Abstract. Our work explores the impact of two important dimensions of land system changes, land use and land cover change (LULCC) and direct agricultural reactive nitrogen (N_r) emissions from soils, on ozone (O₃) and fine particulate matter (PM_{2.5}) air quality over contemporary (1992 to 2014) time scales. We account for LULCC and agricultural N_r emissions changes with consistent remote sensing products and new global emission inventories, respectively, estimating their impacts on global 10 surface O₃ and PM_{2.5} concentrations and N_r deposition using the GEOS-Chem global chemical transport model. Over this time period, our model results show that agricultural N_r emission changes cause a reduction of annual mean PM_{2.5} levels over Europe and northern Asia (up to -2.1 $\mu\text{g m}^{-3}$), while increasing PM_{2.5} levels India, China and eastern US (up to +3.5 $\mu\text{g m}^{-3}$). Land cover changes induce small reductions in PM_{2.5} (up to -0.7 $\mu\text{g m}^{-3}$) over Amazonia, China and India due to reduced 15 biogenic volatile organic compounds (BVOC) emissions and enhanced deposition of aerosol precursor gases (e.g. NO₂, SO₂). Agricultural N_r emission changes only lead to minor changes (up to ± 0.6 ppbv) in annual mean surface O₃ level, mainly over China, India and Myanmar. Meanwhile, our model result suggests a stronger impact of LULCC on surface O₃ over the time 20 period across South America, the combination of changes in dry deposition and isoprene emissions results in -0.8 to +1.2 ppbv surface ozone changes. The enhancement of dry deposition reduces surface ozone level (up to -1 ppbv) over southern China, eastern US and central Africa. The enhancement of soil NO_x emission due to crop expansion also contribute to surface ozone 25 changes (up to +0.6 ppbv) over sub-Saharan Africa. In certain regions, the combined effects of LULCC and agricultural N_r emission changes on O₃ and PM_{2.5} air quality can be comparable (> 20%) to that of anthropogenic emission changes over the same time period. Finally, we calculate that the increase in global agricultural N_r emissions leads to a net increase in global land area ($+3.67 \times 10^6 \text{ km}^2$) that potentially faces exceedance in critical N_r load (> 5 kgN ha⁻¹ yr⁻¹). Our result demonstrates the impacts of contemporary LULCC and agricultural N_r emission changes on PM_{2.5} and O₃ air quality, and the importance of land system changes on air quality over multi-decadal timescales.

1 Introduction

The broad term of land use and land cover change (LULCC) encapsulates both the anthropogenic (e.g. agricultural expansion) and natural (e.g. ecological succession) dimensions of terrestrial biome changes (Reick et al., 2013), which alter the physical and ecophysiological properties of the land surface. These perturbations alter the transfer and uptake of air pollutants by 30 ecosystems, and can also have large impacts on the emission of biogenic volatile organic compounds (BVOCs), which play

vital roles in tropospheric ozone (O_3) and secondary organic aerosol (SOA) formation (Fu and Tai, 2015; Ganzeveld et al., 2010; Heald and Geddes, 2016; Heald and Spracklen, 2015; Squire et al., 2014; Wu et al., 2012a).

Agricultural activities, in addition to being a large driver of LULCC (e.g. Ellis, 2015; Ellis et al., 2013; Goldewijk et al., 2017; Kaplan et al., 2011), also introduce an enormous amount of reactive nitrogen into the soil (Galloway et al., 2008), which can be emitted into the atmosphere either as oxidized or reduced nitrogen. The reactive nitrogen oxides emitted from soil, NO_x ($\equiv NO + NO_2$), enhance O_3 production when volatile organic compounds (VOCs) are relatively abundant (i.e. NOx-limited regimes), but suppresses O_3 production when the concentration of VOCs is relatively low (i.e. VOC-limited regimes) (Sillman et al., 1990). Reactive nitrogen also contributes to aerosol formation. Ammonia (NH_3) can combine with the nitrate and sulphate ions to form secondary inorganic aerosol, while the emissions of NOx can oxidize further and contribute to particulate nitrate formation (Ansari and Pandis, 1998). Indeed, agricultural emissions are the dominant global anthropogenic source of NH_3 (Hoesly et al., 2018), and identified as a major contributor to global premature mortality due to particulate matter (PM) pollution (Lelieveld et al., 2015). Trends in atmospheric reactive nitrogen also affect nitrogen deposition (e.g. Geddes and Martin, 2017), with potentially negatively impacts on biodiversity (e.g. Bobbink et al., 2010; Payne et al., 2017; WallisDeVries and Bobbink, 2017), or eutrophication of aquatic ecosystems (e.g. Fenn et al., 2003). These ecosystem impacts may contribute to economic loss comparable to the benefits of extra crop output from LULCC and agricultural emissions (Poulton and Jacob, 2014; Sobota et al., 2015).

Even while land cover at a particular location may not change, modifications in human management of the land (e.g. intensification of agriculture, irrigation practices, fertilizer application, selective harvesting) may still be associated with changes in pollutant emission and uptake. An obvious example would be a region where direct agricultural emissions may have changed, without any concomitant changes in land cover classification. Reducing NH_3 emission, particularly from the agricultural sector, has been explored as a potent strategy of controlling PM pollution (Giannadaki et al., 2018; Pinder et al., 2007; Pozzer et al., 2017). Bauer et al. (2016) suggest agricultural emissions are the main source of present-day $PM_{2.5}$ (fine particulates with an aerodynamic diameter less than $2.5 \mu m$) over eastern US, Europe and northern China. However, as anthropogenic NO_x and SO_2 emissions are expected to lower in the future, some aerosol formation chemistry is expected to become less sensitive to NH_3 emissions.

