET), as the optical
observations are limited in our simulation region. As shown in Figure 3, the calculated AAOD and AOD can generally represent
220 the observations.

For the fire region, even though the surrounding BC concentrations are small, BC concentrations at fire sites are extremely
high. In this study, we selected three fire sites to evaluate the morphological effects on the BC ARI. The positions of the
selected sites are shown in Table S5, and they represent the fire sites with high aerosol concentrations. As shown in Figure 4,
BC concentrations at fire sites can even exceed approximately $400 \mu\text{g}/\text{m}^3$, which should have a strong impact on the aerosol
225 radiative effects. In East China, we select Beijing, Shanghai, Tianjin, and Nanjing as the typical sites to represent the polluted
urban cities. As shown in Figure 4, even though maximum BC concentrations in the polluted urban cities are much smaller
than the fire site, the mean BC concentrations are also high, which can reach approximately $12 \mu\text{g}/\text{m}^3$. The simulated BC
concentrations generally agree with the measurements of Zhang et al. (2012) for the urban region, where BC concentrations
were observed to be approximately $4 - 12.7 \mu\text{g}/\text{m}^3$.

230 Figure 5 shows the mean BC AOD and AAOD as a percentage of the total AOD and AAOD. In typical China polluted cities, BC AOD accounts for approximately 4.6% – 7% of the total AOD, while BC AOD in fire sites can account for larger than 10% of the total AOD. At 450 nm, in both polluted urban and fire sites, the fractions of BC AAOD are close, which is approximately 30%. This means that the relative proportions of BC and OC in polluted urban sites are close to those of fire sites.

BC morphologies can have significant impacts on the BC AOD and AAOD fractions. As BC morphologies change from from
235 a fractal dimension of 1.8 to a spherical structure, BC AOD fraction can vary in the range of approximately 4.6% – 5.8%, 5.0% – 6.2%, 5.5% – 6.9%, 4.8% – 6.0%, 9.0% – 11.1%, 10.3% – 12.7%, 9.1% – 11.2% in Beijing, Shanghai, Tianjin, Nanjing, Fire Loc1, Fire Loc2, and Fire Loc3, respectively. The variations can be above 25%. For BC AAOD fraction, the values can vary in the range of approximately 28.1% – 31.0%, 25.0% – 27.7%, 30.2% – 33.2%, 26.5% – 29.2% , 25.4% – 28.1%, 27.0% – 30.0%, 25.4% – 28.0% in Beijing, Shanghai, Tianjin, Nanjing, Fire Loc1, Fire Loc2, and Fire Loc3, respectively. The variations are
240 approximately 10%. Therefore, BC morphologies should have significant effects on determining the BC fractions based on the total AOD and AAOD.

Figure 6 shows the AOD of BC with different morphologies. By deriving the BC AOD of three urban cities (Beijing, Hefei, and Taihu), Zhuang et al. (2019) demonstrated that the mean BC AOD in three urban cities was approximately 0.05 – 0.06. Our simulations are generally in agreement with their results, and the simulated BC AOD varies from approximately 0.01
245 to approximately 0.12 in the selected urban cities. in Beijing and Tianjin, BC AOD can reach approximately 0.12, while in Shanghai and Nanjing, the maximum BC AOD is approximately 0.07 and 0.1, respectively. In fire sites, BC AOD is much larger, BC AOD can reach approximately 0.5, 0.9, and 0.6 in Loc1, Loc2, and Loc3, respectively. From Figure 6, we can also see that BC AOD calculated using the sphere model is relatively higher than those using fractal aggregate models. Besides, with the given size distribution, the more compact structure can lead to larger AOD, which is consistent with the findings of Liu and
250 Mishchenko (2005). As shown in Figure 7, in the polluted urban area, a spherical assumption for BC lead to an underestimation of less than 0.03 for AOD, while the underestimation can reach approximately 0.15 in fire sites. The underestimation accounts for a large proportion of BC AOD, which can exceed 20% of the total BC AOD. Therefore, BC AOD and AAOD suffer a non-negligible uncertainty from BC morphologies.

