Abstract

We examined the impacts of aerosol-radiation interactions, including the effects of aerosol-photolysis interaction (API) and aerosol-radiation feedback (ARF), on surface-layer ozone (O_3) concentrations during one multi-pollutant air pollution episode characterized by high O_3 and $\text{PM}_{2.5}$ levels from 28 July to 3 August 2014 in North China, by using the Weather Research and Forecasting with Chemistry (WRF-Chem) model embedded with an integrated process analysis scheme. Our results show that aerosol-radiation interactions decreased the daytime shortwave radiation at surface by 93.2 W m^{-2} averaged over the complex air pollution areas. The dimming effect reduced the 2 m temperature and near-surface photolysis rates of $\text{J}[\text{NO}_2]$ and $\text{J}[\text{O}^1\text{D}]$ by $0.56 \text{ }^\circ\text{C}$, $1.8 \times 10^{-3} \text{ s}^{-1}$ and $6.1 \times 10^{-6} \text{ s}^{-1}$, respectively. However, the daytime shortwave radiation in the atmosphere was increased by 72.8 W m^{-2} , which made the atmosphere more stable. The stabilized atmosphere decreased the planetary boundary layer height and 10 m wind speed by 129.0 m and 0.12 m s^{-1} , respectively, and increased the relative humidity at 2 m by 2.4%. The weakened photolysis rates and changed meteorological conditions reduced daytime surface-layer O_3 concentrations by up to 11.4 ppb (13.5%), with API and ARF contributing 74.6% and 25.4% of the O_3 decrease, respectively. Process analysis indicated that the weakened O_3 chemical production made the greatest contribution to API effect while the reduced vertical mixing was the key process for ARF effect. This study implies that future $\text{PM}_{2.5}$ reductions will lead to O_3 increases due to weakened aerosol-radiation interactions. Therefore, tighter controls of O_3 precursors are needed to offset O_3 increases caused by weakened aerosol-radiation interactions in the future.

1 Introduction

China has been experiencing severe air pollution in recent years, characterized by high loads of PM_{2.5} (particulate matter with an aerodynamic equivalent diameter of 2.5 micrometers or less) and high levels of ozone (O₃). Observational studies exhibited positive correlations and synchronous occurrence of PM_{2.5} and O₃ pollution in North China during summer (Zhao et al., 2018; Zhu et al., 2019), indicating that complex air pollution is becoming a major challenge for North China.

Aerosols can absorb and scatter solar radiation to affect Earth's energy balance. They can also act as cloud condensation nuclei and ice nuclei, and further modify the microphysical characteristics of clouds (Albrecht et al., 1989; Haywood et al., 2000; Lohmann et al., 2005). Both ways perturb meteorological variables, e.g., temperature, planetary boundary layer height (PBLH), and precipitation, and eventually influence air pollutants (Petäjä et al., 2016; Miao et al., 2018; Zhang et al., 2018). Many studies are focused on the feedback between aerosol and meteorology (Gao et al., 2015; Gao et al., 2016a; Qiu et al., 2017; Chen et al., 2019; Zhu et al., 2021). Gao et al. (2015) used the WRF-Chem model to investigate the feedbacks between aerosols and meteorological variables over the North China Plain in January 2013, and pointed out that aerosols could cause a decrease in surface temperature by 0.8-2.8 °C but an increase of 0.1-0.5 °C around 925 hPa. The more stable atmosphere caused by surface cooling and higher-layer heating led to the decreases of surface wind speed and PBLH by 0.3 m s⁻¹ and 40-200 m, respectively, which further resulted in overall PM_{2.5} increases by 10-50 µg m⁻³ (2-30%). By using the same WRF-Chem model, Qiu et al. (2017) reported that the surface downward shortwave radiation and PBLH were reduced by 54.6 W m⁻² and 111.4 m due to aerosol radiative forcing during 21 and 27 February 2014 in the North China Plain. As a result, the surface PM_{2.5} concentration averaged over the North China Plain was increased by 34.9 µg m⁻³ (20.4%).

Aerosols can also influence O₃ through aerosol-radiation interactions, including aerosol-photolysis interaction and aerosol-radiation feedback. Aerosols can scatter and absorb UV radiation, and therefore directly affect O₃ photochemistry reactions, which

is called aerosol-photolysis interaction (API) (Dickerson et al., 1997; Liao et al., 1999; Li et al., 2011; Lou et al., 2014). The changed meteorological variables due to aerosol radiative forcing can indirectly affect O₃ concentrations, which is called aerosol-radiation feedback (ARF) (Hansen et al., 1997; Gao et al., 2018; Liu et al., 2020). Although the effects of API or ARF on O₃ have been examined by previous studies (Xing et al., 2017; Gao et al., 2018; Gao et al., 2020), the combined effects of API and ARF on O₃, especially under the conditions of synchronous occurrence of high PM_{2.5} and O₃ concentrations, remain largely elusive.

The present study aims to (1) quantify the respective/combined contributions of API and ARF on surface O₃ concentrations by using the WRF-Chem model; (2) explore the prominent physical and/or chemical processes responsible for API and ARF effects by using an integrated process rate (IPR) analysis embedded in WRF-Chem model. The analysis is conducted during one multi-pollutant air pollution episode characterized by high O₃ and PM_{2.5} levels from 28 July to 3 August 2014 in North China. The model configuration, numerical experiments, observational data, and the integrated process rate analysis are described in section 2. Section 3 shows the model evaluation. The presentation of the model results and the corresponding analyses are exhibited in section 4. The discussion is provided in section 5, and the conclusion and uncertainties of this study are given in section 6.

2 Methods

2.1 Model configuration

The version 3.7.1 of the online-coupled Weather Research and Forecasting with Chemistry (WRF-Chem) model (Grell et al., 2005; Skamarock et al., 2008) is used in this study to explore the impacts of aerosol-radiation interactions on surface-layer O₃ in North China. WRF-Chem can simulate gas phase species and aerosols coupled with meteorological fields, and has been widely used to investigate air pollution over North China (Gao et al., 2016a; Gao et al., 2020; Wu et al., 2020). As shown in Fig. 1, we design two nested model domains with the number of grid points of 57 (west–east) × 41 (south–north) and 37 (west–east) × 43 (south–north) at 27 and 9 km horizontal

resolutions, respectively. The parent domain centers at 39 °N, 117 °E. The model contains 29 vertical levels from the surface to 50 hPa, with 14 levels below 2 km for the fully description of the vertical structure of planetary boundary layer (PBL).

The Carbon Bond Mechanism Z (CBM-Z) is selected as the gas-phase chemical mechanism (Zaveri and Peters, 1999), and the full 8-bin MOSAIC (Model for Simulating Aerosol Interactions and Chemistry) aerosol module with aqueous chemistry is used to simulate aerosol evolution (Zaveri et al., 2008). The photolysis rates are calculated by the Fast-J scheme (Wild et al., 2000). Other major physical parameterizations used in this study are listed in Table 1.

The initial and boundary meteorological conditions are provided by the National Centers for Environmental Prediction (NCEP) Final Analysis data with a spatial resolution of $1^{\circ} \times 1^{\circ}$. In order to limit the model bias of simulated meteorological fields, the four-dimensional data assimilation (FDDA) is used with a nudging coefficient of 3.0×10^{-4} for the wind, temperature and humidity (no analysis nudging is applied for the inner domain) (Lo et al., 2008; Otte, 2008). Chemical initial and boundary conditions are obtained from the Model for Ozone and Related chemical Tracers, version 4 (MOZART-4) forecasts (Emmons et al., 2010).

