15 **Abstract** Heatwaves (HWs) paired with higher ozone (O₃) concentration at surface level pose a serious threat to human health. Their combined modulation of synoptic patterns and urbanization remains unclear. By using five years of summertime temperature and O₃ concentrations observation in Beijing, this study explored potential drivers of compound HWs and O₃ pollution events and their public health effects. Three favourable synoptic weather patterns were identified to dominate the compound HWs and O₃ pollution events. These weather patterns contributing to enhance those conditions are characterized by sinking air motion, low boundary layer height, and hot temperatures. Under the synergistic of HWs and O₃ pollution, the mortality risk from all non-accidental causes increased by approximately 12.31% (95% confidence interval: 4.66%, 20.81%). Urbanization caused higher risks for HWs and O₃ at urban areas than rural stations. Particularly, due to O₃ depletion caused by NO titration at traffic and urban stations, the health risks related to O₃ pollution in different regions are characterized as follows: suburban stations > urban stations > rural stations > traffic stations. In general, favourable synoptic patterns and urbanization enhanced the health risk of these compound events in Beijing by 33.09% and 18.95%, respectively. Our findings provide robust evidence and implications for forecasting compound heatwaves and O₃ pollution event and its health risks in Beijing or in other urban areas all over the world having high concentrations of O₃ and high-density populations.

Key words: Heatwaves, ozone pollution, health risks, synoptic weather pattern, urbanization

1 Introduction

30 Climate warming and rapid urbanization have led to increases in the frequency and duration of extreme high-temperature episodes (Lehner et al., 2018; Li et al., 2020; Meehl and Tebaldi, 2004; Wang et al., 2021b; Yang et al., 2017). Such prolonged

extreme high-temperature exposure can induce an increase in the morbidity and mortality due to cardiovascular and respiratory diseases, posing a serious threat to human health (Patz et al., 2005; Xu et al., 2016). Therefore, the extreme high-temperature events are recognized as one of the most serious types of meteorological disaster worldwide. However, high temperatures during summer heatwaves are paired with serious O₃ pollution frequently, for instance, significantly increased O₃ concentrations have been observed in the UK and France during the August 2013 heatwave event (Lee et al., 2006; Vautard et al., 2005, 2007). High concentrations of O₃ exposure would stimulate the human respiratory system, damage lung cells, and aggravate other chronic lung diseases (WHO, 2021), which poses a great threat to human health. Consequently, residents may suffer from dual health risks caused by both high temperatures and O₃ exposures in summer. Although extreme hot events have received extensive attention from academia and society, the research on health risks aroused by O₃ pollution associated with high temperature has been neglected. As a result, it might be greatly underestimated that the health risks to the human body enduringly exposed to the outdoors during hot days.

As a continuous extreme case of high temperature weather in summer, heat waves (HWs) have previously been shown by numerous epidemiological studies to cause significantly higher overall deaths than non-heatwave (NHW) periods (Conti et al., 2005; Fouillet et al., 2006). Subsequently, many scholars launched investigations on the relationship between high temperature exposure and mortality (Abbas and Tewtel-Salem, 2005; Huang et al., 2015; Zhang et al., 2017), and they found that when the temperature was higher than a certain threshold temperature, the mortality rate increased with the increase of temperature. Most studies suggested that there were a U-, V-, W-, or J-shaped non-linear change relationship between daily mortality and daily temperature (Goggins et al., 2012; Huang et al., 2015; Zhang et al., 2017). Similar studies on O₃ concentration and mortality have also been progressing (Atkinson et al., 2012; Gu et al., 2018; Pope et al., 2016). Particularly, some epidemiological evidences showed that the coefficient of the O₃ concentration–response relationship for mortality in summer was higher with respect to other seasons (Pattenden et al., 2010; Pope et al., 2016), suggesting that the health effects and mortality related to O₃ pollution were exacerbated by hot temperatures. Therefore, the significant increase in O₃ concentrations during summertime is also greatly responsible for the increase in excess mortality, that is, high temperatures and O₃ exhibit a joint impact on public health (Hertig et al., 2020; Katsouyanni et al., 1993; Pattenden et al., 2010). Numerous previous studies have been devoted to the individual impacts of a single extreme high-temperature or air pollution event on human health (Ma et al., 2015; Ning et al., 2020; Wang et al., 2020; Wong et al., 2013; Xu et al., 2016). However, with the co-occurrence of extreme HW and O₃ pollution events in summer becoming more frequent, it is imperative to reveal the underlying mechanisms of extreme HW–O₃ compound events and to improve the level of risk assessment related to extreme events in urban areas (Hertig et al., 2020; Sartor et al., 1995).

Together with the rapid development of economic globalization and urbanization, human activities and the changes in the urban underlying surface have induced frequent occurrences of both extreme high surface air temperature and air pollution issues (Chew et al., 2021; Li et al., 2016; Luo and Lau, 2018, 2019; Meehl et al., 2007; Rastogi, 2020; Wang et al., 2007; Yang et al., 2020). Particularly, HWs paired with the urban heat island (UHI) effect exposes urban residents to more sustained extreme high temperatures (Chew et al., 2021; Jiang et al., 2019; Tan et al., 2010; Wang et al., 2017; Zong et al., 2021b).

Meanwhile, rapid urbanization induced many more emissions of hydrocarbons and nitrogen oxides into the atmosphere from traffic vehicle and industries, the rising concentrations of these precursors coupled with high temperature and intense solar radiation during HWs can accelerate photochemical reaction rate and generate more O₃ (Sillman, 1999; Yim et al., 2019; Zanis et al., 2000). As a result, urban residents may face more severe stresses from both heat and O₃ pollutions. However, note that the improvement of economic level, medical infrastructure and air-conditioning utilization associated with urbanization can alleviate the health burden of the human body in the face of high temperature and O₃ exposure to a certain extent (Bai et al., 2016; Kovach et al., 2015; Li et al., 2017). Therefore, it can be concluded that there still are some uncertainties in affecting the excess mortality of high temperature and O₃ pollution. To sum up, clarifying the formation mechanism of HW–O₃ compound events and quantifying their health risks to urban residents are important scientific issues that warrant further investigation.

Beijing, the capital of China, is the second largest city in the country, with a permanent population of 21.89 million. It is not only one of the fastest developing metropolises in China in recent decades, but also a typical heat island city (Ren et al., 2007; Wang et al., 2017; Yang et al., 2013). Taking Beijing as a typical example, therefore, this study focuses on the health risks of extreme HW–O₃ compound events during summertime of 2014–2019, and comprehensively investigates the roles of synoptic weather patterns and urbanization in these compound events based on surface observation and reanalysis data. Then, the contributions of weather types and urbanization to the excess mortality induced by combined heat and O₃ stress were quantified according to the established health assessment model. The findings are expected to provide a scientific reference for the monitoring and forecasting of summertime HW–O₃ compound events and their health risks from the perspective of synoptic patterns and urbanization in high-density mega cities.