Figure 8 shows the calculated BC AAOD using different BC models. Our modeling results show a more compact structure
255 may lead to a smaller AAOD, and this is consistent with the findings of Liu and Mishchenko (2005) for a single BC particle. The reason may be that a more compact structure blocks the light into inner BC, so the smaller absorption efficiency was observed (Kahnert and Devasthale, 2011). By deriving BC AAOD at 440 nm from AERONET, Shin et al. (2019a) showed that most BC AAOD in Asia are within the range of 0 – 0.12. Our simulated BC AAOD at 450 nm is generally consistent with their findings. At fire sites, BC AAOD at 450 nm wavelength can reach approximately 0.7. Our results also show that the sphere model can
260 underestimate BC AAOD. As shown in Figure 9, at typical polluted cities, the sphere model can underestimate AAOD by approximately 0.016, while at fire sites, the AAOD underestimation using the sphere model can reach approximately 0.04. In general, the AAOD underestimation using the sphere model is approximately 8% of the total BC AAOD.

4.2 Impacts of BC morphology on AAE and EAE

The absorption Ångström exponent (AAE) calculated using different models is shown in Figure 10. Obvious deviations between fractal aggregate models and the sphere model are found for AAE estimation. With more compact structures, smaller AAE can be observed, which agrees with the findings of Li et al. (2016) and Liu et al. (2018). At typical polluted cities, AAE at 450 – 850 nm wavelength pair varies from approximately 1.5 to approximately 2.5, while AAE at fire site can reach as large as approximately 3.0. The observed large AAE is caused by large portions of brown carbon, which significantly absorbs radiation in ultra-violet (UV) and short visible wavelengths. However, as this study mainly focuses on the effects of BC morphologies, the AAE uncertainties caused by OC absorption are not considered in this work. Figure 11 shows that the sphere model can underestimate the AAE by approximately 0.17, which is approximately 17% of BC AAE. As AAE is commonly used to determine the aerosol type, BC morphologies may affect the threshold values for distinguishing the aerosol types.

EAE, as the spectral-dependence of extinction, is widely used to determine the size information of aerosols. Smaller aerosols normally have larger EAE. Figure 12 shows the EAE calculated using different BC models. By using AERONET observation data, in Beijing, Shaheen et al. (2019) showed that the mean EAE at 440 – 870 nm in winter was approximately 1.06 ± 0.36 . The Sun-sky radiometer Observation NETWORK (SONET) data conducted by Xie et al. (2015) demonstrated that EAE in the winter of Beijing was commonly within the range of approximately 0.5 – 1.5. Our calculated results generally agree with the observation from previous studies. In most cases, the calculated EAE is commonly within the range of 0.5 – 1.5, even though some smaller EAE is also observed. In the four typical urban cities, EAE values at 450 – 850 nm are similar, and they commonly vary from approximately 0.3 to approximately 1.5. However, EAE at fire sites is commonly within the range of approximately 1.5 – 1.85, which is much larger than the values in the polluted urban area. The reason may be that dominating aerosols in the fire region is commonly occupied by carbonaceous aerosols, which are commonly in fine mode. Compared to AAE, the effects of BC morphologies on the total EAE is relatively small. As shown in Figure 13, the EAE differences between fractal BC and spherical BC are within 0.05.

4.3 Impacts of BC morphology on SSA

SSA, as the ratio of scattering to extinction, is widely used to infer aerosol types. Figure 14 shows the comparison of SSA using different BC models. By using AERONET data, Shin et al. (2019b) showed the mean SSA at 440 nm was approximately 0.89 – 0.92 in Beijing, and Shaheen et al. (2019) demonstrated mean SSA at 440 nm was approximately 0.897 in winter in Beijing. At 450 nm, the calculated SSA at typical urban cities is within the range of approximately 0.86 – 0.92, which are generally consistent with the observations in previous studies. While in the fire region, SSA varies in a wider range. At 450 nm, SSA at the selected fire sites can vary in the range of approximately 0.75 – 0.9, which is a little smaller than that in polluted urban areas due to large portions of carbonaceous aerosols in the fire region.

With more compact structures, SSA presents a larger value, which is consistent with the findings of Kahnert and Devasthale (2011). However, the effects of BC morphologies on total SSA at 450 nm are not obvious due to the small percentage of BC in the atmosphere. As shown in Figure 15, the overestimations of the spherical BC model for SSA at 450 nm are generally within

0.005 at typical polluted cities and within 0.012 at fire sites, which is less than 1% of the total SSA. However, these values may have relatively larger impacts when evaluating the climate effect of BC, as BC commonly presents a relatively small value of 0.2 – 0.4 (Kahnert and Devasthale, 2011).