The potential impacts of LULCC and agricultural emission changes on air quality have been explored previously. To date, this work has focused on future projections in land use (Bauer et al., 2016; Ganzeveld et al., 2010; Hardacre et al., 2013; Heald et al., 2008; Squire et al., 2014; Tai et al., 2013; Wu et al., 2012b), contrasted pre-industrial estimates of land cover and agricultural emissions with present-day conditions (Heald and Geddes, 2016; Hollaway et al., 2017), or are regional in focus (Fu and Tai, 2015; Geddes et al., 2015; Silva et al., 2016). For example, Wu et al. (2012) propose that LULCC induced by climate, CO_2 abundance, and agriculture could significantly affect surface O_3 in the future mainly through modulating dry

65 deposition and isoprene emissions. Over more contemporary timescales (e.g. across the last 20-30 years), Fu et al. (2016), Fu and Tai (2015) and Silva et al., (2016) find that LULCC could have impacts O₃ and PM air quality over China and Southeast Asia.

Given the large spatial scale of LULCC (e.g. Hansen et al., 2013; Li et al., 2018) and agricultural emission changes (e.g. Crippa et al., 2018; Hoesly et al., 2018; Xu et al., 2019) over recent decades, these two land system changes could be contributing 70 substantially to global trends in O₃ and PM pollution. While changes in land cover and agricultural emissions actually occur simultaneously across the globe, they are rarely considered together in simulations of air quality from chemical transport models. As a result, it is not clear to what extent LULCC may either amplify or offset the impacts of some of the associated agricultural emission changes, how this may vary regionally, and to what extent these land system impacts may compare to concomitant changes resulting from other direct anthropogenic emissions (e.g. emissions from industrial and transport sectors).

75

Consistent long-term land records of land cover derived from satellite remote sensing observations and global anthropogenic emission inventories have become readily available. This opens an opportunity for a more holistic and observationally-constrained assessment of the impacts on global O₃ and PM air quality from contemporary changes in LULCC and agricultural emissions simultaneously, and a comparison of these with the effects from direct anthropogenic emissions. In this study, we 80 model the effects of contemporary LULCC and agriculture emissions changes on global surface O₃ and PM_{2.5} levels, and gauge their importance relative to changes in other direct anthropogenic emissions over the same period of time. We also highlight the effect of agricultural emissions changes on nitrogen deposition on land ecosystems. Through our chemical transport model predictions, we aim to identify potential global hotspots of contemporary land changes that may be substantially altering trends in air quality and nitrogen deposition.

85 2 Method

To simulate global changes in surface O₃ and PM_{2.5} concentrations due to LULCC, agricultural emissions, and direct anthropogenic emissions over 1992 to 2014, we use the GEOS-Chem chemical transport model (version 12.7.0, <https://doi.org/10.5281/zenodo.3634864>). We choose our timeframe due to the availability of consistent high-resolution 90 remote sensing products (PFT and LAI maps) and concurrent global emission inventories. We define “direct anthropogenic” and “agricultural” emissions separately in more detail below.

We perform five sets of simulations summarized in Table 1: (1) a “baseline” scenario where land cover, agricultural emissions, and direct anthropogenic emissions are all set to 1992 levels; (2) an “anthropogenic emission” scenario where direct anthropogenic emissions are updated to 2014 levels; (3) an “anthropogenic emissions and land cover change” scenario where anthropogenic emissions remain updated to 2014, with land cover inputs now prescribed based on updated 2014 data; and (4) 95 an “anthropogenic emissions, land cover, and agricultural emission change” scenario where direct anthropogenic emissions

and land cover inputs remain updated to 2014, with agricultural emissions also updated to 2014 levels. To test the chemical sensitivity of our results, (5) is performed where anthropogenic emissions are held at 1992 levels, but land cover change and agricultural emissions are updated to 2014 levels.

100 The role of direct anthropogenic emission changes can be evaluated by comparing simulation (1) and (2); the additional role played by land cover changes over this time period is evaluated by comparing simulation (2) and (3); and finally the additional impact of agricultural emission changes is evaluated by comparing simulation (3) and (4). The latter two effects will be the focus of this paper, but we compare these to the role of direct anthropogenic emission changes for context. Since changes in surface ozone and PM_{2.5} should be sensitive to NO_x-VOC ratio and availability of NO₃⁻ and SO₄²⁻ ions, the sensitivity of the effects from land cover change and agricultural emission changes to anthropogenic emission changes can be quantified by 105 evaluating simulation (5).

We use assimilated meteorological fields from Modern-Era Retrospective analysis for Research and Applications Version 2 (MERRA-2) (Gelaro et al., 2017) to drive GEOS-Chem. All simulations are carried out at 2° latitudes by 2.5° longitudes resolution over the globe, using identical meteorological fields from 2011 to 2014 in order to exclude meteorological variability from the analysis. The output from 2011 is discarded as spin-up. The GEOS-Chem model simulates O₃ chemistry with a 110 comprehensive HO_x-NO_x-VOC-O₃-BrO_x chemical mechanism (Bey et al., 2001; Mao et al., 2013). Gaseous dry deposition follows Wang et al. (1998) and Wesely (1989), while particle deposition follows Zhang et al. (2001). Wet deposition is described by Liu et al. (2001) with updates from Amos et al. (2012) and Wang et al. (2011, 2014). The recent update from Luo et al., (2019) on wet deposition parameterization is also included to improve model-observation agreement for sulfate-nitrate-ammonium (SNA) aerosol. The thermodynamics and gas-aerosol partitioning of the NH₃-H₂SO₄-HNO₃ system is simulated 115 by ISORROPIA II module (Fountoukis and Nenes, 2007). A simple yield-based secondary organic aerosol (SOA) estimate is also included (Kim et al., 2015). Other types of aerosol represented in the model include sea salt, dust, primary black carbon (BC) and organic carbon (OC). The total PM_{2.5} mass is then calculated at 35% relative humidity for consistency with the measurement standard in US.