2 Data and Methods

2.1 Data

Ground-level O₃ observation data during summertime (June–August) of 2014–2019 were retrieved from Beijing Municipal Ecological and Environmental Monitoring Center. After quality control, and excluding stations with a missing-values rate for the O₃ concentration of more than 10%, 31 air quality stations [AQSS; including 11 for urban stations, 11 for suburban stations, three for traffic stations (road monitoring stations for traffic air quality), and six for rural stations] are ultimately used in this study. In order to better assess the relationship between O₃ pollution and the meteorological variables, we selected 29 automatic weather stations (AWSs) closest to the environmental monitoring stations from the high-density AWS network. For specific geographic location information, see [Figure 1](#) and [Table 1](#). Hourly 2-m air temperature, relative humidity (RH), the daily maximum temperature (T_{\max}), and 10-m wind speed (WS) of these 29 AWSs were obtained from the National Meteorological Information Center of the China Meteorological Administration, and then heat index (HI) was retrieved as shown in Rothfus (1990) as Eq. (1):

$$HI = -42.379 + 2.04901523 \times T + 10.14333127 \times RH - 0.22475541 \times T \times RH - 0.00683783 \times T^2 - 0.05481717 \times RH^2 + 0.00122874 \times T^2 \times RH + 0.00085282 \times T \times RH^2 - 0.00000199 \times T^2 \times RH^2, \quad (1)$$

Where T indicates the temperature (unit: °F), and RH (unit: %) indicates relative humidity.

100 In addition, we also used the hourly geopotential height (GH), boundary layer height (BLH), wind vector, vertical velocity, and temperature fields to further analyze the weather type and local boundary layer characteristics under the joint occurrence of HW and O₃ pollution (Fifth major global reanalysis produced by the European Centre for Medium-Range Weather Forecasts, with spatiotemporal resolution of 0.25°).

2.2 Methods

105 2.2.1 Compound HW and O₃ pollution events

An HW event is usually characterized by the daily maximum temperature reaching or exceeding a certain threshold (it can be a relative value or an absolute threshold) for several consecutive days (Ngarambe et al., 2020). In this paper, we selected 33°C (which corresponds to the 90th percentile of T_{\max} during 2014–2019 in Beijing) as threshold for T_{\max} lasting for 3 days or more to determine an HW event; otherwise, it was a non-heat wave (NHW) event. Moreover, the occurrence of precipitation during 110 the day inhibits the photochemical reaction of O₃ production (Yu et al., 2020; Zhang et al., 2015; Zhao and Wang, 2017), here a daytime precipitation event (accumulated precipitation ≥ 2 mm during 0700–1900 LST) was excluded to avoid the impact of precipitation on compound HW and O₃ pollution events. O₃ pollution was identified as when the MDA8 O₃ concentration exceeded 160 $\mu\text{g m}^{-3}$, which is in accordance with the Ambient Air Quality Standards issued by the Ministry of Ecology and Environment of the People’s Republic of China. Based on the above criteria, 84 days of co-occurring HW and O₃ pollution 115 events during 2014–2019 were finally obtained.

2.2.2 Weather type classification

The T-mode principal component analysis (T-PCA) is an improved mathematical method to classify the circulation pattern, which has a low dependence on preset parameters, and has advanced temporal and spatial stability of classification (Huth et al., 2008). Consequently, T-PCA has been widely used in the studies of atmospheric circulation effects of extreme weather 120 (Liu et al., 2019; Miao et al., 2019; Yang et al., 2018, 2021; Zhang and Villarini, 2019; Zong et al., 2021a). It decomposes the original data matrix into the product of the principle component matrix and the load matrix (two low-dimensional matrices), then rotates the first r ($r \leq n$) principal components with larger variance contributions obliquely, and finally obtains the synoptic patterns and classifications of each time according to the magnitude of the load (Huth, 2000). Here, T-PCA was applied in 125 COST733class to classify the 850-hPa GH field of the joint occurrence of HW and O₃ pollution events and the number of classifications was determined based on the explained cluster variance, more specific details on T-PCA were introduced in our previous study (Zong et al., 2021a). As for the categorical data, we mainly focused on the domain (110°–125°E, 32°–47°N), including Beijing, associated with these 84 days of compound events during summertime (June–August) 2014–2019.

2.2.2 Excess mortality

In epidemiology, the relative risk (RR) is usually used to evaluate the intensity of the association between exposure and disease, which refers to the ratio of the incidence of the exposed group to the incidence of the non-exposed group (Chen et al., 2018; Pope et al., 2016). The RR is calculated by Eq. (2):

$$RR_i = \exp^{\beta_i \cdot \Delta X_i}, \quad (2)$$

where i indicates the risk factor (high temperature or O₃ concentration), β_i is the coefficients of the exposure response function between the risk factor i and total mortality through nonlinear regression (Cao et al., 2021; Du et al., 2020; Gu et al., 2018), ΔX_i is the difference between the risk factor i and its reference health threshold. The excess risk (ER) is calculated by Eq. (3):

$$ER_i = (RR_i - 1) \times 100\%, \quad (3)$$

Previous studies indicated that there were distinctly different magnitudes of human morbidity and mortality caused by high temperature and O₃ overexposure over various geographic regions (Huang et al., 2015; Ma et al., 2015; Wang et al., 2020; Yin et al., 2017). For instance, Huang et al. (2015) revealed that for a 1°C increase above the minimum mortality temperature, the daily mortality increased by 1.04% [95% confidence interval (CI): 0.90 to 1.18], 1.25 (95% CI: 0.71 to 1.79), 1.19 (95% CI: 0.79 to 1.58), and 1.38 (95% CI: 0.54 to 2.23) in the nationwide, central China, eastern China, and south China, respectively. Here, we refer to the coefficients of exposure response function (β) for the high temperature as suggested by Liu et al. (2021), while that O₃ concentration as suggested by Yin et al. (2017) in northern China. In detail, Liu et al. (2021) investigated the mortality caused by high temperature in 84 cities in China from 2013 to 2016, and found that for every 1°C increase in the daily T_{max} above 31.5°C, the largest RR of mortality caused by high temperature in northern China was 1.002 (95% CI: 1.001, 1.004). According to Eq. (2), we can deduce that $\beta_{T_{max}}=0.997\%$ (95% CI: 0.996%, 0.999%), note that RR equals to 1 when T_{max}=31.5°C. For O₃ exposure, a 10-μg m⁻³ increase in MDA8 O₃ was related to an increase in the total daily mortality of 0.39% (95% CI: 0.04%, 0.75%) in northern China during the warm season (Yin et al., 2017), that is, $\beta_{Ozone}=0.39\%$ (95% CI: 0.04%, 0.75%). Since the two models have removed the mutual influence, the final joint ER is the sum of the ERs of both high temperature and O₃.

2.2.3 Urbanization and Synoptic contribution rates

To estimate the impact of urbanization and weather patterns on compound HW and O₃ pollution events, we further determined their contribution rates to the excess mortality of compound events. With reference to Ma and Yuan (2021) and Yang et al. (2017), the urbanization effect is calculated by Eq. (4):

$$\Delta ER_{i,urbanization} = ER_{i,urban} - ER_{i,rural}, \quad (4)$$

and contribution rate is calculated by Eq. (5):

$$CR_{i,urbanization} = \frac{\Delta ER_i}{ER_{i,urban}} \times 100\%, \quad (5)$$

Where i indicates risk factor (high temperature or ozone pollution), ER is excess mortality, and CR is contribution rate.