4.4 Impacts of BC morphology on ARI

300 BC ARI at the TOA using different BC models is presented in Figure 16. BC ARI varies in different regions and the reported BC ARI varies in previous studies. For example, a global mean BC ARI of $+1.1 \text{ W m}^{-2}$ has been reported by previous studies (Bond et al., 2013), while much larger BC ARI was observed in some regions. Based on situ measurements, Lamb et al. (2018) have estimated the column BC ARI to be $+0.48$ to $+2.01 \text{ W m}^{-2}$ over South Korea. Zhuang et al. (2018) estimated BC ARI to be $+1.85 \text{ W m}^{-2}$ in East Asia. Much larger BC ARI during December ($+15 \text{ W m}^{-2}$) and November ($+8 \text{ W m}^{-2}$) over Ahmedabad
305 and Gurushikhar, respectively, were reported by Rajesh and Ramachandran (2018). In eastern China, Zhuang et al. (2019) showed that clear-sky TOA ARI averaged over East Asia ($100\text{--}130^\circ\text{E}$, $20\text{--}50^\circ\text{N}$) were $+0.02$ to $+1.34 \text{ W m}^{-2}$ in summer. While in some sites (such as Beijing), the average BC ARI can reach approximately $+4.5 \text{ W m}^{-2}$. Based on different measured BC profiles, Lu et al. (2020) showed BC ARI was within the range of $+3.9$ – 5.1 W m^{-2} in the Beijing region. Our calculated BC ARI in winter generally agrees with their results. In winter, BC ARI at typically polluted cities commonly varies in the range
310 of approximately $+2$ – 9.0 W m^{-2} , and the mean BC ARI is approximately $+3.5$ – 5 W m^{-2} . While in large fire sites, the mean BC ARI can reach approximately $+7.0 \text{ W m}^{-2}$, and the maximum BC ARI can exceed $+11 \text{ W m}^{-2}$.

Table 1. BC ARI at different sites (W m^{-2}).

Location	$D_f=1.8$	$D_f=2.2$	$D_f=2.6$	Sphere
Beijing	+3.83	+3.72	+3.59	+3.47
Shanghai	+4.29	+4.15	+3.96	+3.72
Tianjin	+4.92	+4.77	+4.60	+4.45
Nanjing	+4.03	+3.90	+3.73	+3.54
Fire Loc1	+5.90	+5.78	+5.63	+5.52
Fire Loc2	+7.05	+6.91	+6.74	+6.64
Fire Loc3	+5.23	+5.12	+4.99	+4.91

Generally, with a more compact structure, BC presents smaller ARI at the TOA. Figure 17 shows the difference of BC ARI at the TOA between fractal aggregate models and the sphere model. In the polluted urban area, the spherical assumption can underestimate BC ARI by approximately 1.0 W m^{-2} , and the underestimation at fire sites can reach approximately 0.6
315 W m^{-2} . As shown in Table 1, using the sphere model, mean BC ARI are $+3.47$, $+3.72$, $+4.45$, $+3.54 \text{ W m}^{-2}$ in Beijing, Shanghai, Tianjin, and Nanjing, respectively, while using a fractal aggregate model with a D_f of 1.8, BC ARI can reach $+3.83$, $+4.29$, $+4.92$, $+4.03 \text{ W m}^{-2}$, respectively. The relative deviations are approximately 10.4%, 15.3%, 10.6%, 13.8% in Beijing, Shanghai, Tianjin, and Nanjing, respectively. In fire sites, the BC ARI differences using different models are relatively smaller. When modifying BC structure from a sphere to a fractal aggregate with a D_f of 1.8, mean BC ARI increases from

320 +5.52 to +5.90 Wm^{-2} , +6.64 to +7.05 Wm^{-2} , +4.91 to +5.23 Wm^{-2} at Loc1, Loc2, and Loc3, respectively, and the relative
uncertainties are approximately 6.9%, 6.2%, 6.5%, respectively. By using different measured BC profiles, Lu et al. (2020)
showed BC shape can introduce approximately 5% relative uncertainties in East China. However, our results show that much
larger uncertainties can be introduced from BC morphologies. The reason is that in the study of Lu et al. (2020), $D_f = 2.8$ was
assumed for BC aggregates, which is close to spherical shape. This D_f value is maybe a little larger than the observed D_f .
325 Besides, due to different mean solar angles, our results show the ARI uncertainties caused by BC morphologies may vary in
different regions. Therefore, the BC morphological effects on the BC ARI should be carefully considered in different regions.