Anthropogenic emissions are taken from the 2010 MIX Asian emission inventory (Li et al., 2017a), which provides emissions of sulfur dioxide (SO₂), nitrogen oxides (NO_x), carbon monoxide (CO), non-methane volatile organic compounds (NMVOCs), carbon dioxide (CO₂), ammonia (NH₃), black carbon (BC), organic carbon (OC), PM₁₀ (particulate matter with aerodynamic diameter is 10 μm and less) and PM_{2.5}. Emissions are aggregated from four sectors, including power generation, industry, residential, and transportation, with $0.25^{\circ} \times 0.25^{\circ}$ spatial resolution. Biogenic emissions are calculated online by the Model of Emissions of Gases and Aerosols from Nature (MEGAN) (Guenther et al., 2006).

2.2 Numerical experiments

To quantify the impacts of API and ARF on O₃, three case simulations have been conducted: (1) BASE – the base simulation coupled with the interactions between

aerosol and radiation, which includes both impacts of API and ARF; (2) NOAPI – the same as the BASE case, but the impact of API is turned off (aerosol optical properties are set to zero in the photolysis module), following Wu et al. (2020); (3) NOALL – both the impacts of API and ARF are turned off (removing the mass of aerosol species when calculating aerosol optical properties in the optical module), following Qiu et al. (2017). The differences between BASE and NOAPI (i.e., BASE minus NOAPI) represent the impacts of API. The contributions from ARF can be obtained by comparing NOAPI and NOALL (i.e., NOAPI minus NOALL). The combined effects of API and ARF on O₃ concentrations can be quantitatively evaluated by the differences between BASE and NOALL (i.e., BASE minus NOALL).

Each simulation is conducted from 26 July to 3 August 2014, with the first 40 hours as the model spin-up. Simulation results from the BASE case during 28 July and 3 August 2014 are used to evaluate the model performance.

2.3 Observational data

Simulation results are compared with meteorological and chemical measurements. The surface-layer meteorological data (2 m temperature (T₂), 2 m relative humidity (RH₂), and 10 m wind speed (WS₁₀)), with a temporal resolution of 3 h, at ten stations (Table S1) are obtained from NOAA's National Climatic Data Center (<https://gis.ncdc.noaa.gov/maps/ncei/cdo/hourly>). The radiosonde data of temperature at 08:00 and 20:00 LST in Beijing (39.93 °N, 116.28 °E) are provided by the University of Wyoming (<http://weather.uwyo.edu/>). Observed hourly concentrations of PM_{2.5} and O₃ at thirty-two sites (Table S2) in North China are collected from the China National Environmental Monitoring Center (CNEMC). The photolysis rate of nitrogen dioxide (NO₂) (J[NO₂]) measured at the Peking University site (39.99 °N, 116.31 °E) is also used to evaluate the model performance. More details about the measurement technique of J[NO₂] can be found in Wang et al. (2019). The satellite-retrieved 550 nm AOD products from the Moderate Resolution Imaging Spectroradiometer (MODIS) are also used to compare with the simulated ones. The model results from 10:00 to 11:00 and 13:00 to 14:00 LT are extracted and averaged, due to instruments on board the Terra

and Aqua platforms pass over China at around 10:30 and 13:30 LT, respectively.

2.4 Integrated process rate analysis

Integrated process rate (IPR) analysis has been widely used to quantify the contributions of different processes to O₃ variations (Goncalves et al., 2009; Gao et al., 2016b; Tang et al., 2017; Gao et al., 2018). In this study, four physical/chemical processes are considered, including vertical mixing (VMIX), net chemical production (CHEM), horizontal advection (ADVH), and vertical advection (ADVZ). VMIX is initiated by turbulent process and closely related to PBL development, which influences O₃ vertical gradients. CHEM represents the net O₃ chemical production (chemical production minus chemical consumption). ADVH and ADVZ represent transport by winds (Gao et al., 2016b). In this study, we define ADV as the sum of ADVH and ADVZ.

3 Model evaluation

Reasonable representation of observed meteorological and chemical variables by the WRF-Chem model can provide foundation for evaluating the impacts of aerosols on surface-layer ozone concentration. The model results presented in this section are taken from the BASE case. The concentrations of air pollutants are averaged over the thirty-two observation sites in Beijing, Tianjin and Baoding. To ensure the data quality, the mean value for each time is calculated only when concentrations are available at more than sixteen sites.

3.1 Chemical simulations

Figure 2 shows the spatial-temporal variations of observed and simulated PM_{2.5} and O₃ concentrations over North China during 28 July to 3 August 2014. The observed higher concentrations in Beijing and Baoding than those in Tianjin are well reproduced by WRF-Chem. The model can also reasonably capture the temporal variations of observed PM_{2.5} and O₃ with correlation coefficients (R) of 0.66 for PM_{2.5} and 0.86 for O₃, although simulated results underestimate the observed PM_{2.5} by -19.2% and O₃ by -12.0%. The failure to reproduce PM_{2.5} peak values may be attributed to incomplete treatments of chemical reactions in WRF-Chem, e.g., The failure to reproduce PM_{2.5}

peak values may be attributed to incomplete treatments of chemical reactions in WRF-Chem, e.g., missing the heterogeneous chemistry in the model (Cheng et al., 2016) and the lack of secondary organic aerosols (SOA) formation pathways in the aerosol module (Chen et al., 2019). More statistical parameters between simulations and observations are presented in Table 2.

Figure S1 shows the spatial distributions of aerosol optical depth (AOD) at 550 nm retrieved from MODIS and simulated by WRF-Chem during 28 July to 3 August 2014. In the WRF-Chem model, the AOD at 550 nm are calculated by using the values at 400 and 600 nm according to the Ångström exponent. Analyzing Fig. S1, the model can well reproduce the spatial distribution of observed AOD but slightly underestimate the value. The spatial correlation coefficient between the simulated and observed AOD is 0.98.

3.2 Meteorological simulations

Figure 3 shows the time series of observed and simulated T_2 , RH_2 , and WS_{10} averaged over ten meteorological observation stations, and $J[NO_2]$ at Peking University during 28 July to 3 August 2014. The statistical metrics for T_2 , RH_2 , WS_{10} , and $J[NO_2]$ are also presented in Table 2. Generally, the model can depict the temporal variations of T_2 fairly well with R of 0.98 and the mean bias (MB) of $-1.5\text{ }^{\circ}\text{C}$. For RH_2 , the R and MB are 0.91 and 0.5%, respectively. Although WRF-Chem model overestimates WS_{10} with the MB of 0.7 m s^{-1} , the R for WS_{10} is 0.89 and the root-mean-square error (RMSE) is 0.9 m s^{-1} , which is smaller than the threshold of model performance criteria (2 m s^{-1}) proposed by Emery et al. (2001). The large positive bias in wind speed was also reported in other studies (Zhang et al., 2010; Gao et al., 2015; Liao et al., 2015; Qiu et al., 2017). The predicted $J[NO_2]$ agrees well with the observations with R of 0.97 and NMB of 6.8%. We also conduct comparison between observed and simulated temperature profiles at 08:00 and 20:00 LST in Beijing during 29 July to 1 August 2014 in Figure S2. The vertical profile of observed temperature, especially the thermal inversion layer occurred on 31 July around 1600 m, is well captured by the model. Generally, the WRF-Chem model reasonably reproduces the temporal variations of

observed meteorological parameters.