Similarly, we also defined synoptic effects as Eq. (6):

$$\Delta ER_{i,synoptic} = ER_{i,synoptic} - ER_{i,average}, \quad (6)$$

and the contribution rate as Eq. (7):

$$CR_{i,synoptic} = \frac{\Delta ER_i}{ER_{i,synoptic}} \times 100\%, \quad (7)$$

Where i , ER, and CR are same as Eq. (6).

3 Results

165 3.1 Compound HW–O₃ pollution events and associated public health in Beijing

Figure 2 shows the time series of the HW, NHW, O₃ pollution, and precipitation days, and the interannual and intraseasonal variations of HW and O₃ pollution days. For interannual variation, the total days of O₃ pollution in summer was relative stable, while the total days of HW increased slightly. For intraseasonal variation, O₃ pollution was the most serious in June, while the most frequently HW events in July. Obviously, higher O₃ pollution levels (>160 µg m⁻³) were always accompanied by most HW periods (approximately 79.2% of HW days) in Beijing (Figures 2a and 3b), which were mainly in the middle of summer. In addition, note that there was an increase in the maximum duration of HW events and the number of HW–O₃ paired days during summertime of 2014–2019 (Figure 3), especially in 2019, when the most durable HW event lasted for 10 days, resulting in more extreme enduring dual heat and O₃ stresses to residents. As shown in Figure 4, relative to NHW days, MDA8 O₃ increased significantly on HW days, exceeding 160 µg m⁻³ across all stations, with an average of 189.35 µg m⁻³. Both surface O₃ concentration and MDA8 O₃ concentration in Beijing showed significant differences ($P < 0.001$) through analysis of variance among three conditions (Table S1).

In general, the difference in O₃ concentration was mainly due to meteorological conditions and the precursors emission paired with photochemical reactions in the boundary layer. We further investigated the diurnal variation for surface air temperature (T), RH, HI, BLH and WS under HW, NHW and precipitation periods (Figure 5), and these five variables also showed significant differences (passed the Kruskal-Wallis test of 0.001, more details see Table S2) in the three periods. For HW days, HI raised more by increased air temperature, and although the RH was relative lower, people still suffered from higher apparent temperature than actual air temperature. Under HW conditions, solar radiation reaching the ground heats the atmosphere increasing the near-surface temperature. Warmer air convection promotes atmospheric instability, with increased WS and higher BLH. It is clear that the meteorological variables at daytime were significantly different during HW periods with respect to NHW periods. Similarly, hourly O₃ concentrations also showed significantly difference under different meteorological conditions, and reached the peaks in the afternoon on HW days (Figure 5f). Note that the contribution of local and regional emissions (transport of pollution between urban and rural areas) to air quality at a city scale should be focused (Thunis et al., 2021), which can also induce urban-rural differences. We assumed that the intraseasonal differences in precursor emissions can be ignored, and further compared the diurnal variation differences in NO₂, CO and O₃ among different stations (Figure 6 and Table S3). CO and NO₂ levels were higher at traffic stations than urban and suburban stations due to enhanced emission

from vehicles, and the lowest CO and NO₂ levels appeared at rural stations. Generally speaking, high precursor levels are supposed to correspond to high resultants levels, but the lowest O₃ levels were found at traffic stations, followed by rural stations, then urban and suburban stations. Since automobile exhaust in the traffic and urban stations also caused heavily NO emission (Colvile et al., 2001), ambient O₃ can be titrated by NO via the reaction $\text{NO} + \text{O}_3 \rightarrow \text{NO}_2 + \text{O}_2$ (Gao et al., 2020; 195 Murphy et al., 2007; Sillman, 1999), this process in turn led to higher NO₂ levels and the loss of O₃ in traffic and urban areas. As for rural stations, low pollutant emissions may be the primary reason for the lower O₃ levels. Note that although the CO and NO₂ emissions were significantly higher at urban stations than those of suburban stations, there was less difference in O₃ concentrations between these two-type stations, which may be due to O₃ consumption induced by titration at urban stations, or more biogenic VOCs at suburban stations. This is because that the difference in O₃ concentrations between the rural and the 200 suburban stations were the largest in the afternoon, while the difference in CO and NO₂ levels were the smallest indicating that anthropogenic emissions have less impact in suburban areas, coupled with more than half of suburban stations are covered by vegetations leading to more bio-VOC emissions.

Moreover, the high temperatures on HW days not only induce a higher public risk related to high-temperature exposure, but also increase mortality related to O₃ exposure. During HW periods, high temperatures and strong solar radiation accelerate the 205 rate of the photochemical reaction that produces O₃ (Pu et al., 2017; Sun et al., 2017), favouring the production and accumulation of O₃, thereby aggravating health risks. The health risks related to both O₃ and high-temperature has greatly increased during HW days for all-type stations. Specifically, for all stations, HWs have increased the ER caused by high temperatures and O₃ by 3.867% (90% CI: 3.863%, 3.875%) and 7.9% (90%CI: 0.78%, 15.78%), respectively (Table 2). The high temperature risks were mainly manifested as followings: urban stations > traffic stations > suburban stations > rural 210 stations, but the health risks aroused by O₃ exposure in different underlying surface stations were more difficult to quantifying due to the complexity of O₃ photochemical reactions. As mentioned above, urbanization-enhanced NO or CO titration reduced more O₃ loss in urban areas, which was more pronounced over traffic stations. For suburban stations, the abundant biogenic VOC emitted by vegetation also contributed to O₃ generation, bio-VOC emissions enhanced more especially in hot days (Ma et al., 2019; Trainer et al., 1987; Wang et al., 2021a). As a result, O₃ exposure risks in Beijing were mainly characterized by 215 suburban stations > urban stations > rural stations > traffic stations. Urbanization seems to have increased the ER induced by both high temperatures and O₃ exposure. In details, summertime HW, O₃ and compound ER increased by 1.67%, 0.20%, and 1.89%, respectively, compared to rural stations. Note that urbanization has alleviated O₃ pollution to a certain extent, and the health risk of O₃ at stations with developed transportation was even lower than that of rural stations.

3.2 Role of synoptic weather pattern and urbanization

220 To further clarify the mechanism underlying the joint occurrence of HW–O₃ events in Beijing, three favourable synoptic weather patterns were identified as follows: (1) Type 1, characterized by the western Pacific subtropical high being located in the southeast of Beijing with prevailing southwesterly winds; (2) Type 2, controlled by a high-pressure system accompanied by weak southerly winds; and (3) Type 3, a low-vortex located over northeast Beijing with prevailing northwesterly winds

(Figures 7a–7c, and detailed HW–O₃ date and type see Table S4). Additionally, vertical cross-sections of the potential
225 temperature and wind vectors at 1400 LST under the three patterns are shown in Figures 7e–7f. Under Type 1, low boundary
layer paired with weak vertical motion favours pollutants' accumulation. Besides, the prevailing southwesterly wind may blow
pollutants from the upwind direction to Beijing, and the northern mountains block the pollutants from continuing to be
transported in the downward wind direction, causing the pollutants to gather in Beijing. For Type 2, a lower BLH and vertical
convection together regulate the transportation and accumulation of O₃ in the boundary layer. Under Type 3, there is a valley–
230 plain wind circulation in the boundary layer, and the strong downdraft over urban areas and the higher boundary layer cause
the lowest MDA8 O₃ concentrations among the three weather types.