5 Summary and Conclusions

In this study, we numerically investigated the effects of BC morphologies on ARI at four cities in East China and three locations
in the northwest US. At 550 nm wavelength, the spherical BC model can overestimate the AOD up to 0.03 and 0.15 at typical
330 polluted cities in East China and fire regions in the northwest US, respectively. The overestimations roughly account for 20%
of the total BC AOD. Besides, the spherical BC model can underestimate BC AAOD at 450 nm up to 0.016 and 0.04 at typical
polluted cities in East China and fire sites in US, respectively, when modifying BC structure from spheres to fractal aggregates
with a D_f of 1.8. The underestimations account for approximately 8% of the total BC AAOD. Even though BC morphologies
have small impacts on total SSA and EAE, their effects on the AAE are rather significant. At 450 – 850 nm wavelength pair,
335 AAE is approximately 1.5 – 2.5 and 2.0 – 3.0 in typical polluted urban area and fire region, respectively. The calculated AAE
difference between the spherical BC model and fractal aggregate model can reach approximately 0.17.

BC morphologies have non-negligible impacts on the BC ARI. Using the spherical BC model, the calculated mean ARI is
approximately +3.47 Wm^{-2} , +3.72 Wm^{-2} , +4.45 Wm^{-2} , +3.54 Wm^{-2} in Beijing, Shanghai, Tianjin, and Nanjing, respec-
tively, while the values increase to approximately +3.83 Wm^{-2} , +4.29 Wm^{-2} , +4.92 Wm^{-2} , and +4.03 Wm^{-2} , respectively,
340 when using a fractal aggregate model with a D_f of 1.8. The relative variations are 10.4%, 15.3%, 10.6%, and 13.8%, respec-
tively. At fire sites, the uncertainties are smaller but still non-negligible. When modifying BC from spheres to fractal aggregates
with a D_f of 1.8, the mean BC ARI increases from +5.52 to +5.90 Wm^{-2} , +6.64 to +7.05 Wm^{-2} , +4.91 to +5.23 Wm^{-2} at
Loc1, Loc2, and Loc3, respectively, and the relative variations are approximately 6.9%, 6.2%, 6.5%, respectively. Therefore,
the effects of BC morphologies on the regional radiative effects should be carefully evaluated.

Figure 1. Typical morphologies of fractal BC.

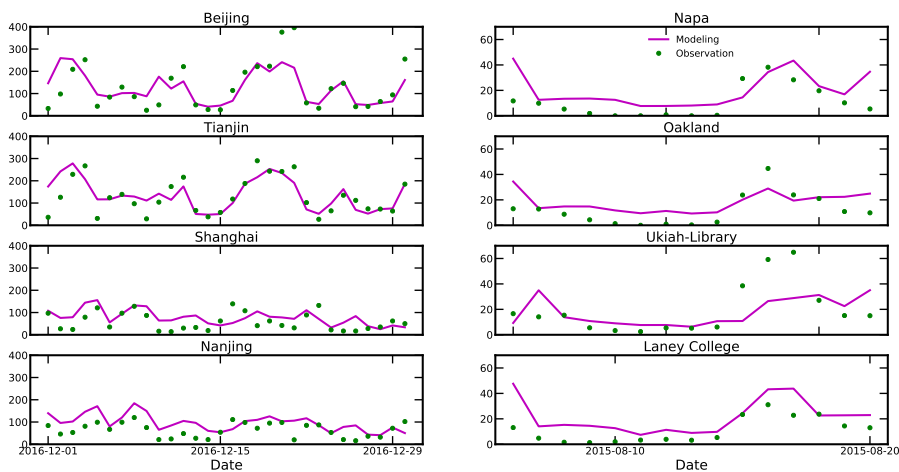

Figure 2. Comparison of measured and calculated PM_{2.5} concentrations.

Figure 3. Comparison of measured and calculated AOD and AAOD in Beijing, where $\lambda=500$ nm for AOD. $\lambda=440$ nm and 450 nm for measured and calculated AAOD, respectively, and the observations were obtained from AERONET.