120 We use anthropogenic and agricultural emissions based on the Community Emission Data System (CEDS) inventory (Hoesly et al., 2018), which contains the estimates of anthropogenic NO_x, non-methane volatile organic compounds (NMVOCs), CO, BC, OC, SO₂ and NH₃ emissions harmonized from a wide range of global and regional inventories. In this inventory, emissions are from six major sectors: energy production, industry, transportation, RCO (residential, commercial, other), agriculture, and waste. For this study, “agricultural emissions” specifically refer to NO_x and NH₃ emitted from fertilizer application and manure 125 management, which correspond directly to agricultural nitrogen input. We do not consider the changes in agricultural of other trace species (e.g. CH₄, SO₂, CO).

Biogenic volatile organic compound emissions are calculated by Model of Emissions of Gases and Aerosols from Nature (MEGAN) v2.1 (Guenther et al., 2012). Soil NO_x emission follows Hudman et al. (2012), with fertilizer emissions zeroed out
130 to avoid double counting with the agricultural NO_x emission in CEDS inventory. Fire (Global Fire Emissions Database v4.1, Van Der Werf et al., 2017) and lightning (Murray et al., 2012) emissions are held constant at 2014 level.

We use the European Space Agency Climate Change Initiative (ESA CCI) land cover map (Li et al., 2018) to characterize
135 LULCC and drive the biosphere-atmosphere emission fluxes in our simulations. The ESA CCI land cover map is a consistent global annual land cover time series derived from the satellite observations from the AVHRR, MERIS, SOPTVGT and PROBA-V instruments. It has a native spatial resolution of 300 m following the United Nations Land Cover Classification System. Time-consistent land surface characterization also requires leaf area index (LAI) data. We use the Global Land Surface Satellite (GLASS) product (Xiao et al., 2016) (retrieved from <http://globalchange.bnu.edu.cn/>), which is a global LAI time series combining AVHRR and MODIS observation. 3-year average (1991 – 1993 average LAI for 1992 land cover, 2013 –
140 2015 average LAI for 2014 land cover) is used as input for LAI to GEOS-Chem to reduce the possible effect of interannual variability.

This satellite-derived land surface characterization on its own is not directly compatible with the input to the vegetation-related modules in GEOS-Chem, thus requires further harmonization (dry deposition, BVOC emissions, soil NO_x emissions), which is a common problem for simulations involving land change (e.g. Geddes et al., 2016). We first aggregate and process the
145 ESACCI land cover map with the tool and crosswalk table provided with the land cover product to derive the percentage coverage of plant functional type (PFT) at 0.05° resolution, which is the native resolution of GLASS LAI. The dominant surface type can be readily mapped to the 11 deposition surface type in the Wesely dry deposition model. We adopt the approach of Geddes et al. (2016) to replace roughness length (z_0) from assimilated meteorology with that prescribed for each deposition surface type. We ignore changes in displacement height as they are expected to be much less important than the
150 changes in z_0 (Text S1). To derive the MODIS-Koeppen type land map (Steinkamp and Lawrence, 2011) required for soil NO_x module, we first use translate the PFT map according to International Geosphere-Biosphere Programme (IGBP) land cover classification system (<http://www.eomf.ou.edu/static/IGBP.pdf>). We use global monthly temperature climatology (Matsuura and Willmott, 2012) to further differentiate the land types by climate with criteria outlined by Kottek et al. (2006). Finally, the
155 ESA CCI PFT map is converted to Community Land Model (CLM) PFT map, which is required for MEGAN BVOC emissions module, by the temperature criteria specified by Bonan et al. (2002). As the method of deriving C3:C4 grass ratio was subsequently updated (Lawrence and Chase, 2007), this ratio is directly taken from CLM land surface data set.

In the Supplementary Material, we provide an evaluation of the annual mean simulated SNA aerosol mass concentration and surface O₃ mixing ratios from the Simulation 4 (representative of 2014 conditions) with globally available observations from
160 the same time period. In general, the model captures the spatial distributions of individual SNA species reasonably well (Fig.

S1). The model is able to capture regional annual means of individual SNA species (Table S1) over Europe. Over the US and China, where annual means of all SNA species are underestimated by 21 – 55%, and in regions covered by Acid Deposition Monitoring Network in East Asia (Japan, Korea and southeast Asia) where SO_4^{2-} is underestimated by 36%, we expect the model may underestimate the sensitivity of SNA concentration to NH_3 emission perturbations. This may imply that results from our study should be interpreted as conservative. Figure S2 shows the reasonable agreement on annual mean surface O_3 between our model output and the gridded observation dataset from Sofen et al. (2016) (mean bias = +1.81 ppbv and mean absolute error = 3.97 ppbv). Our model therefore captures the present-day annual means of surface SNA and O_3 concentrations, providing basis for our subsequent analyses. We also provide definitions for geographical regions, which largely follow Integrated modelling of global environmental change (IMAGE) 2.4 classifications, in Table S2.

170 **3 Changes in Land Cover, and Biospheric Fluxes, and Agricultural Emissions**

Table 2 shows the changes in global coverage of the major land cover types from 1992 to 2014 derived by the ESA CCI land cover product. The coverage of managed grass (including cropland and pasture) and built-up area, both of which are unmistakably related to human activities, have increased mainly at the expense of forest coverage. This is consistent with a global trend in deforestation over this period. Figure 1 shows the spatial distribution of changes in fractional coverage of the major land cover types. Expansion of agricultural land at the expense of broadleaf forest coverage is most notable in South America and Southeast Asia, which is well-documented in other studies based on remote sensing (Hansen et al., 2013) and national surveys (Keenan et al., 2015). The expansion of agricultural land over this time period is also observed in central Asia, southern China and Africa, but usually at the expense of land types other than broadleaf forests (mainly primary grassland and needleleaf forests). Meanwhile, transitions from agricultural land to forests and built-up areas is observed in northern China and eastern Europe, consistent with the findings of Potapov et al. (2015) and Lai et al. (2016).