Overall, Type 1 tends to be associated with the highest excess mortality caused by O₃, and Type 3 is related with the highest
excess mortality caused by HWs. For excess mortality induced by the HW–O₃ compound events, Type 1 (12.59%) > Type 3
(12.05%) > Type 2 (11.66%). Although there is little difference in the HW–O₃ compound ER under the three weather types,
235 the mechanisms of the three types are quite different. Under the modulation of weather circulation and boundary layer
meteorological elements, Type 1, Type 2, and Type 3 were associated with high O₃ and intermediate T_{max} exposure,
intermediate O₃ and low T_{max} exposure, and low O₃ and high T_{max} exposure (Figure 8 and Table 3), respectively. Therefore,
the synoptic weather pattern plays an important role in regulating the formation mechanism of HW–O₃ compound events,
which also further leads to it having a significant impact on morbidities and deaths caused by HW–O₃ compound events.

240 To sum up, urbanization shows a positive regulation on health risks of O₃ and high-temperature under different synoptic
weather patterns. In particular, HWs extended the urban-rural air temperature difference (the UHI effect) in Beijing (Table 2),
which was also found in our previous study (Zong et al., 2021b). That is, the urbanization effect on health risk associated with
heat exposure was amplified during hot days. But for O₃ pollution, urbanization and anthropogenic activities have significantly
increased the emission of pollutants. On the one hand, it promotes photochemical reactions to generate O₃ during HW days.
245 On the other hand, the titration of NO and CO in cities can deplete O₃. Under Type 1, the strong southerly airflow caused the
horizontal transportation of O₃ and its precursors from the southwest (urban) to the northeast (suburban and rural), which is
favourable for the accumulation of pollutants under the topography of Yanshan Mountains (to the north of Beijing). Therefore,
urban-rural differences in O₃ concentration were narrowed, and the risk related to O₃ exposure in the suburban areas were the
greatest under this weather pattern. Type 3 is mainly dominated by the northerly airflow at 850 hPa and the southerly wind at
250 the lower level, the transport of local circulation has a weak adjustment to the urban-rural difference of O₃. However, the BLH
difference between urban and rural areas (north-south difference) should be responsible for the decrease in urban-rural
difference of health risk induced by O₃ concentration. For the stable weather and lower BLH under Type 2, the difference in
O₃ concentration between urban and rural areas was the largest. Based on statistical analysis, the contribution rates of
urbanization to the excessive mortality caused by high temperatures and O₃ exposure were 45.68% and 5.05%, respectively,
255 while 80.21% and 13.9% caused by synoptic pattern, respectively. In summary, urbanization and the synoptic pattern
respectively contributed 18.95% and 33.09% to the total HW–O₃ excess mortality (Table 4).

4 Discussions

In addition to heatstroke, heat exhaustion, heat fainting and heat cramps and other diseases, high temperature during HW days can also lead to increased mortality of residents. Several studies have proposed that the mortality because of respiratory diseases, cardiovascular diseases and cardiopulmonary diseases induced by high temperature and O₃ exposure is particularly relevant (Chen et al., 2018; Du et al., 2020; Hu et al., 2019). Therefore, patients with pre-existing conditions as respiratory and cardiovascular diseases, should pay more attention and limit outdoor activity under heatwaves and O₃ polluted days. Furthermore, demographic, and socio-economic factors related to the level of urbanization, including age structure, education and healthcare services, occupational types, and air-conditioning use, also greatly affect the exposure response function of high temperature and O₃. For instance, females, elderly and people with a lower degree of instruction have suffered significantly higher health risks from overexposure of high temperature and O₃ than the average population (Huang et al., 2015; Yin et al., 2017; Zhang et al., 2017). However, this study mainly considers mortality by all-causes for all the population caused by high temperature and O₃ exposure. Health risks for high-risk groups such as the elderly, children, and patients with cardiovascular and respiratory diseases should be higher than our results. Consequently, especially during synoptic weather patterns that can cause paired HW and O₃ pollution events, the responsible departments should strengthen the risk management of extreme compound events such as HW and O₃ pollution, establish an early warning system, configure emergency plans, strengthen the health precautions of respiratory and cardiovascular diseases, as well as the elderly and other vulnerable groups, and protect public health.

To date, there is no exact consensus on urbanization effects on risk of paired high temperature and O₃ exposure. Previously, a common perception was that urban residents were more prone to risks of heat effect in the context of global warming and UHI effect (Clarke, 1972; Goggins et al., 2012; Heaviside et al., 2017). Indeed, air temperature is one of the main reasons dominate the change in excess mortality caused by compound HW and O₃ events. In terms of the urban areas, the higher density of buildings, roads and population, greater heat capacity and anthropogenic heat, temperature of urban areas is significantly higher than that of rural areas (Roth, 2007; Stewart and Oke, 2012). The heatwaves increase the urban and rural areas temperature difference, as well as the maximum temperature difference, so urban residents may expose to a higher temperature environment. However, the urban-rural difference in O₃ concentration modulated by HW days is inconsistent with that in temperature. Since urban O₃ can be consumed by NO titration (Gao et al., 2020; Murphy et al., 2007; Sillman, 1999), urbanization alleviates the ozone exposure risk of residents to a certain extent. But suburban forests emit additional VOCs that generate O₃ during hot days (Ma et al., 2019; Wang et al., 2021a; Werner et al., 2020), resulting in O₃ pollution slightly lower in urban than suburban areas (Gao et al., 2020). Based on the regional exposure response function model, urban areas suffer from higher mortality related to high temperature, while suburban areas experience higher public mortality associated with O₃ pollution. Overall, there is little difference in the risk of O₃ exposure from urbanization. It should be highlighted that also urbanization brought also some positive aspects. For example, a better economic level and medical conditions, can help to prevent more deaths to a certain extent; high air-conditioning utilization rate can also effectively reduce heat exposure; and the reduction in the

290 proportion of highly exposed people engaged in agriculture, forestry and animal husbandry in urban areas also greatly reduces
the risk of outdoor high-temperature and O₃ overexposure. As a result, rural residents are more vulnerable to face the dual high
temperature and O₃ stress, and their exposure response function coefficients may also be higher than that of urban residents
(Hu et al., 2019; Kovach et al., 2015; Li et al., 2017; Williams et al., 2013; Xing et al., 2020; Zhang et al., 2017). This also
means that under co-occurring heatwaves and ozone-polluted weather patterns, vulnerable groups in the suburbs should be
295 warned on the risks of outdoor activity and limiting their exposure to the pollutants.

Regarding with the paired HW–O₃ events, though we moved a step forward in exploring role of synoptic weather pattern and
urbanization, there are still some limitations in our study. As mentioned earlier, in a specific area, the health risks faced by
residents adjusted by different levels of urbanization may be quite different. Moreover, the high temperature and O₃ compound
health risk model for special populations (e.g., patients with cardiovascular and respiratory diseases, the elderly, children, etc.)
300 can also be further established and analysed. Therefore, in the future research on compound climate and pollution health
impacts it is necessary to consider a more refined discussion in a city based on the level of urbanization and among different
population groups.