4 Results

It is known that co-occurrence of PM_{2.5} and O₃ pollution is frequently observed nowadays over China (Dai et al., 2021). The complex air pollution characterized by high PM_{2.5} and O₃ levels has already received widespread attention from both scientists and policy-makers. Therefore, we examine the impacts of aerosol-radiation interactions on O₃ concentrations with a special focus on the complex air pollution areas (CAPAs, Fig. S3), where the mean simulated daily PM_{2.5} and MDA8 (maximum daily 8-h average) O₃ concentrations are larger than 75 $\mu\text{g m}^{-3}$ and 80 ppb, respectively, based on the National Ambient Air Quality Standards (<http://www.mee.gov.cn>).

4.1 Impacts of aerosol-radiation interactions on meteorology

Figure 4 shows the impacts of aerosol-radiation interactions on shortwave radiation at the surface (BOT_SW), shortwave radiation in the atmosphere (ATM_SW), PBLH, T₂, RH₂, and WS₁₀ during the daytime (08:00-17:00 LST) from 28 July to 3 August 2014. As a result of the interactions between aerosol and radiation (the combined impacts of API and ARF), BOT_SW is decreased over the entire simulated domain. Over CAPAs, the BOT_SW is decreased by 93.2 W m⁻² (20.5%). Contrary to the changes in BOT_SW, ATM_SW is increased significantly with an increase of 72.8 W m⁻² (25.3%) over CAPAs. The decreased BOT_SW perturbs the near-surface energy flux, which weakens convection and suppresses the development of PBL (Li et al., 2017b). The PBLH averaged over CAPAs is calculated to decrease by 129.0 m (13.0%). The reduced surface radiation budget can directly lead to changes in near-surface temperature. Therefore, the changes in T₂ have the similar spatial patterns with BOT_SW; the surface temperature is decreased by 0.56 °C averaged over CAPAs. RH₂ is increased over most of the domain with an average rise of 2.4%, which is beneficial for the hygroscopic growth of aerosols. WS₁₀ exhibits overall reductions over CAPAs and is calculated to decrease by 0.12 m s⁻¹ on average. We also examine the changed meteorological variables caused by API and ARF respectively. As shown in Fig. S4, API has little impact on meteorological variables; the above changes are mainly caused

by ARF.

4.2 Impacts of aerosol-radiation interactions on photolysis

Figure 5 shows the spatial distribution of mean daytime surface-layer $\text{PM}_{2.5}$ concentrations simulated by BASE case and the changes in $J[\text{NO}_2]$ and $J[\text{O}^1\text{D}]$ due to aerosol-radiation interactions from 28 July to 3 August 2014. When the combined impacts (API and ARF) are considered, $J[\text{NO}_2]$ and $J[\text{O}^1\text{D}]$ are decreased over the entire domain; the spatial patterns of changed $J[\text{NO}_2]$ and $J[\text{O}^1\text{D}]$ are similar to that of simulated $\text{PM}_{2.5}$. The surface $J[\text{NO}_2]$ and $J[\text{O}^1\text{D}]$ are decreased by $1.8 \times 10^{-3} \text{ s}^{-1}$ (40.5%) and $6.1 \times 10^{-6} \text{ s}^{-1}$ (48.8%) averaged over CAPAs. Figure S5 exhibits the percentage changes in surface $J[\text{NO}_2]$ and $J[\text{O}^1\text{D}]$ caused by API and ARF respectively. It is found that $J[\text{NO}_2]$ and $J[\text{O}^1\text{D}]$ are significantly modified by API and little affected by ARF.

4.3 Impacts of aerosol-radiation interactions on O_3

Figure 6 shows the changes in surface-layer O_3 due to API, ARF, and the combined effects (denoted as ALL). As shown in Fig. 6a, API alone leads to overall surface O_3 decreases over the entire domain with an average reduction of 8.5 ppb (10.1%) over CAPAs. The change can be explained by the substantially diminished UV radiation due to aerosol loading, which significantly weakens the efficiency of photochemical reactions and restrains O_3 formation. The decreased surface O_3 concentration due to ARF, however, is only 2.9 ppb (3.1%, Fig. 6b), which indicates that API is the dominant way for O_3 reduction related to aerosol-radiation interactions. The combined effects of API and ARF are shown in Fig. 6c. Generally, aerosol-radiation interactions decrease the surface O_3 concentration by 11.4 ppb (13.5%) averaged over CAPAs.

4.4 Influencing mechanism of aerosol-radiation interactions on O_3

Figure 7a shows diurnal variations of simulated surface (first layer) daytime O_3 concentrations over CAPAs in three cases (BASE, NOAPI, and NOALL). All cases present O_3 increases from 08:00 LST. It is shown that the simulated O_3 concentrations in BASE case increase more slowly than that in NOAPI and NOALL cases. To explain the underlying mechanisms of API and ARF impacts on O_3 , we quantify the variations in contributions of different processes (ADV, CHEM, and VMIX) to O_3 by using the

IPR analysis.

Figure 7b shows hourly surface O₃ changes induced by each physical/chemical process (i.e., ADV, CHEM, and VMIX) in BASE case. The significant positive contribution to the hourly variation in O₃ is contributed by VMIX, and the contribution reaches the maximum at about 10:00 LST. After 14:00 LST, the contribution from VMIX remains constant (nearly +2 ppb h⁻¹), which is probably attributed to the stable boundary layer development (Tang et al., 2016). The CHEM process makes negative contributions at around 09:00 and 16:00 LST, which means that the chemical consumption of O₃ is stronger than the chemical production. At noon, the net chemical contribution turns to be positive due to stronger solar UV radiation. The contribution from all the processes (NET, the sum of VMIX, CHEM, and ADV) to O₃ is peaked at the noon and then becomes weakened. After sunset (17:00 LST), the NET contribution turns to be negative over CAPAs, leading to O₃ decrease.

Figure 7c shows the changes in hourly process contributions caused by API. The chemical production of O₃ is suppressed significantly due to aerosol impacts on photolysis rates. The weakened O₃ chemical production decreases the contribution from CHEM, and results in a negative value of CHEM_DIF (-3.5 ppb h⁻¹). In contrast to CHEM_DIF, the contribution from changed VMIX (VMIX_DIF) to O₃ concentration due to API is always positive, and the mean value is +3.1 ppb h⁻¹. The impact of API on ADV process is relatively small (-0.36 ppb h⁻¹). NET_DIF, namely the sum of VMIX_DIF, CHEM_DIF and ADV_DIF, indicates the differences in hourly O₃ changes caused by API. As shown in Fig. 7c, NET_DIF is almost negative during the daytime over CAPAs with the mean value of -0.76 ppb h⁻¹. This is because the decreases in CHEM and ADV are larger than the increases in VMIX caused by API; the O₃ decrease is mainly attributed to the significantly decreased contribution from CHEM. The maximum difference in O₃ between BASE and NOAPI appears at 17:00 LST with a value of -10.1 ppb (Fig. 7a).