Figure 2 shows the global changes in 3-year (2012-2014 minus 1991-1993) annual mean LAI calculated from the GLASS LAI data set. Over southern China and South America, the area with regionally consistent deforestation experience general increase in LAI, while the opposite effect is observed in Sahel and Former Soviet Union. In Europe, LAI increases in most parts despite a fairly consistent retraction of agricultural land is observed. The agricultural expansion and deforestation over Southeast Asia is mostly concurrent with the LAI decreases. LAI increases notably in northern China where agricultural land decreases. The fact that LAI change can be driven by factors other than changes in land cover type (e.g. temperature, precipitation, atmospheric CO_2 level) (e.g. Zhu et al., 2016) may explain the regionally divergent trends response of LAI to agricultural land use change. For example, the general increase of LAI in China is not only driven by changes in biome types, but also the greening within cropland (mainly attributable to agricultural intensification) and forests (mainly attributable to ambitious tree planting programmes) (Chen et al., 2019). Similarly, some deforested land in South America might have been cultivated intensively, resulting in an increase rather decrease in LAI. We also note that since the relationship between satellite-derived surface

reflectance and retrieved LAI depends on land cover, the use of static land cover map in long-term LAI retrievals (Claverie et al., 2016; Xiao et al., 2016; Zhu et al., 2013) may not fully capture the effect of LULCC on LAI (Fang et al., 2013). In particular, Fang et al. (2013) show that LAI could be substantially overestimated when grasses and crops are misclassified as forest. We may therefore overestimate dry deposition velocity over regions with significant deforestation. Such impact on biogenic emissions is secondary as biogenic emissions are expected to be much more sensitive to land cover type than LAI (e.g. Guenther et al., 2012).

These changes in land cover produce changes in the biogenic fluxes of reactive trace gases between the Earth's surface and atmosphere derived by GEOS-Chem. Figure 3a shows the calculated changes in annual mean isoprene emission due to land cover change over 1992 to 2014, and suggests that global isoprene emission could have decreased by 5.12 Tg/yr (-1.5%). The largest local reductions in isoprene emissions (up to 30%) are observed in parts of South America, where deforestation from highly isoprene-emitting broadleaf forests is most strongly observed. We note that the decrease of isoprene emission simulated in Southeast Asia does not agree with the result from Silva et al. (2016), since our remote sensing data does not have separate land cover class for oil palm plantations which have expanded dramatically in the region. Our model may not therefore capture the full effects of LULCC on isoprene emission, and its effect on PM_{2.5} and O₃ over the region. Elsewhere in the world, the signals of land cover change on isoprene emissions are mostly small and follow the local patterns of changes in LAI. Changes in monoterpenes (< 5 ng m⁻² s⁻¹) and sesquiterpene (< 1 ng m⁻² s⁻¹) emissions are relatively small.

Figure 3b shows the changes in annual mean soil NO emission due to LULCC, which represent the change in soil emission driven purely by LAI and land cover changes (i.e. without considering the changes in nitrogen input). LULCC leads to a small signal of +0.04 TgN/yr (+0.6%) in global soil NO emission. The magnitude of changes in soil NO emission induced by LULCC is comparable to that in agricultural NO emissions inventory (see below) over certain regions (e.g. South America, Australia, Africa). Relatively large increases in soil NO is simulated over western Africa.

Figure 3c shows the changes in annual mean O₃ dry deposition velocity (v_d), which also closely follow the pattern of LAI changes. Slight increases of v_d are observed in China, India, Southeast US, central America, South America, Europe and southern Africa. In Southeast Asia v_d decreases concurrently with deforestation and reduction in LAI. In central Brazil, the increase in LAI is offset by the deforestation of tropical evergreen broadleaf forests that have higher v_d than other land types (Song-Miao Fan et al., 1990; Wang et al., 1998), leading to small overall change in v_d . Likewise, despite deforestation observed further south, these losses are offset by strong increases in LAI so that v_d increases by up to 0.1 cm s⁻¹. Significant changes in the v_d of O₃ due to LAI also imply that v_d of other relevant trace gases (e.g. NO₂, SO₂) would also be perturbed by land cover change in our model, which will be discussed briefly in the subsequent section.

225

Figure 4 shows the changes in agricultural NH_3 and NO_x emissions between 1992 and 2014, which consists mostly of emissions from fertilizer application and manure management (Hoesly et al., 2018). According to the CEDS inventory, global direct agricultural NH_3 emissions increased by 7.6 Tg N/yr since 1992, equivalent to a 19 % increase in total anthropogenic NH_3 emissions. Direct agricultural soil NO_x emissions increased by 0.37 Tg N/yr since 1992, and while this is a substantial increase 230 in agricultural soil NO_x emissions (26 %), it represents only a 1 % increase in total anthropogenic NO_x emissions.

The increases in agricultural emissions are most substantial over South Asia, followed by China, parts of Middle East, Southeast Asia and South America, and to a less degree in central America, North America and Sahel. The sharpest decline of agricultural emissions is observed in Europe and Former Soviet Union, followed by milder declines over Japan and Korea. 235 The particularly sharp decline of agricultural emissions in Europe is mainly attributable to the implementation of emission control protocols (National Emissions Ceilings (NEC) and Integrated Pollution Prevention and Control (IPPC) directives) within the European Union (Skjøth and Hertel, 2013). According to the CEDS inventory, changes in agricultural emissions dominates the trend of total NH_3 emissions in all major regions except Africa, where large part of the NH_3 emissions trend is attributable to the waste management and the RCO (residential, commercial, other) sectors (Hoesly et al., 2018) (Figure S3). 240 In contrast, the increase in agricultural emissions of NO_x does not contribute significantly to the global increase of total NO_x emissions over our period of concern.