5 Conclusions

In this study, the complex mechanism of co-occurring HW–O₃ events in the boundary layer in Beijing was systematically
305 investigated by combining meteorological observations, environmental monitoring observations, and reanalysis data, and the
regulatory role on health risks induced by such compound events was explained from the perspective of the synoptic pattern
and urbanization.

The Beijing area not only experienced a stronger UHI effect during the summertime high-temperature HWs, but was also often
accompanied by more serious O₃ pollution. In the period under study, the max temperature T_{\max} and MDA8 O₃ concentrations
310 during HW days were $\sim 4.21^{\circ}\text{C}$ and $\sim 37.98 \mu\text{g m}^{-3}$ higher than those on NHW days, respectively, excluding rainy daytime
days. When people are exposed to the dual stress of high temperatures and O₃ pollution during HW–O₃ days, the increase in
 T_{\max} and MDA8 O₃ concentrations is associated with an 12.31% (95% CI: 4.66%, 20.81%) higher excess mortality from all
non-accidental causes. Three favourable synoptic weather patterns that dominate such compound events and were identified
as: (1) Type 1, a high-pressure system located in the southeast of Beijing and accompanied by southwesterly winds, under
315 which the weak downdraft and relative stable boundary layer weaken the vertical mixing of O₃ and induce heavy O₃ pollution,
consequently meaning that people consistently experience high health risks; (2) Type 2, in which Beijing is under the influence
of a high-pressure system accompanied by weak southerly winds and sinking airflow in the boundary layer that favours O₃
transport together with its precursors. This translates into a lower excess mortality under Type 2 with respect to Type 1; and
(3) Type 3, a low-pressure system located in the northeast of Beijing accompanied by northwesterly winds. Under this type,
320 people endure stronger heat stress owing to higher temperatures and lower RH, but the higher BLH and large atmospheric
environment capacity alleviate O₃ exposure to a certain extent, which results in a decrease in O₃ concentration and ER

compared with the other two patterns. Overall, the unfavourable weather types contributed ~33.09% to the excess mortality attributed to the HW–O₃ compound events.

325 In addition, urbanization has also exacerbated the combined health risks of high temperature and O₃ pollution, which contributed ~18.95%. During the co-occurring HW–O₃ days, urbanization greatly affected the increase in high temperatures and related excess mortality risks in urban areas, which were significantly higher than those in rural areas. However, O₃ pollution and its health risks in urban areas were slightly higher than those in rural areas, and urbanization effect was attenuated due to the reaction of O₃ and NO. Note that O₃ pollution and its health risks in suburban areas were quite prominent due to less O₃ depletion and more bio-VOCs emissions.

330 In summary, our findings help to better understand the formation mechanism of HW–O₃ compound events in Beijing, with robust supporting evidence from the perspective of synoptic patterns and urbanization. Our results also suggest that forecasting of identified synoptic patterns could help to avoid exposure of compound HW–O₃ events. However, the urbanization effect has different regulatory effect on HWs and O₃, meaning that high temperatures and O₃ exposure is deserving of the establishment of a more refined health model that takes into account the differences between urban and rural areas.

335 **Data availability**

The datasets that are analyzed and used to support the findings of this study are available in the public domains: The ground-level O₃ observation data can be obtained from Beijing Municipal Ecological and Environmental Monitoring Center (<http://www.bjmemc.com.cn/>, last access on November 20, 2021). The hourly meteorological data can be obtained from the National Meteorological Information Center of the China Meteorological Administration (<http://data.cma.cn/>, last access on
340 November 20, 2021). The ERA5 reanalysis data set is available at the European Centre for Medium-Range Weather Forecasts (<https://cds.climate.copernicus.eu/cdsapp#!/home>, last access on November 20, 2021).