Figure 7d shows the impacts of ARF on each physical/chemical process contribution to the hourly O₃ variation. At 08:00 LST, the change in VMIX due to ARF is large with a value of -4.6 ppb h⁻¹, resulting in a net negative variation with all

processes considered. The decrease in O_3 reaches the maximum with the value of 6.1 ppb at around 09:00 LST over CAPAs (Fig. 7a). During 10:00 to 16:00 LST, the positive VMIX_DIF (mean value of $+0.59 \text{ ppb h}^{-1}$) or the positive CHEM_DIF (mean value of $+0.16 \text{ ppb h}^{-1}$) is the major process to positive NET_DIF.

When both impacts of API and ARF are considered, the variation pattern of the difference in hourly process contribution shown in Fig. 7e is similar to that in Fig. 7c, which indicates that API is the dominant factor to surface-layer O_3 reduction.

Figure 8 presents the vertical profiles of simulated daytime O_3 concentrations in three cases (BASE, NOAPI, and NOALL), and the differences in contributions from each physical/chemical process to hourly O_3 variations caused by API, ARF and the combined effects during 28 July to 3 August 2014 over CAPAs. As shown in Fig. 8a, the O_3 concentration is lower in BASE than that in other two scenarios (NOAPI and NOALL), especially at the lower 12 levels (below 731.9 m), owing to the impacts of aerosols (API and/or ARF).

The changes in each process contribution caused by API are presented in Fig. 8b. The contribution from CHEM_DIF is -2.14 ppb h^{-1} for first seven layers (from 23.4 to 290.7 m). Conversely, the contribution from VMIX_DIF shows a positive value under the 290.7 m (between first layer to seventh layer) with the mean value of $+1.7 \text{ ppb h}^{-1}$. The positive variation in VMIX due to API may be associated with the different vertical gradient of O_3 between BASE and NOAPI cases. The contributions of changed advections (ADVH_DIF and ADVZ_DIF) are relatively small, with mean values of $+0.25$ and -0.47 ppb h^{-1} respectively below the first seven layers, which may result from small impact of API on wind field (Fig. S4a). The net difference is a negative value (-0.66 ppb h^{-1}); API leads to O_3 reduction not only nearly surface but also aloft.

Figure 8c shows the differences in O_3 budget due to ARF. When the ARF is considered, the vertical turbulence is weakened and the development of PBL is inhibited, which makes VMIX_DIF negative at the lower 7 layers (below the 290.7 m) with a mean value of -0.55 ppb h^{-1} , but the variation in CHEM caused by ARF is positive with a mean value of $+0.6 \text{ ppb h}^{-1}$. The enhanced O_3 precursors due to ARF can promote the chemical production of O_3 (Tie et al., 2009). The changes of ADVZ

and ADVH (ADVZ_DIF and ADVH_DIF) caused by ARF are associated with the variations in wind field. When ARF is considered, the horizontal wind speed is decreased (Fig. S6a), which makes ADVH_DIF positive at the lower twelve layers with a mean value of $+0.5 \text{ ppb h}^{-1}$. However, ADVZ_DIF is negative at these layers with a mean value of -0.48 ppb h^{-1} because aerosol radiative effects decrease the transport of O_3 from the upper to lower layers (Fig. S6b).

In Fig. 8d, the pattern and magnitude of the differences in process contributions between BASE and NOALL are similar to those caused by API, indicating again the dominate role of API on O_3 changes. The impacts of API on O_3 both near the surface and aloft are greater than those of ARF.

5 Discussions

In order to make the analysis and conclusions more robust, another two complex air pollution episodes (8-13 July 2015 and 5-11 June 2016) in this region are also selected to conduct simulations for generating general conclusions. Simulated air pollutants ($\text{PM}_{2.5}$ and O_3) and meteorological variables (T_2 , RH_2 , and WS_{10}) during 8-13 July 2015 (Episode 2) and 5-11 June 2016 (Episode 3) are compared with observations (Fig. S7-Fig. S8). In general, both the observed meteorological parameters and pollutant concentrations can be reasonably reproduced by the model, with correlation coefficients (R) of 0.56~0.98 and normalized mean bias (NMB) of $-7.1\%\sim+33.4\%$. More details about the model evaluation are listed in the supporting information (Text S1).

As shown in Fig. S9(a1-a2), API alone leads to the decrease in surface O_3 over the entire domain with an average reduction of 9.0 ppb (10.6%) and 8.3 ppb (10.4%) over CAPAs in Episode 2 and Episode 3, respectively. The decreased surface O_3 concentrations over CAPAs due to ARF are only 1.0 ppb (1.2%, Fig. 9(b1)) and 1.0 ppb (1.1%, Fig. 9(b2)) during Episode 2 and Episode 3, respectively. All the results indicate that API is the dominant factor for O_3 reduction related to aerosol-radiation interactions, the same as the conclusion analyzed from the case during 28 July to 3 August 2014. The combined effects of API and ARF decrease surface O_3 by 10.0 ppb (11.9%) and

9.3 ppb (11.6%) over CAPAs in Episode 2 and Episode 3, respectively. Analyzing Fig. S10 and Fig. S11, similar variation characteristics are shown in Episode 2 and Episode 3 as that during 28 July to 3 August 2014, with the larger impacts of API on O₃ both near the surface and aloft than those of ARF, indicating the dominant role of API on O₃ reduction related with aerosol-radiation interactions.

6 Conclusions

In this study, the fully coupled regional chemistry transport model WRF-Chem is applied to investigate the impacts of aerosol-radiation interactions, including the impact of aerosol-photolysis interaction (API) and the impact of aerosol-radiation feedback (ARF), on O₃ during a summertime complex air pollution episode from 28 July to 3 August 2014. Three sensitivity experiments are designed to quantify the respective and combined impacts from API and ARF. Generally, the spatiotemporal distributions of observed pollutant concentrations and meteorological parameters are captured fairly well by the model with high correlation coefficients of 0.66–0.86 for pollutant concentrations and 0.70–0.98 for meteorological parameters.

Sensitivity experiments show that aerosol-radiation interactions decrease BOT_SW, T₂, WS₁₀, PBLH, J[NO₂], and J[O¹D] by 93.2 W m⁻², 0.56 °C, 0.12 m s⁻¹, 129 m, 1.8×10^{-3} s⁻¹, and 6.1×10^{-6} s⁻¹ over CAPAs, and increase ATM_SW and RH₂ by 72.8 W m⁻² and 2.4%. The changed meteorological variables and weakened photochemistry reaction further reduce surface-layer O₃ concentration by up to 11.4 ppb (13.5%), with API and ARF contributing 74.6% and 25.4%, respectively.

We further examine the influencing mechanism of aerosol-radiation interactions on O₃ by using integrated process rate analysis. API can directly affect O₃ by reducing the photochemistry reactions within the lower several hundred meters and therefore amplify the O₃ vertical gradient, which promotes the vertical mixing of O₃. The reduced photochemistry reactions of O₃ weaken the chemical contribution and reduce surface O₃ concentrations, even though the enhanced vertical mixing can partly counteract the reduction. ARF affects O₃ concentrations indirectly through the changed meteorological variables, e.g., the decreased PBLH. The suppressed PBL can weaken

the vertical mixing of O₃ by turbulence. Generally, the impacts of API on O₃ both near the surface and aloft are greater than those of ARF, indicating the dominant role of API on O₃ reduction related with aerosol-radiation interactions.