We note that the hotspots of change in managed land cover and of change in agricultural emissions are not always overlapping. For example, agricultural emissions increase significantly over northern China and northern India, while the cropland coverage 245 over those regions does not increase correspondingly over this same period. Such agricultural intensification in turn contribute significantly to the positive LAI trend over the above regions (Chen et al., 2019). Similarly, agricultural emissions have declined over Kazakhstan, while the area of managed land has not decreased significantly. This highlights a degree of independence between land management and LULCC, with both being components of land change but having potentially distinct spatial patterns and impacts on air quality. This also highlights the importance of treating both in our chemical transport 250 model simulations as they occur contemporaneously around the globe, and may have different impacts on air quality.

4 Impact of LULCC and agricultural emission changes on surface $\text{PM}_{2.5}$

Figure 5 shows the modeled impacts of LULCC, changes in agricultural emissions, and the combined effects of both, on annual mean surface $\text{PM}_{2.5}$ (under 2014 anthropogenic emissions). We have calculated the impacts of LULCC on $\text{PM}_{2.5}$ (“ $\Delta\text{PM}_{2.5, \text{LULCC}}$ ” as the difference in $\text{PM}_{2.5}$ predicted by Simulation 2 and Simulation 1; the impacts of agricultural emission changes on $\text{PM}_{2.5}$ (“ $\Delta\text{PM}_{2.5, \text{agr_emis}}$ ” as the difference in $\text{PM}_{2.5}$ predicted by Simulation 3 and Simulation 2; and the impacts of these 255 combined (“ $\Delta\text{PM}_{2.5, \text{LULCC+agr_emis}}$ ” as the difference in $\text{PM}_{2.5}$ predicted Simulation 3 and Simulation 1 (see Table 1).

The effect of LULCC on $PM_{2.5}$ (Fig. 5a) is mainly through perturbing BVOC emissions as they are a precursor to SOA. Over parts of South America and Southeast Asia, where isoprene emissions drop significantly due to deforestation, $PM_{2.5}$ is reduced by up to $0.7 \mu\text{g m}^{-3}$. Land cover changes also lead to changes in the dry deposition velocity of some SNA precursor gases where stomatal uptake is an important deposition pathway (e.g. NO_2 and SO_2 , Fig. S4). Indeed, over India and China, where our model suggests high levels of SNA aerosol precursors, contemporary LULCC enhances dry deposition of these constituents which reduces $PM_{2.5}$ overall by up to $0.3 \mu\text{g m}^{-3}$, similar to the finding of Fu et al. (2016).

We find that the agricultural emissions generally have larger impact on annual mean surface $PM_{2.5}$ level (Fig. 5b) than LULCC. The largest increases in annual mean surface $PM_{2.5}$ due to changes in agricultural emissions over 1992 to 2014 occur across China ($+0.7 \mu\text{g m}^{-3}$) and India ($+1.6 \mu\text{g m}^{-3}$). Over some hot spots in the two countries (e.g. northwestern India and North China Plain), the local changes in $PM_{2.5}$ exceed $3.5 \mu\text{g m}^{-3}$, supporting the previously emphasized importance of controlling NH_3 emissions on PM air quality of China (Fu et al., 2017), but potentially India as well. Some moderate increases ($< 2 \mu\text{g m}^{-3}$ in most locations) in annual mean $PM_{2.5}$ concentrations are also observed in the Middle East, North America, central America and South America.

The largest decreases (up to $2.1 \mu\text{g m}^{-3}$) in annual mean $PM_{2.5}$ due to changes in agricultural emissions are simulated in central and eastern Europe and Former Soviet Union. Despite comparable reductions in agricultural NH_3 emissions, decreases in $PM_{2.5}$ over western Europe are smaller because of weaker sensitivity of SNA aerosol to NH_3 emissions, which is consistent with the finding of Lee et al. (2015) and Pozzer et al. (2017). In general, reductions in annual mean $PM_{2.5}$ due to agricultural emission changes simulated over western Europe are weaker than over central and eastern Europe and Former Soviet Union.

Figure 5c shows the combined effect of agricultural emissions and LULCC on annual mean surface $PM_{2.5}$, which we have already shown is mostly dominated by the effect of agricultural emissions. Nevertheless, we find that the effects of LULCC are able to partially offset the increase in $PM_{2.5}$ due to agricultural emissions changes over China and India. These offsets are occurring in densely populated areas, so that the effects on population-weighted average (method described in text S2) $PM_{2.5}$ concentrations (see below), and therefore potentially exposure, may be noteworthy. This is discussed in further detail below.

We note that the difference between Figure S5a and Figure 5c illustrates how $\Delta PM_{2.5, \text{LULCC+agr_emis}}$ is sensitive to the anthropogenic emissions background. We find that surface $PM_{2.5}$ over US, Europe and Former Soviet Union are less sensitive to NH_3 emissions under 2014 anthropogenic emissions background, since both SO_2 and NO_x emissions in these regions have decreased significantly ($> 42\%$ for NO_x and $> 58\%$ for SO_2) over 1992 and 2014. The opposite is simulated in over China and India, where SO_2 and NO_x emissions have increased by $> 50\%$.

290

Table 3 summarizes the simulated effects of LULCC and agricultural emission changes on $\text{PM}_{2.5}$ air quality, and compares their magnitudes with the concomitant effects from direct anthropogenic emission changes (“ $\Delta\text{PM}_{2.5, \text{anth}}$ ”) over the same time period. We additionally compare area-averaged and population-weighted global and regional metrics. While the resolution of our simulations does not capture urban-scale gradients and non-linearities in urban chemistry, the use of population weighting 295 allows us to explore whether signals of change in land cover or land management are concentrated over areas of high population, or whether they are primarily observed over less populated areas.