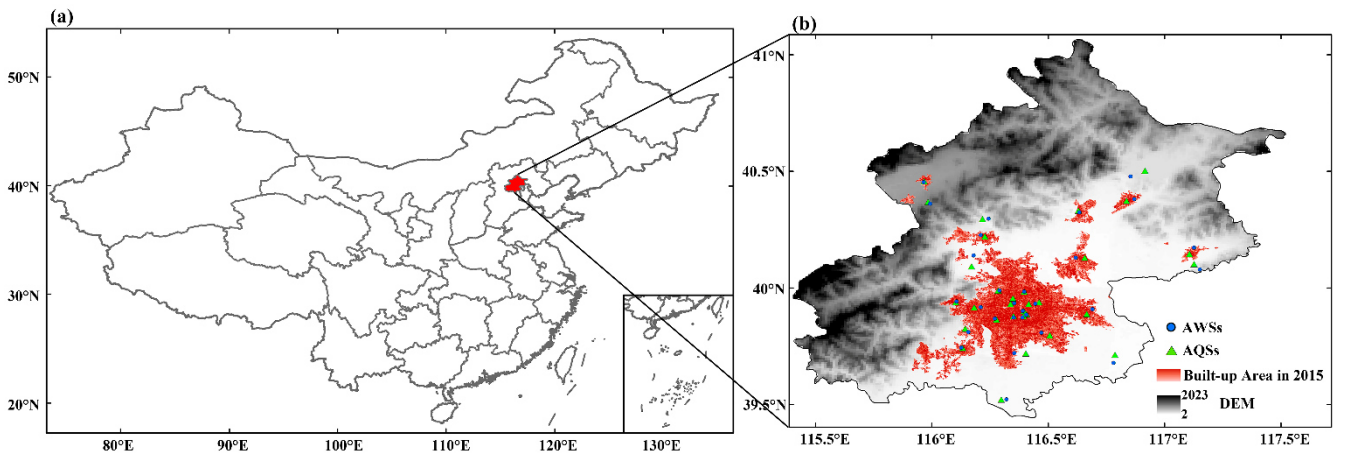

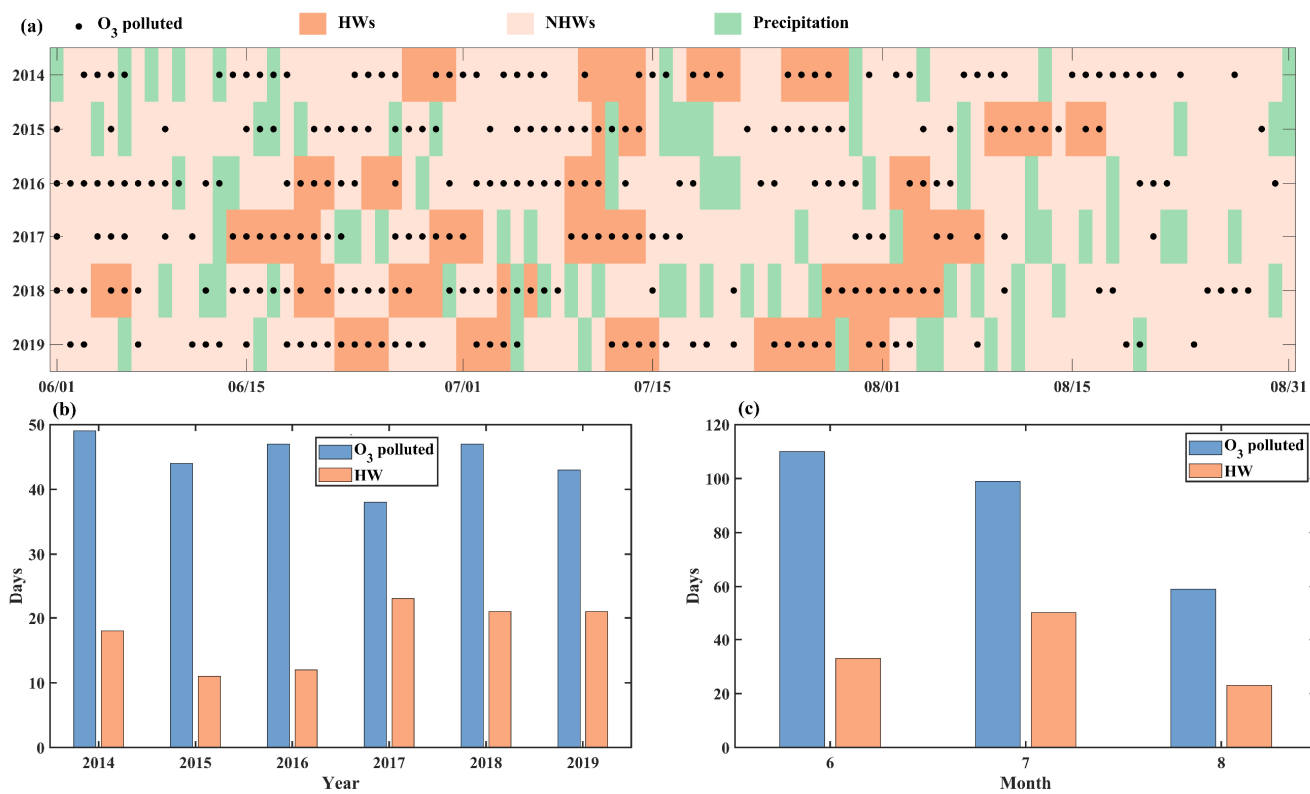

Figure 1: (a) Geography of Beijing. (b) Distribution of AWSs and air quality stations (AQSS) in Beijing (superimposed on the built-up area data for 2015 from digital elevation model data).

575 **Figure 2: (a) Time series of weather types, in which the black dots indicate O₃ pollution that occurred on that day. Interannual (b) and intraseasonal (c) variations in summertime O₃ pollution and HW days.**

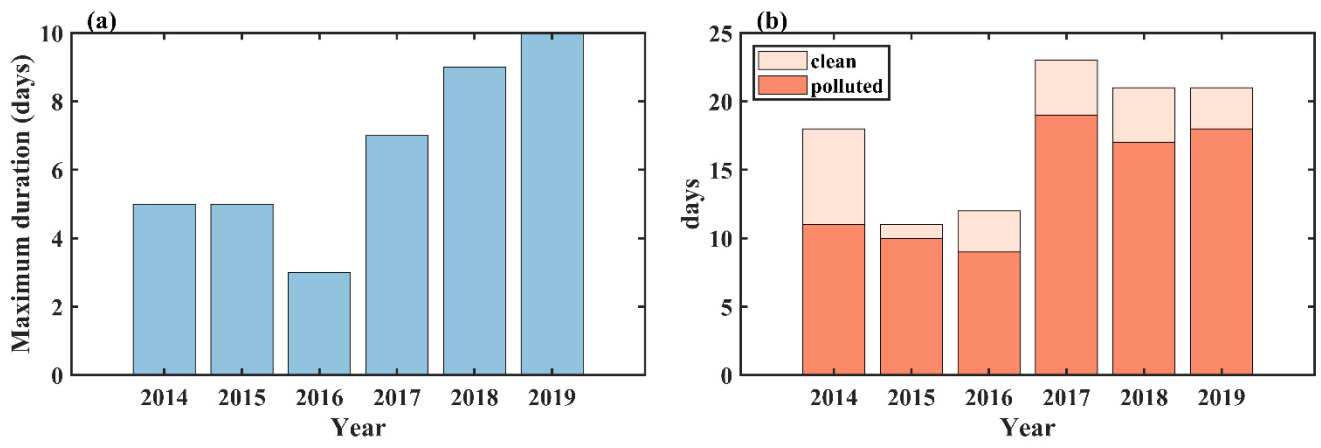

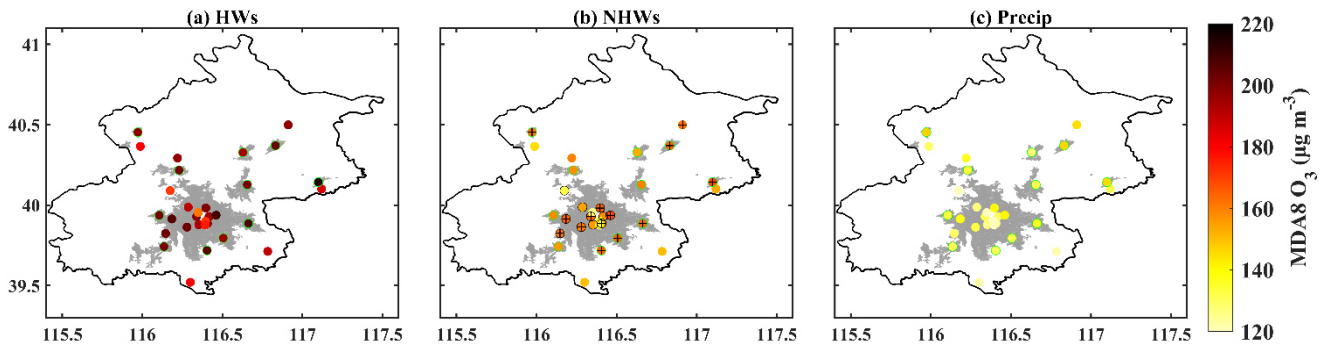

Figure 3: (a) Maximum number of days of HW events each year. (b) Proportion of O₃ pollution during HW events each year.

580

585 **Figure 4: Distribution of MDA8 O₃ under (a) HWs, (b) NHWs, and (c) precipitation periods (superimposed on built-up area data for 2015, black and green circles represent urban and suburban stations, respectively).**