This study provides a detailed understanding of aerosol impacts on O₃ through aerosol-radiation interactions (including both API and ARF). The results imply that future PM_{2.5} reductions will lead to O₃ increases due to weakened aerosol-radiation interactions. A recent study emphasized the need for controlling VOCs emissions to mitigate O₃ pollution (Li et al., 2019). Therefore, tighter controls of O₃ precursors (especially VOCs emissions) are needed to counteract future O₃ increases caused by weakened aerosol-radiation interactions, and the contributions of different mitigation strategies with the impacts of aerosol-radiation interactions to O₃ air quality will be discussed detailedly in our future work.

There are some limitations to this work. The uncertainty of the lack of secondary organic aerosols (SOA), and the missing mechanisms of some heterogeneous reactions may result in large uncertainties in the final simulation results. Gao et al. (2017) added some SOA formation mechanisms into the MOSAIC module by using the volatility basis set (VBS) in WRF-Chem and found that the surface PM_{2.5} concentrations in urban Beijing were reduced by 1.9 µg m⁻³ due to the weakened ARF effect during Asia-Pacific Economic Cooperation (APEC). Similar magnitude can also be found in Zhou et al. (2019) (-1.8 µg m⁻³) who did not consider the impacts of SOA in WRF-Chem when analyzing the impacts of weakened ARF on PM_{2.5} during APEC. Therefore, more work should be conducted to explore the impacts of ARF on PM_{2.5} and O₃ concentrations under consideration of SOA in future.

Data availability

The observed hourly surface concentrations of air pollutants are derived from the China National Environmental Monitoring Center (<http://www.cnemc.cn>). The observed surface meteorological data are obtained from NOAA's National Climatic Data Center (<https://gis.ncdc.noaa.gov/maps/ncei/cdo/hourly>). The radiosonde data are provided by the University of Wyoming (<http://weather.uwyo.edu/>). The photolysis rates of nitrogen dioxide in Beijing are provided by Xin Li (li_xin@pku.edu.cn). The MODIS data are obtained from the NASA Level 1 and Atmosphere Archive and Distribution System (<https://ladsweb.modaps.eosdis.nasa.gov>). The simulation results can be accessed by contacting Lei Chen (chenlei@nuist.edu.cn) and Hong Liao (hongliao@nuist.edu.cn).

Author contributions

HY, LC, and HL conceived the study and designed the experiments. HY and LC performed the simulations and carried out the data analysis. JZ, WW, and XL provided useful comments on the paper. HY prepared the paper with contributions from all co-authors.

Competing interests

The authors declare that they have no competing interests.

1 **Table 2.** Statistical parameters between simulated and observed PM_{2.5} (μg m⁻³), O₃
2 (ppb), 2 m temperature (T₂, °C), 2 m relative humidity (RH₂, %), 10 m wind speed
3 (WS₁₀, m s⁻¹), and photolysis rate of NO₂ (J[NO₂], s⁻¹) during 28 July to 3 August 2014.

Variables	O ^a	M ^a	R ^b	MB ^c	ME ^d	NMB ^e (%)	NME ^f (%)	RMSE ^g
PM _{2.5}	113.3	90.7	0.66	-21.8	25.2	-19.2	22.2	30.1
O ₃	47.7	44.1	0.86	-5.7	15.5	-12.0	32.4	18.2
T ₂	28.4	28.0	0.98	-1.5	1.6	-5.7	5.8	1.8
RH ₂	70.9	65.7	0.91	0.5	5.3	0.7	7.9	7.0
WS ₁₀	2.4	3.0	0.89	0.7	0.8	28.5	32.1	0.9
J[NO ₂]	1.6×10 ⁻³	1.8×10 ⁻³	0.97	1.1×10 ⁻⁴	3×10 ⁻⁴	6.8	18.5	5.3×10 ⁻⁴

4 ^a**O** and **M** are the averages for observed and simulated results, respectively. O =

5 $\frac{1}{n} \times \sum_{i=1}^n O_i$, $M = \frac{1}{n} \times \sum_{i=1}^n M_i$.

6 ^b**R** is the correlation coefficient between observations and model results. R=

7
$$\frac{\sum_{i=1}^n |(O_i - O) \times (M_i - M)|}{\sqrt{\sum_{i=1}^n (O_i - O)^2 \times \sum_{i=1}^n (M_i - M)^2}}.$$

8 ^c**MB** is the mean bias between observations and model results. $MB = \frac{1}{n} \times \sum_{i=1}^n (M_i -$
9 $O_i)$.

10 ^d**ME** is the mean error between observations and model results. $ME = \frac{1}{n} \times \sum_{i=1}^n |M_i - O_i|$.

11 ^e**NMB** is the normalized mean bias between observations and model results. NMB =

12 $\frac{1}{n} \times \sum_{i=1}^n \frac{M_i - O_i}{O_i} \times 100\%$.

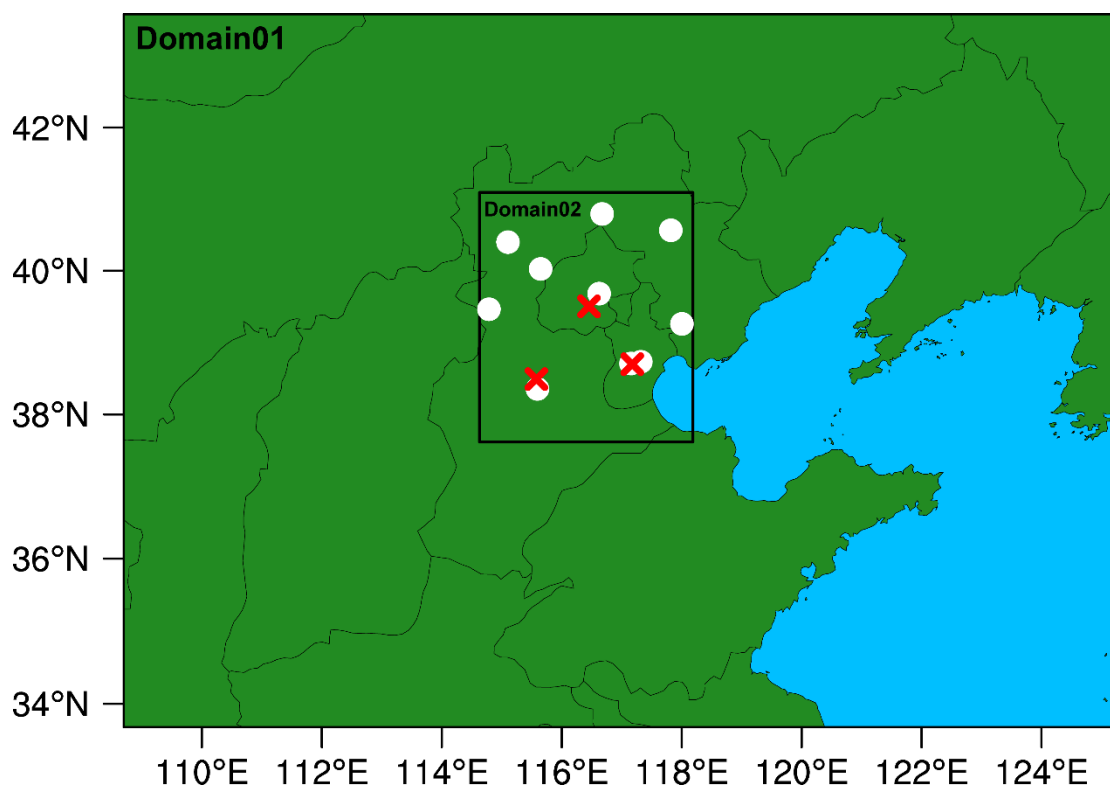

13 ^f**NME** is normal mean error between observations and model results. NME=

14 $\frac{1}{n} \times \sum_{i=1}^n \frac{|M_i - O_i|}{O_i} \times 100\%$.