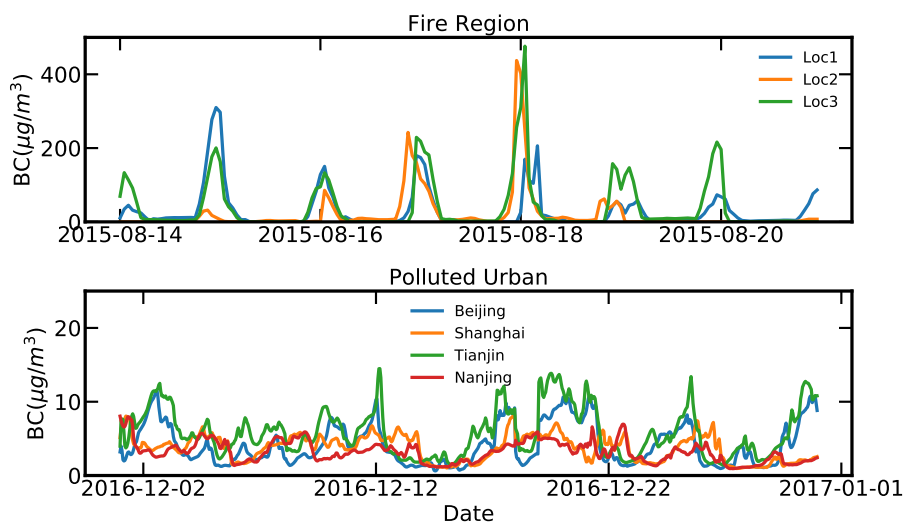

Figure 4. The time series of BC concentrations in typical north America and East China.

Figure 5. BC AOD (550 nm) and AAOD(450 nm) as a percentage of total AOD and AAOD.

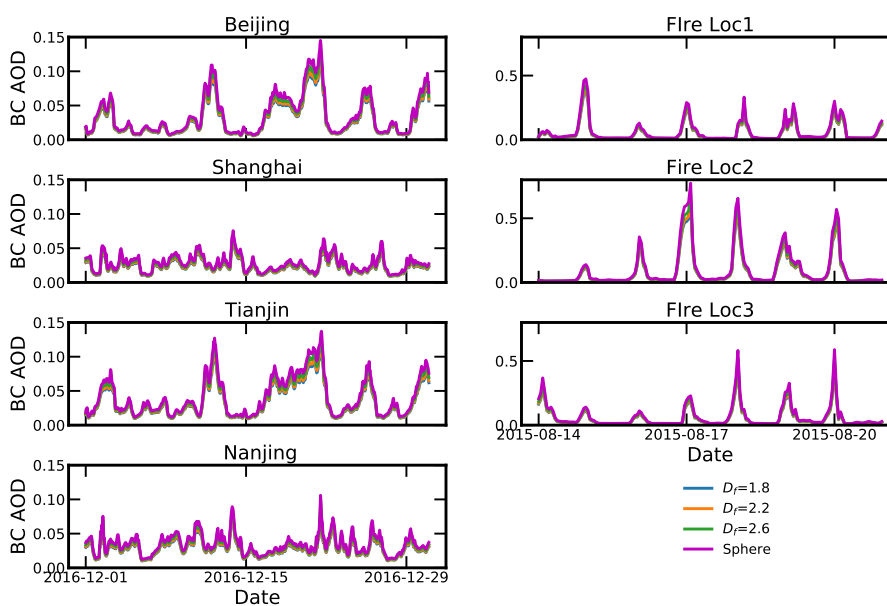

Figure 6. The comparison of BC AOD for different BC morphologies, $\lambda=550$ nm.

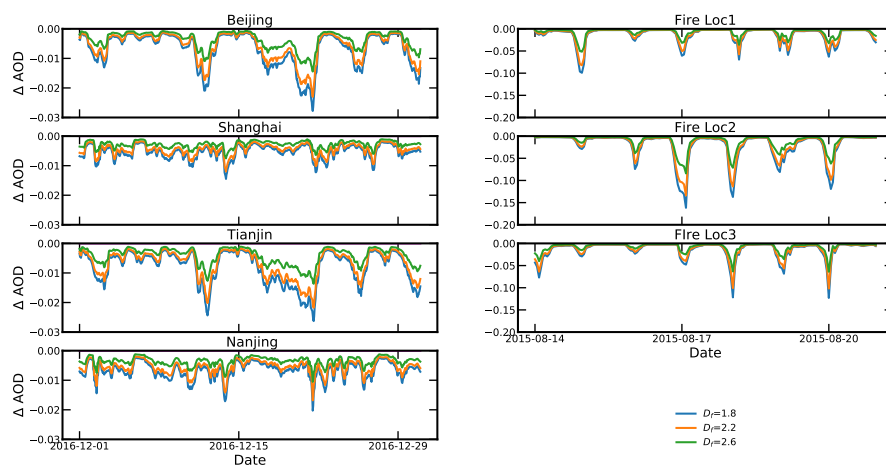

Figure 7. The AOD difference between fractal aggregate models and the sphere model, $\lambda=550$ nm.