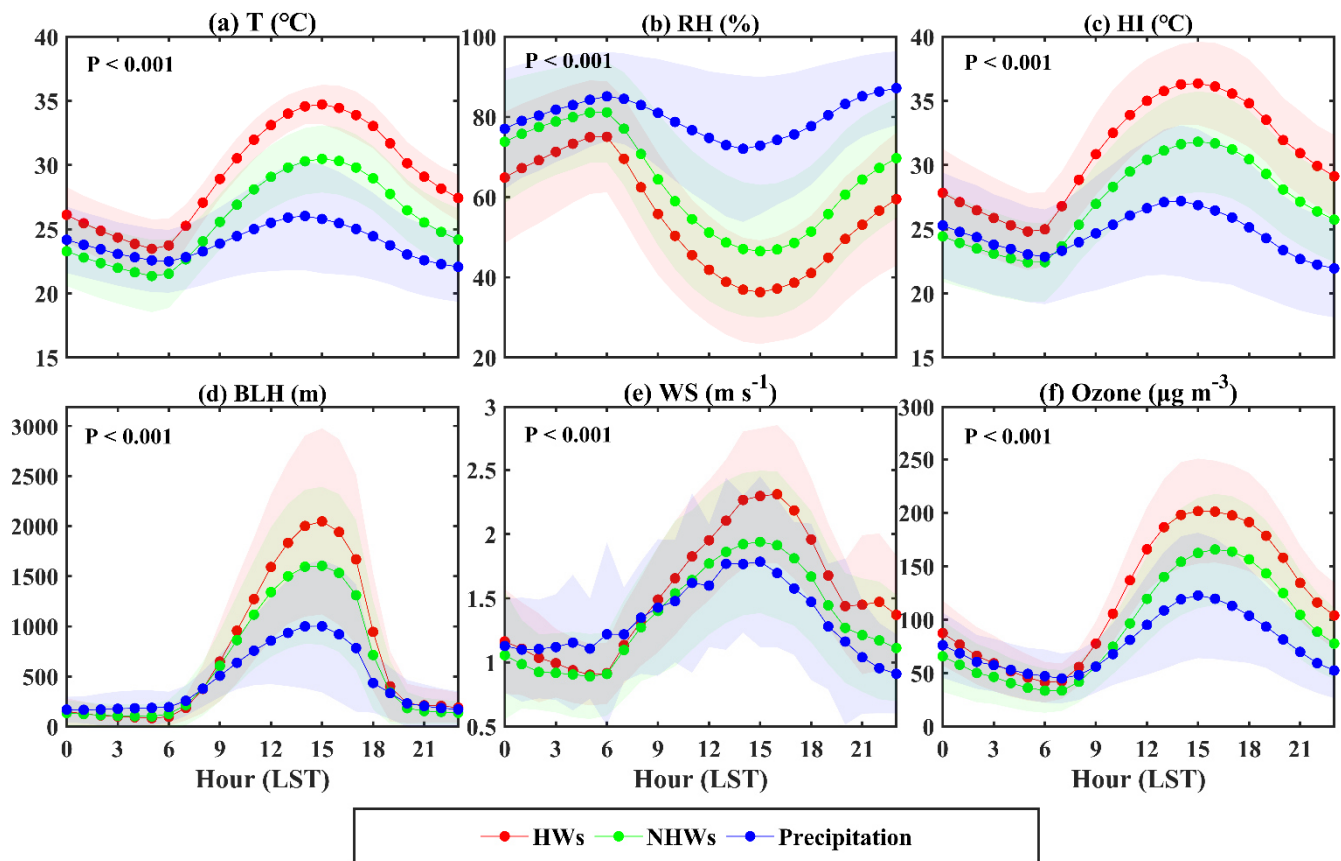

Figure 5: The diurnal variation of (a) air temperature, (b) RH, (c) HI, (d) BLH, (e) WS and (f) O₃, under HWs, NHWs and precipitation periods (shading indicates standard deviation, $P < 0.001$ means pass the significance test).

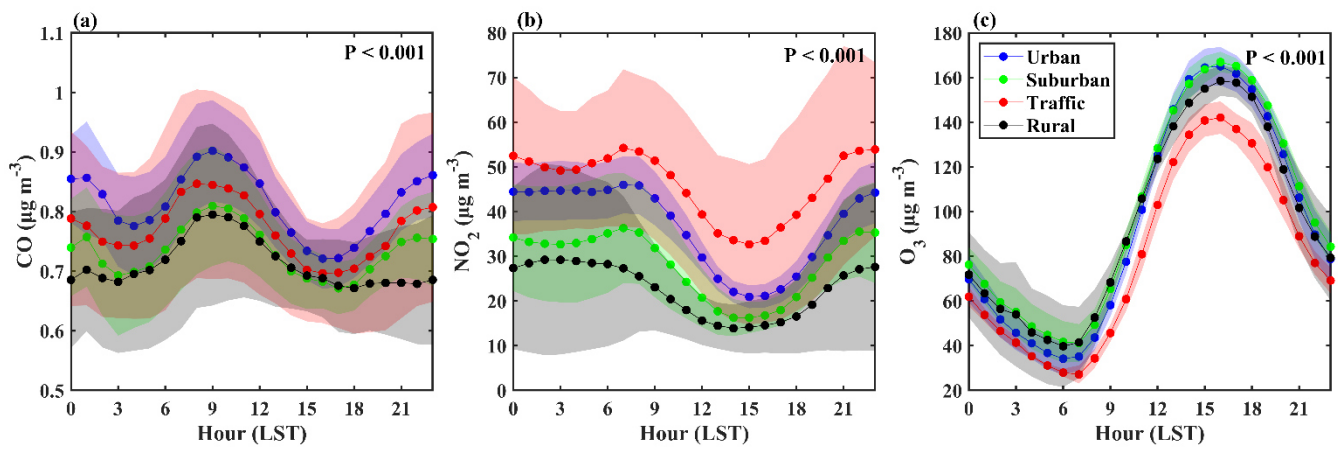

Figure 6: The diurnal variation of (a) CO, (b) NO₂, (c) O₃, under different stations (shading indicates standard deviation, $P < 0.001$ means pass the significance test).