15 ^g**RMSE** is the root-mean-square error of observations and model results. RMSE=

16 $\sqrt{\frac{1}{n} \times \sum_{i=1}^n (M_i - O_i)^2}$.

17 In the above O_i and M_i are the hourly observed and simulated data, respectively, and n
18 is the total number of hours.

2 **Figure 1.** Map of the two WRF-Chem modeling domains with the locations of
 3 meteorological (white dots) and environmental (red crosses) observation sites used for
 4 model evaluation.

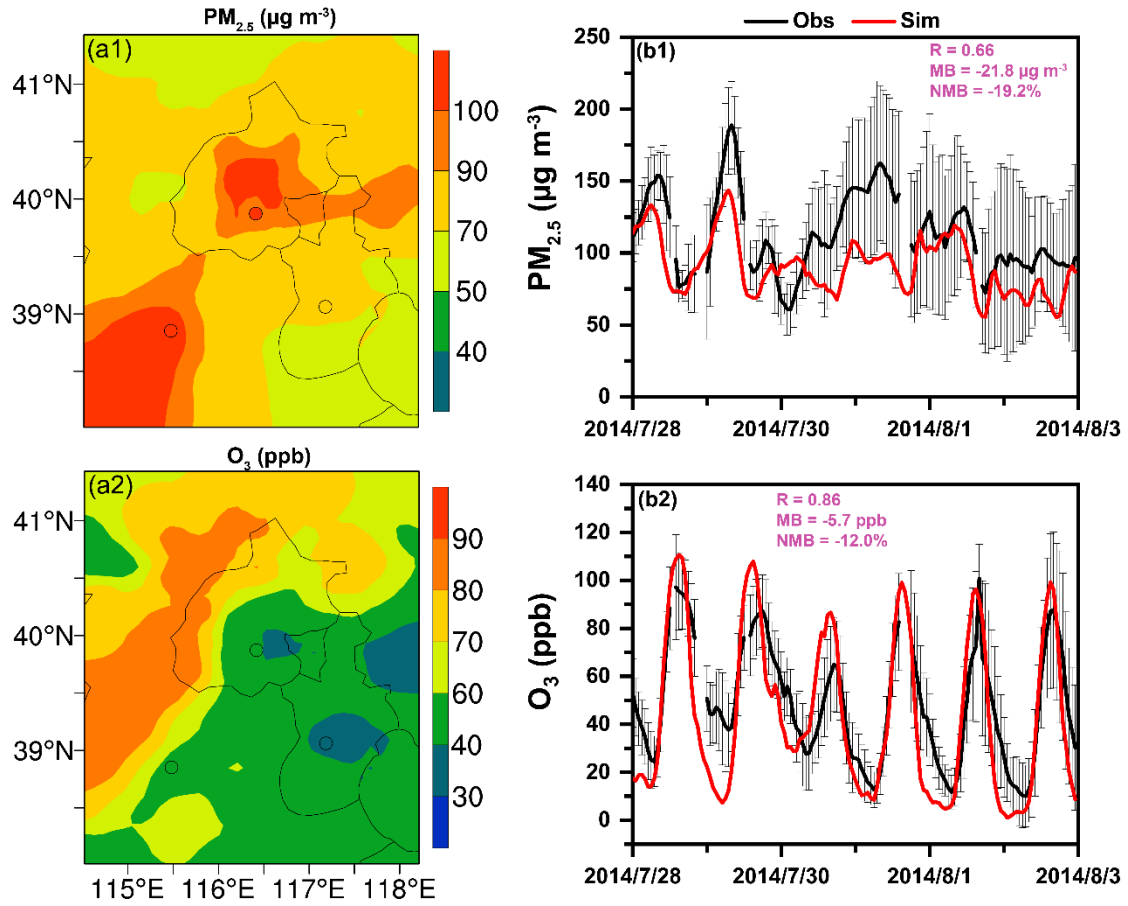

Figure 2. (a1-a2) Spatial distributions of simulated (color counters) and observed (colored circles) surface PM_{2.5} and O₃ concentrations averaged during 28 July to 3 August 2014. (b1-b2) Time series of observed (black) and simulated (red) hourly surface PM_{2.5} and O₃ concentrations averaged over the thirty-two observation sites in Beijing, Tianjin, and Baoding. The error bars in (b1) and (b2) are standard deviation on those average. The calculated correlation coefficient (R), mean bias (MB), and normalized mean bias (NMB) are also shown.

Figure 3. Time series of 3-hourly observed (blue dots) and hourly simulated (red lines) (a) 2-m temperature (T_2), (b) 2-m relative humidity (RH_2), (c) wind speed at 10 m (WS_{10}) averaged over ten meteorological observation stations, and (d) surface photolysis rate of NO_2 ($\text{J}[\text{NO}_2]$) during 28 July to 3 August 2014. The calculated correlation coefficient (R), mean bias (MB), and normalized mean bias (NMB) are also shown.