Globally, our model results estimate that the global population-weighted change in $\text{PM}_{2.5}$ resulting from LULCC and 300 agricultural emission changes ($+0.70 \mu\text{g m}^{-3}$) is on the order of $\sim 10\%$ of the change in $\text{PM}_{2.5}$ resulting from direct anthropogenic emissions ($+7.99 \mu\text{g m}^{-3}$) over 1992 to 2014. Regionally, the largest impact of land change ($\Delta\text{PM}_{2.5, \text{LULCC+agr_emis}}$) on population-weighted annual mean surface $\text{PM}_{2.5}$ is simulated over central and eastern Europe ($-1.01 \mu\text{g m}^{-3}$), Former Soviet Union ($-1.00 \mu\text{g m}^{-3}$), South Asia ($+1.71 \mu\text{g m}^{-3}$) and China ($+1.45 \mu\text{g m}^{-3}$). In most regions, the difference between population-weighted $\Delta\text{PM}_{2.5, \text{agr_emis}}$ and $\Delta\text{PM}_{2.5, \text{LULCC+agr_emis}}$ is very small ($< \sim 0.05 \mu\text{g m}^{-3}$) except in China ($0.12 \mu\text{g m}^{-3}$). Generally, the impacts of land change on population weighted $\Delta\text{PM}_{2.5}$ have the same sign as the impacts of direct anthropogenic emissions. 305 The only exception to this occurs over North America where anthropogenic NO_x and SO_2 emissions have declines, but agricultural emissions have increased. This suggests that the increase in agricultural emissions over NAm has partially canceled out the effects of other emission controls on $\text{PM}_{2.5}$, though this effect is small so far ($\sim 5\%$). In other regions, population-weighted $\Delta\text{PM}_{2.5, \text{LULCC+agr_emis}}$ is generally on the order of 5% to 12% of changes due to direct anthropogenic emissions (e.g. in central and eastern Europe and western Europe). Notably, over Former Soviet Union, the Middle East and central America, 310 $\Delta\text{PM}_{2.5, \text{LULCC+agr_emis}}$ are much more comparable to the effect of anthropogenic emission changes (24%, 42%, and 208% respectively).

Our result shows that the impact of LULCC and land management changes on $\text{PM}_{2.5}$ is mainly from the agricultural emission changes, while LULCC can result in additional impacts in regions with high SNA precursor emissions (e.g. India, China) 315 through modulating dry deposition. The magnitude of population-weighted $\Delta\text{PM}_{2.5, \text{LULCC+agr_emis}}$ suggests that land change may contribute significantly to regional and global changes in human $\text{PM}_{2.5}$ exposures and that the effects of these changes are not isolated to low population regions. Particularly, over the regions experiencing rapid change in land use intensity (e.g. Former Soviet Union) or slow change in anthropogenic emissions (e.g. central America, the Middle East), the effects of land changes on particulate air pollution could be comparable (24% to 208%) to the effects of direct anthropogenic emission changes.

320 5 Impact on surface O_3

Figure 6 shows the modeled impacts of LULCC, changes in agricultural emissions, and the combined effects of both, on annual mean surface O_3 (under 2014 anthropogenic emissions). These changes are calculated identically as for $\text{PM}_{2.5}$ above: the

impacts of LULCC on O_3 (“ $\Delta O_3, LULCC$ ”) is the difference in O_3 predicted by Simulation 2 and Simulation 1; the impacts of agricultural emission changes on O_3 (“ $\Delta O_3, agr_emis$ ”) is the difference in $PM_{2.5}$ predicted by Simulation 3 and Simulation 2; and the impacts of these combined (“ $\Delta O_3, LULCC+agr_emis$ ”) is the difference in $PM_{2.5}$ predicted Simulation 3 and Simulation 1 (see Table 1). We also use predictions of surface HNO_3/H_2O_2 ratios (Figure S6) as a proxy of VOC- vs NO_x - sensitive chemical O_3 production (Peng et al., 2006; Sillman, 1995) in our discussion of the results.

The modelled response of surface O_3 to LULCC ($\Delta O_3, LULCC$) (Fig. 6a) involves several distinct processes (dry deposition, soil NO_x, and BVOC emissions). Over parts of North America and central America, the increase in dry deposition velocity (v_d) reduces annual mean surface ozone by up to 0.5 ppbv overall. In central Brazil, deforestation of tropical rainforests leads to significant reduction in isoprene emissions, reducing surface ozone by up to 0.8 ppbv in this NO_x -limited environment (Fig. S6). In contrast, modelled surface ozone increases by up to 1.2 ppbv further south, where strong increases in LAI lead to largely increases v_d . The modelled reduction of surface ozone (up to 1 ppbv) over central African rainforests is also likely attributable to increased v_d as neither soil NO_x nor isoprene emissions change much in the region. However, in other parts of Africa, up to 0.6 ppbv of surface ozone increases are simulated, mainly because of the relatively large increase in soil NO emission. In southern China, up to 0.5 ppbv reduction in surface ozone is simulated, which is likely attributable to the increase in v_d , and slightly offset by the small increase in isoprene emission under this NO_x -saturated environment (Fig. S6). Small surface O_3 changes, mainly due to transport, are also simulated over the Atlantic Ocean.

340

Overall, the role of agricultural emission changes in fertilizer-associated NO_x plays a minor role in surface O_3 changes (Fig. 6b). An exception to this is observed in the large increase in agricultural NO_x emissions which reduce surface O_3 by up to 0.6 ppbv over NO_x -saturated India and China, but increase surface O_3 in NO_x -limited parts of Southeast Asia by similar magnitude. Slight increases in surface O_3 level due to increased agricultural NO_x emissions are also simulated over parts of eastern Africa and South America. Whether the effect of agricultural emissions strengthens (e.g. China and Sahel) or offsets (e.g. over southern Brazil and India) the effect of LULCC is largely region-dependent. As shown in Fig. 6c, LULCC tend to dominate the impacts on surface O_3 over most regions in the world (unlike $PM_{2.5}$ where the effects of agricultural emission changes dominate).