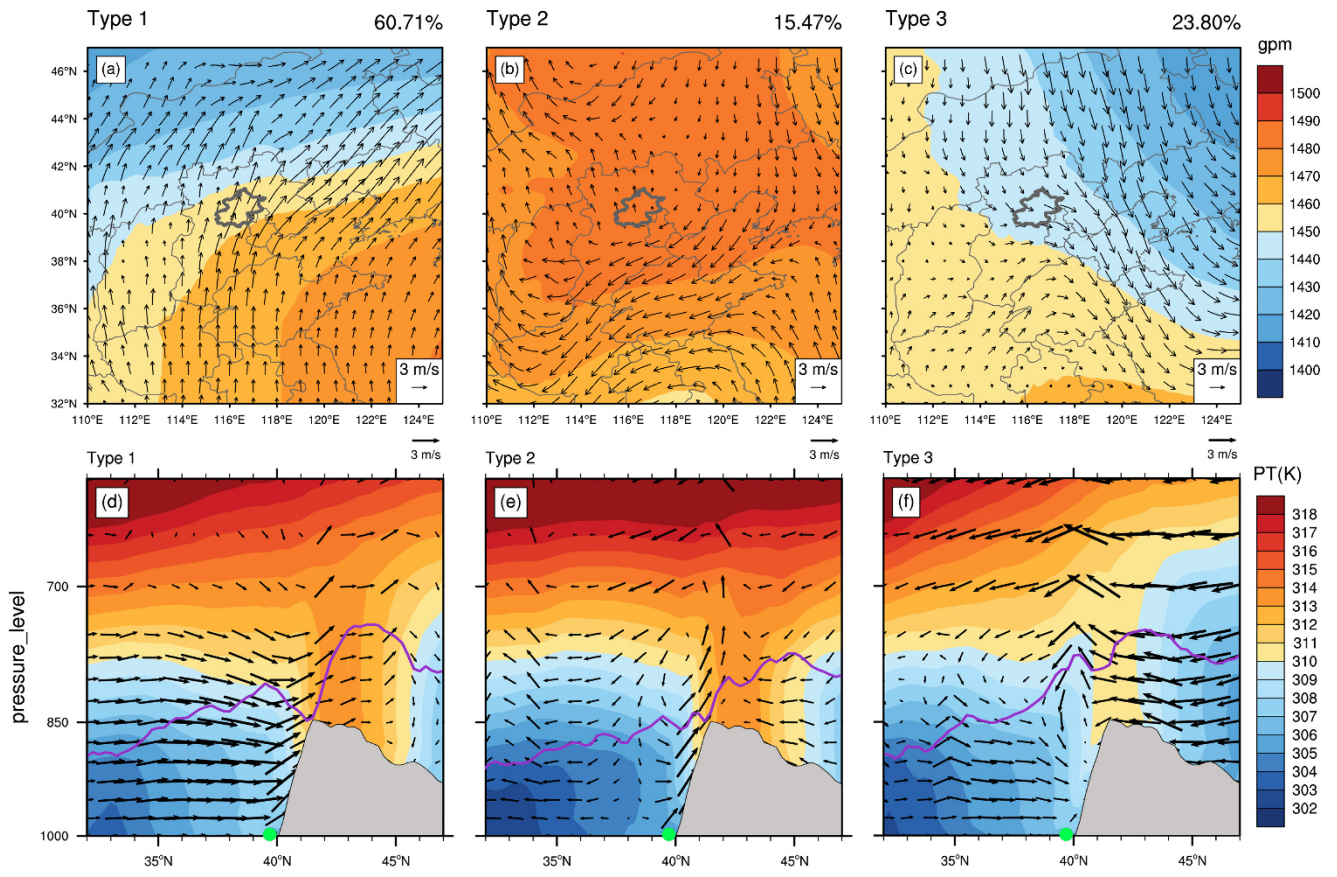

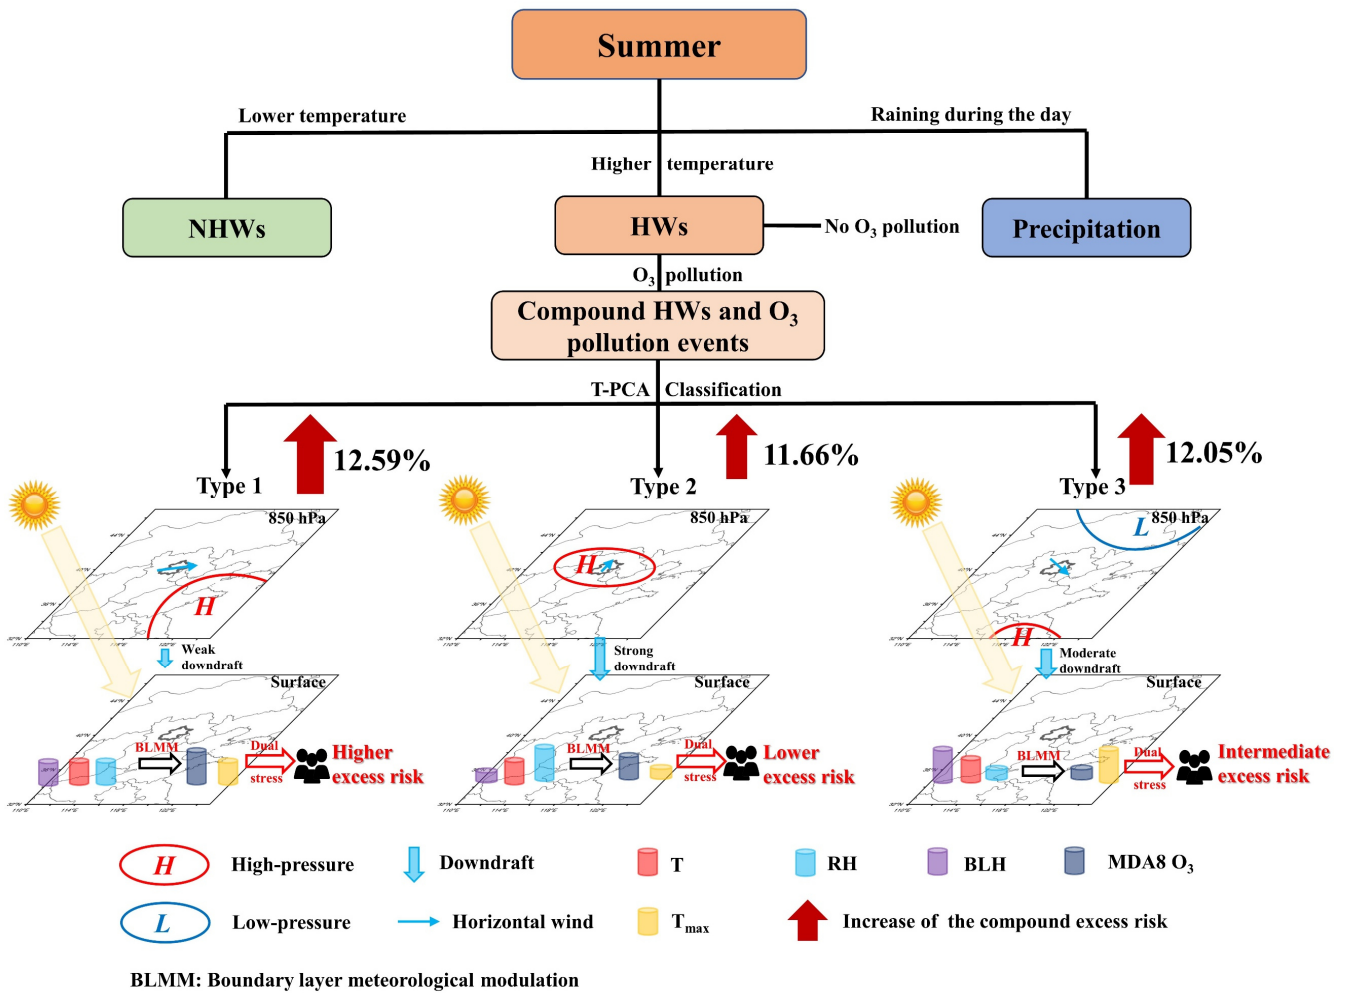

Figure 7: (a–c) 850-hPa GH (contours) and uv -wind (vectors) patterns related to HWs and O_3 pollution compound events based on objective classification (grey outline represents Beijing, and the number in the upper-right corner of each panel indicates the frequency of occurrence of each pattern). (d–f) Vertical cross-sections of the potential temperature (contours) and wind vectors (synthesized by v and scaled ω , ω scaled by 100) averaged between $116.0^\circ E$ and $117.0^\circ E$ associated with the synoptic patterns (purple solid lines mark the BLH, black contours mark the topography, and the green dot marks the location of Beijing).

600

605 **Figure 8:** Schematic illustration of the mechanism of HW and O₃ compound pollution events under different synoptic weather patterns (height of the icon indicates the size of each variable).

Table 1: The location information and station type of AQSs, the corresponding AWSs are the closest matching weather station among 295 AWSs.