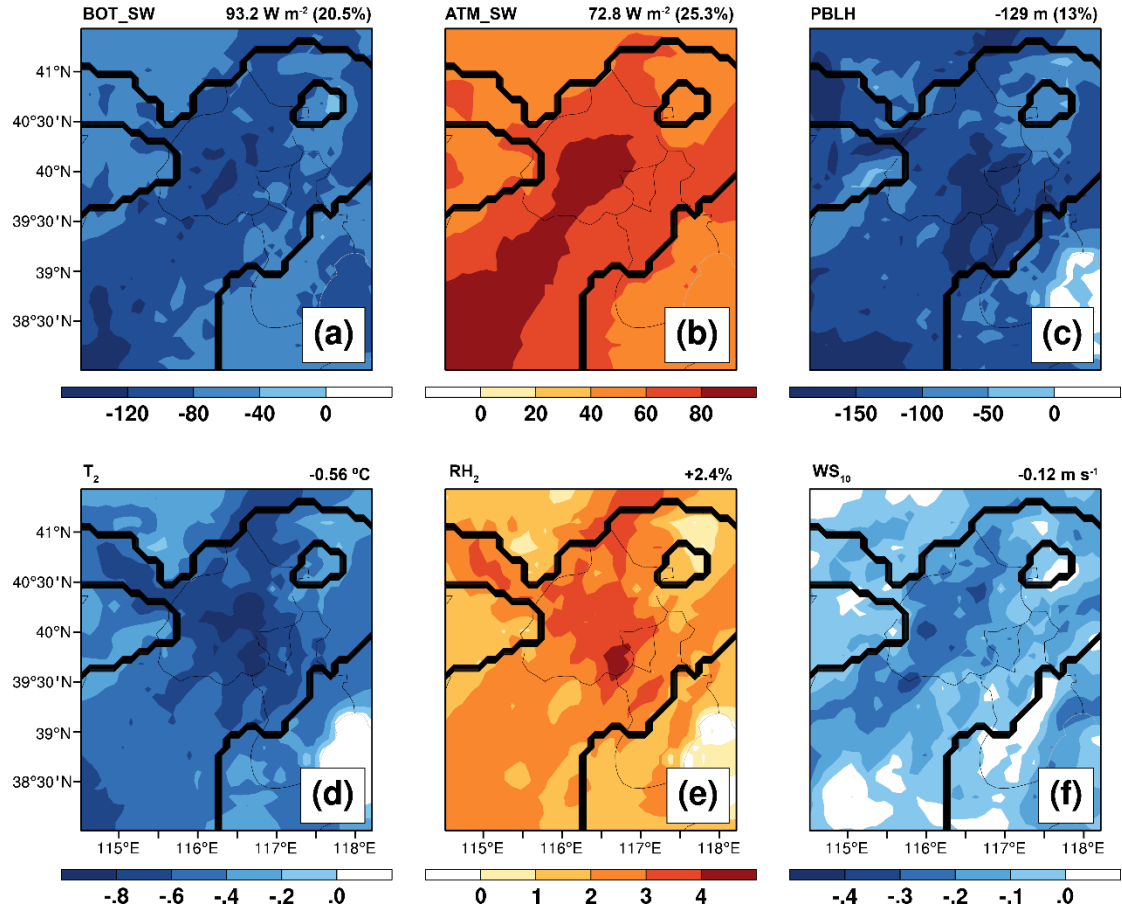

Figure 4. The impacts of aerosol-radiation interactions on (a) shortwave radiation at the surface (BOT_SW), (b) shortwave radiation in the atmosphere (ATM_SW), (c) PBL height (PBLH), (d) 2-m temperature (T_2), (e) 2-m relative humidity (RH_2), and (f) 10-m wind speed (WS_{10}) during the daytime (08:00-17:00 LST) from 28 July to 3 August 2014. The region sandwiched between two black lines is defined as the complex air pollution areas (CAPAs) where the mean daily $PM_{2.5}$ and MDA8 O_3 concentrations in BASE case are larger than $75 \mu\text{g m}^{-3}$ and 80 ppb. The calculated changes averaged over CAPAs are also shown at the top of each panel.

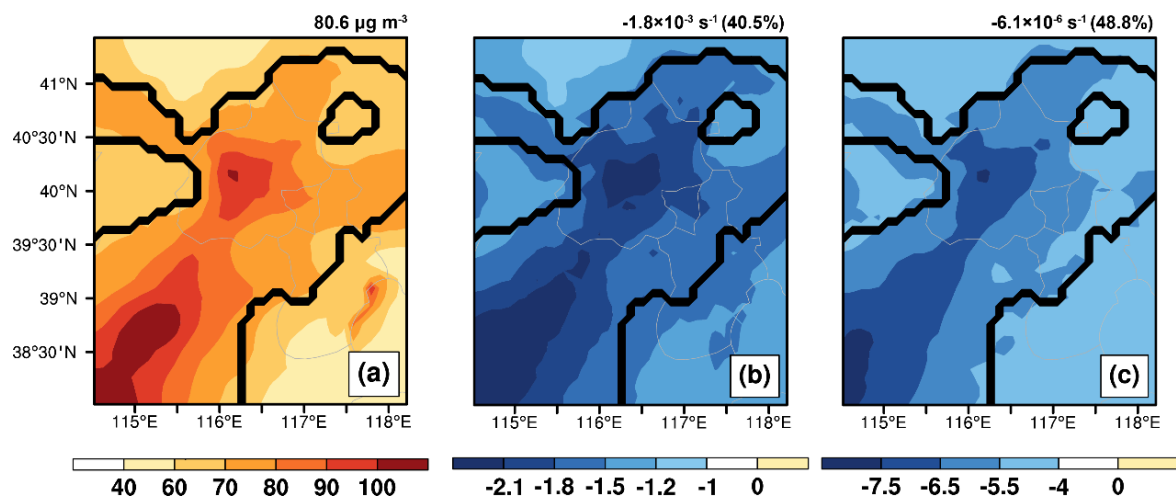

Figure 5. Spatial distributions of (a) simulated surface-layer PM_{2.5} concentrations in BASE case, and changes in surface (b) J[NO₂] and (c) J[O¹D] due to aerosol-radiation interactions during the daytime (08:00-17:00 LST) from 28 July to 3 August 2014. The calculated values (percentage changes) averaged over CAPAs are also shown at the top of each panel.

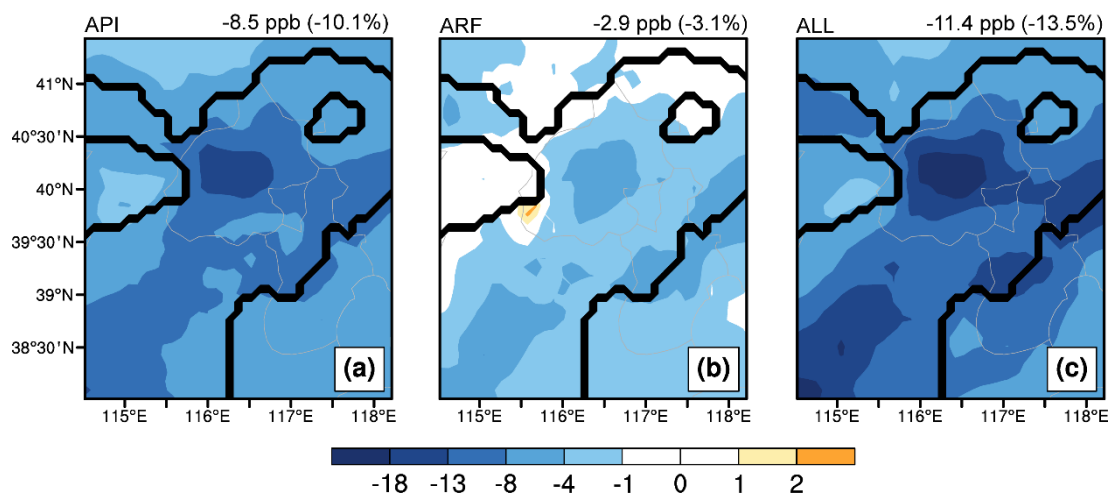

Figure 6. The changes in surface-layer ozone due to (a) aerosol-photolysis interaction (API), (b) aerosol-radiation feedback (ARF), and (c) the combined effects (ALL, defined as API+ARF) during the daytime (08:00-17:00 LST) from 28 July to 3 August 2014. The calculated mean changes averaged over CAPAs are also shown at the top of each panel.