350

Similar to $PM_{2.5}$, we find that the changes in anthropogenic emission background over 1992 to 2014 is strong enough to alter the sensitivity of O_3 to land change. As indicated by Fig. S6, Asia was less NO_x -saturated, while western Europe and coastal United States were more NO_x -saturated in 1992 than in 2014. For example, the increase in soil NO emission over India is more likely to increase rather than decrease surface ozone concentration (fig. S7a), leading to different modelled effect on surface ozone.

355

Table 4 shows the change in area and population-weighted annual mean afternoon surface O_3 due to the effects of anthropogenic emissions (“ $\Delta O_3, \text{anth}$ ”, Fig. S7b), $\Delta O_3, \text{LULCC}$, $\Delta O_3, \text{agr_emis}$ and $\Delta O_3, \text{LULCC+agr_emis}$. In most regions, $\Delta O_3, \text{LULCC+agr_emis}$ is positive. However, this is offset by the negative population-weighted average $\Delta O_3, \text{LULCC+agr_emis}$ over the most populous regions (South Asia and China), resulting in very small globally averaged population-weighted $\Delta O_3, \text{LULCC+agr_emis}$.

360

The magnitudes of population-weighted ΔO_3 (within ± 0.5 ppbv) display less regional variability than that of $\Delta PM_{2.5}$. Over Eastern Africa, Western Africa and Southern Africa, area-averaged $\Delta O_3, \text{LULCC+agr_emis}$ generally has similar magnitudes to population-weighted $\Delta O_3, \text{LULCC+agr_emis}$. In other regions, the differences between area and population-weighted $\Delta O_3, \text{LULCC+agr_emis}$ are more substantial. The largest discrepancies between area and population-weighted $\Delta O_3, \text{LULCC+agr_emis}$ is found 365 over China, where increases in surface O_3 are predicted over less populated western China, while reductions in surface O_3 are simulated over more densely-populated eastern China. In South America, there are large sub-regional signals of $\Delta O_3, \text{LULCC+agr_emis}$, but these the positive and negative largely offset each other, resulting both in small area-weighted and population-weighted $\Delta O_3, \text{LULCC+agr_emis}$.

365

370 Over China, western Africa, eastern Africa, southern Africa, Former Soviet Union and the Middle East, the magnitudes of population-weighted $\Delta O_3, \text{LULCC+agr_emis}$ are more than 20% of that of $\Delta O_3, \text{anth}$, implying that contemporary land system changes could be a regionally important component in contemporary trends of surface O_3 . The effects of agricultural emission changes and LULCC can either noticeably enhance (e.g. over the Middle East, Japan and Korea, China) or offset (e.g. over South Asia) 375 each other because of the dependence of $\Delta O_3, \text{agr_emis+land_cover}$ on regional NO_x -VOC chemistry and details of LULCC, indicating the complexity of diagnosing the effect of land change on surface O_3 at regional and global scale.

375

Our result suggests that contemporary agricultural emission changes and LULCC each have distinct effects on surface O_3 , with LULCC generally stronger in magnitude. Both of the effects are dependent on local NO_x -VOC chemistry, as agricultural emission changes perturb NO_x emissions, while LULCC tends to affect BVOC emissions. In addition, LULCC is also able to 380 affect surface O_3 (and other precursors) directly through dry deposition through LAI changes over our period of concern. These effects are found to affect O_3 pollution over densely populated regions (e.g. China) and could be comparable to the magnitudes of O_3 changes due to anthropogenic emissions over specific regions (e.g. Former Soviet Union, eastern Africa, western Africa), indicating the importance of land change in studying long-term changes in surface O_3 .

6 Impact on Nitrogen Deposition

385

Finally, we estimate the effect of these land changes on nitrogen deposition estimates. Figure 7 shows the global impact of LULCC and agricultural emission changes on total nitrogen deposition (ΔN_{dep}), and Table 5 summarizes the regional and global results. The largest increase and decrease in nitrogen deposition (N_{dep}) are simulated over South Asia ($+1.91 \text{ TgN yr}^{-1}$)

and Former Soviet Union (-1.28 TgN yr⁻¹), respectively. Notable increases in N_{dep} are also simulated over China (+1.55 TgN yr⁻¹), South America (+1.24 TgN yr⁻¹), North America (+0.66 TgN yr⁻¹), western Africa (+0.39 TgN yr⁻¹) and eastern Africa (+0.41 TgN yr⁻¹). Figure 7 also illustrates the simulated changes over 1992 to 2014 in area with nitrogen deposition (N_{dep}) exceeding 5 kgN ha⁻¹ yr⁻¹, which is a proxy of possible exceedance of critical N_{dep} loads for terrestrial and fresh water (Moriarty, 1988).

Globally, there is a net increase in land area with N_{dep} > 5 kgN ha⁻¹ yr⁻¹ of 3.67×10^6 km². The increase is mostly simulated over the Americas, Africa, the Middle East and China, which is partially offset the large decrease over Former Soviet Union. Meanwhile, despite agricultural changes that lead to notable ΔN_{dep} , over most of Europe, eastern US, China, South Asia and Southeast Asia, nitrogen input from other sources are large enough that this signal alone does not lead substantial changes in N_{dep} exceedances of 5 kgN ha⁻¹ yr⁻¹. However, over parts of North America, South America, Africa and China, agricultural changes are simulated to increase N_{dep} from below to above 5 kgN ha⁻¹ yr⁻¹. This implies these natural ecosystems at the edge of these areas are at risk of nitrogen exceedances due to agricultural changes. In contrast, the substantial reduction of N_{dep} in parts of Former Soviet Union may have significantly reduce the risk of nitrogen exceedance of natural ecosystem from agricultural sources.