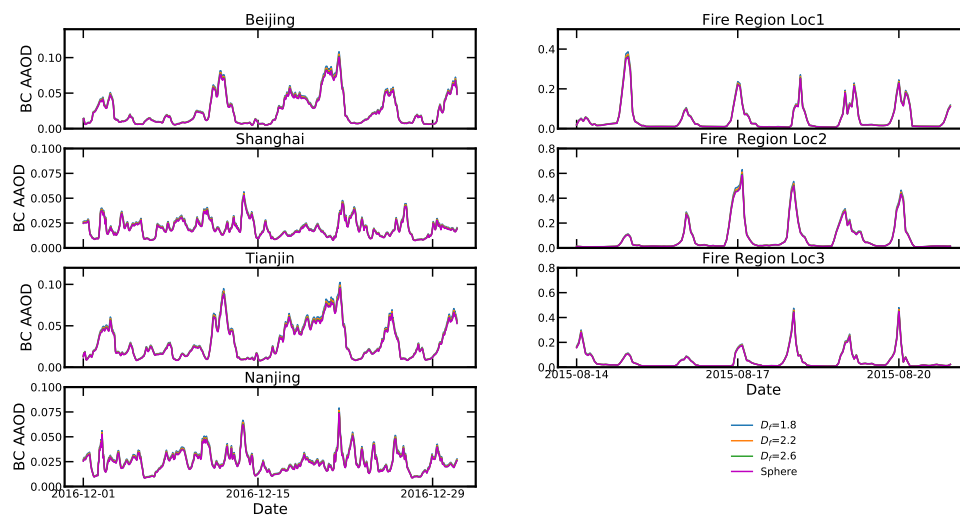

Figure 8. The comparison of BC AAOD for different BC morphologies, $\lambda=450$ nm.

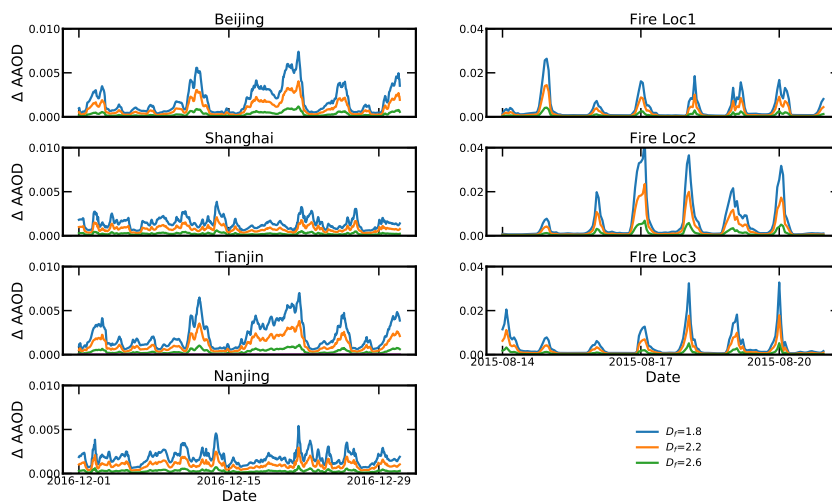

Figure 9. The AAOOD difference between fractal aggregate models and the sphere model, $\lambda = 450$ nm.

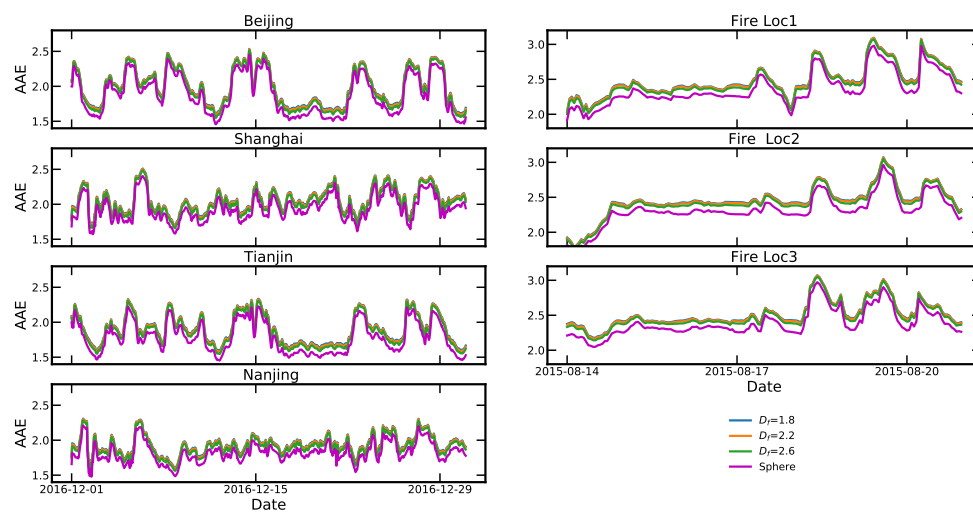

Figure 10. The comparison of BC AAE for different BC morphologies, $\lambda=450$ nm, 850 nm pair.