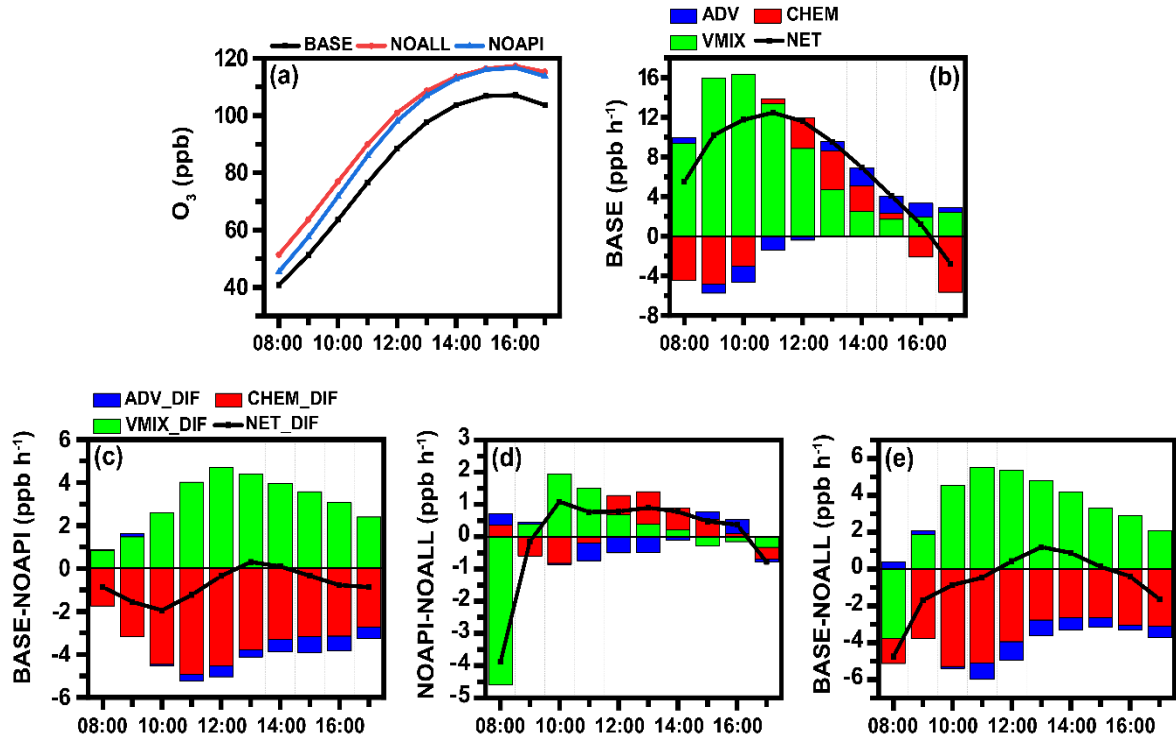

Figure 7. (a) Diurnal variations of simulated surface O_3 concentrations in BASE (black), NOAPI (blue), and NOALL (red) cases over CAPAs. (b) The hourly surface O_3 changes induced by each physical/chemical process using the IPR analysis method in BASE case. (c-e) Changes in hourly surface O_3 process contributions caused by API (BASE minus NOAPI), ARF (NOAPI minus NOALL), and ALL (BASE minus NOALL) over CAPAs during the daytime (08:00-17:00 LST) from 28 July to 3 August 2014. The black lines with squares denote the net contribution of all processes (NET, defined as VMIX+CHEM+ADV). Differences of each process contribution are denoted as VMIX_DIF, CHEM_DIF, ADV_DIF, and NET_DIF.

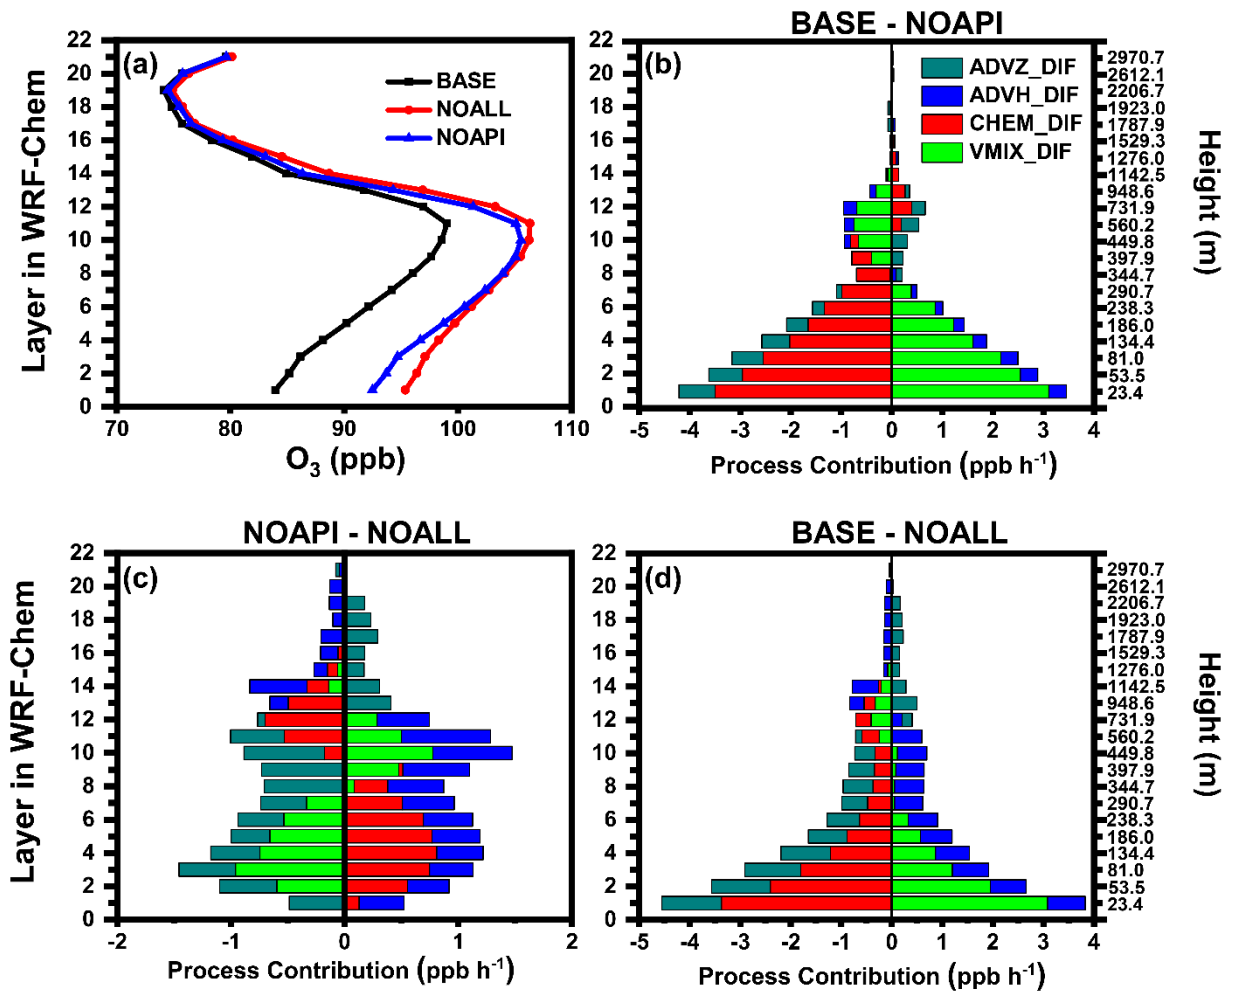

Figure 8. (a) Vertical profiles of simulated O₃ concentrations in BASE (black), NOAPI (blue), and NOALL (red) cases over CAPAs. (b-d) Changes in O₃ budget due to API, ARF, and ALL over CAPAs during the daytime (08:00-17:00 LST) from 28 July to 3 August 2014. Differences of each process contribution are denoted by ADVZ_DIF, ADVH_DIF, CHEM_DIF, and VMIX_DIF.