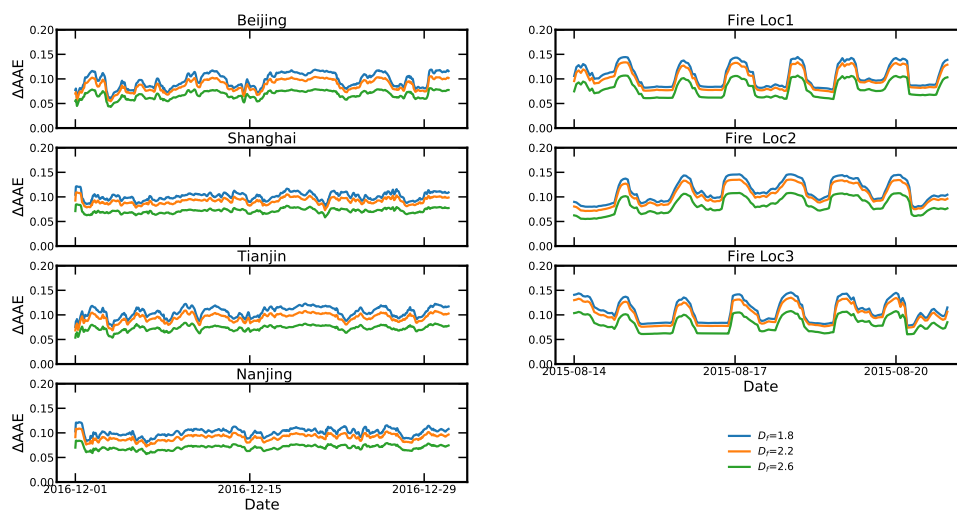

Figure 11. The AAE differences between fractal aggregate models and the sphere model, $\lambda = 450$ nm, 850 nm pair.

Figure 12. The comparison of BC AAE for different BC morphologies, $\lambda=450$ - 850 nm, 850 nm pair.

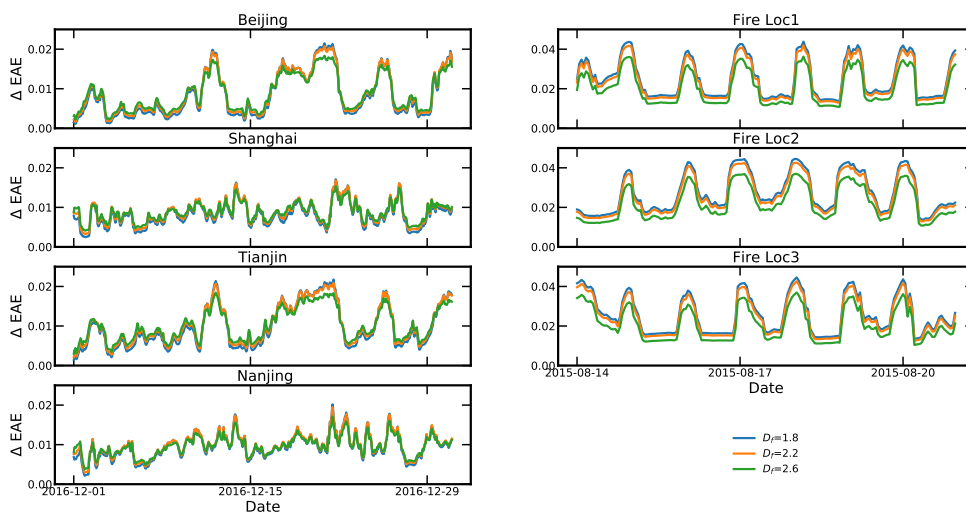

Figure 13. The EAE differences between fractal aggregate models and the sphere model, $\lambda=450$ nm, 850 nm pair.

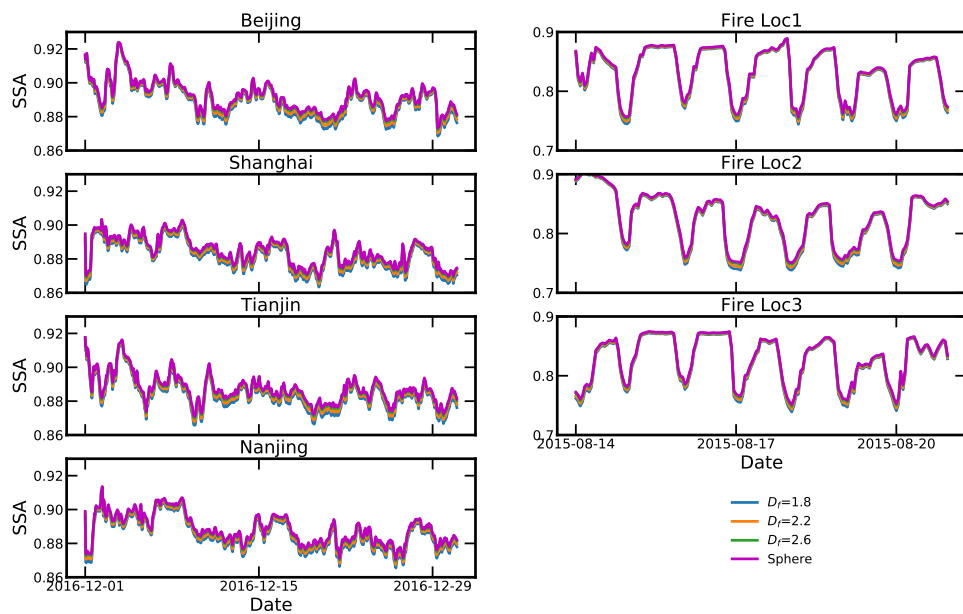

Figure 14. The comparison of SSA using different BC models, $\lambda=450$ nm.

Figure 15. The SSA differences between fractal aggregate models and the sphere model, $\lambda=450$ nm.

Figure 16. The BC ARI at the TOA calculated using different BC models.

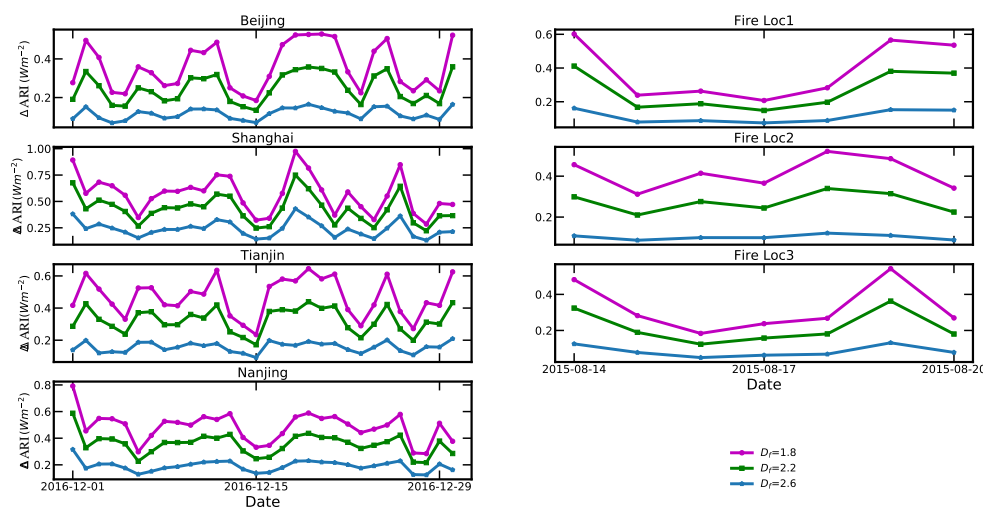

Figure 17. The difference of BC ARI at the TOA between fractal aggregate models and the sphere model.

Code availability. The FlexAOD can be requested from Prof. Curci (<http://pumpkin.aquila.infn.it/flexaod/>).

Data availability. The data can be requested from the corresponding author.

Author contributions. JL and QXZ conceived the presented idea. JL developed the models, performed the computations, and wrote the paper. ZQL, CZ, YMZ, RKC, YZ verified the simulation methods and results. QXZ revised the paper and supervised the findings of this work. GC
595 developed the FlexAOD model. All authors discussed the results and contributed to the final paper.

Competing interests. The authors declare that they have no conflict of interest.