7 Discussion and Conclusions

In this work, we have explored how changes in the global land system, through LULCC and agricultural emission changes, 405 may have impacted contemporary global air quality over 1992 to 2014. We model the effects of contemporary LULCC and agricultural emission changes, individually then in combination, on surface O₃ and PM_{2.5} using the GEOS-Chem CTM. With a uniquely consistent framework, we are able to integrate direct information from global emission inventories (CEDS) with updated land surface remote sensing products (ESA CCI land cover and GLASS LAI). This allows us to avoid invoking extra assumptions on land management practices (e.g. constant N_r input, emissions or emission factors over time) and biophysical 410 properties of PFTs (e.g. constant PFT-specific LAI over time).

We find that changes in agricultural emissions are simulated to increase the annual mean surface PM_{2.5} concentrations in China and India by up to 3.5 $\mu\text{g m}^{-3}$ and to decrease in Europe by up to 3.5 $\mu\text{g m}^{-3}$. Our simulation suggests that though $\Delta \text{PM}_{2.5}$ is mainly attributable to changes in agricultural emissions in global scale, LULCC over India and China can lead to enhanced 415 dry deposition of certain PM_{2.5} precursor gases (SO₂ and NO₂), thus partially offsetting (~10 %) the increase in PM_{2.5} from agricultural regions. This implies a potentially important role of LULCC in determining SNA aerosol level over certain heavily polluted regions. Also, LULCC reduces BVOC emissions over Amazonia which lead to reductions in PM_{2.5} by up to 0.7 $\mu\text{g m}^{-3}$. In a future with decreasing anthropogenic NO_x and SO₂ emissions, which could diminish the importance of agricultural emissions on PM_{2.5} formation (Bauer et al., 2016), LULCC may become increasingly important in the overall effect of land

420 change on $\text{PM}_{2.5}$. Noticeable changes ($> 1 \mu\text{g m}^{-3}$) population-weighted $\Delta\text{PM}_{2.5, \text{LULCC+agr_emis}}$ are simulated over China (+1.45 $\mu\text{g m}^{-3}$), South Asia (+1.71 $\mu\text{g m}^{-3}$), central and eastern Europe (-1.00 $\mu\text{g m}^{-3}$) and Former Soviet Union (-1.01 $\mu\text{g m}^{-3}$), indicating the potential impact of land change on long-term public health through modulating $\text{PM}_{2.5}$ level at regional scale. Our results suggest that contemporary (1996-2014) changes contribute to changes in $\text{PM}_{2.5}$ at regional and global scales that range from on the order of 5 to 10% of changes in $\text{PM}_{2.5}$ resulting from direct anthropogenic emissions over the same time 425 period, and up to ~25% or more in Former Soviet Union, the Middle East specifically.

In contrast, the effect of LULCC is generally stronger than that of agricultural emission change in simulations of surface O_3 . We find that the role of LULCC over 1992 to 2014 is regionally significant enough to induce changes in BVOC emissions and dry deposition which affect surface O_3 , but that the overall effects largely offset each other on the global scale, leading to very 430 small population-weighted $\Delta\text{O}_{3, \text{LULCC+agr_emis}}$. Both the effects of agricultural emission changes and LULCC, through NO_x and BVOC emissions, are sensitive to regional ozone production regime. The increase in agricultural emissions reduces O_3 over NO_x -saturated parts of China and South Asia by up to 0.6 ppbv, while the reduction in BVOC emissions increases surface O_3 over VOC-limited Amazonia by up to 1.2 ppbv; enhancements of dry deposition reduce O_3 over parts of China, North America and South America by up to 1.2 ppbv. Overall, the largest population-weighted $\Delta\text{O}_{3, \text{LULCC+agr_emis}}$ is simulated over western 435 Africa (+0.42 ppbv) and eastern Africa (+0.47 ppbv). We find that the ratio between $\Delta\text{O}_{3, \text{LULCC+agr_emis}}$ and $\Delta\text{O}_{3, \text{anth}}$ varies widely depending on region, with some having $\Delta\text{O}_{3, \text{LULCC+agr_emis}}$ that are comparable (>20%) to $\Delta\text{O}_{3, \text{anth}}$. These results show the complexity and importance of land change on mediating long-term changes in surface O_3 .

We also find that both the modelled $\Delta\text{O}_{3, \text{LULCC+agr_emis}}$ and $\Delta\text{PM}_{2.5, \text{LULCC+agr_emis}}$ are sensitive to the changes in anthropogenic 440 emissions suggested by CEDS inventory over 1992 and 2014, as the changes in NO_x , SO_2 and VOC emissions are large enough to perturb atmospheric HNO_3 and H_2SO_4 production, and ozone production regime considerably in many regions (e.g. Asia and western Europe). This highlights the necessity of accurate and relevant emission inventories when evaluating the impacts of land change on air quality (e.g. Bauer et al., 2016).

445 The increased atmospheric reactive nitrogen (+7.20 Tg/yr) due to agricultural emissions is mostly found to deposit near to source region as the atmospheric lifetime of NH_3 is generally short, which implies the potential risk of excessive nitrogen input over the natural ecosystems near to the regions with increases in agricultural emissions.

Our work suggests that, at contemporary timescales (on the order of ~20 years), the effect of land change on air quality can 450 sometimes be important relative to the air quality changes induced by trends in direct anthropogenic emissions. We also find that agricultural emission changes have stronger effects on $\text{PM}_{2.5}$, while LULCC have stronger effects on O_3 . This finding is comparable to that from Heald and Geddes (2016), which suggest a much more comparable changes in biogenic SOA (mostly induced by LULCC) and particulate nitrate (mostly induced by agricultural emission changes), and stronger surface ozone

changes induced by land change over 1850 – 2000. This shows that both the magnitudes and relative contributions from
455 different components of land change effects on air quality vary significantly as timescale of study, and its potential importance
at longer timescales (e.g. multidecadal, centennial), despite the relative small signal that we obtain here.

We find the effects of agricultural emissions and LULCC to be largely linearly additive over contemporary timescales, which
may be attributable to two factors: 1) LULCC mainly impacts O₃ precursors while agricultural emissions mainly impact SNA
460 precursors, and these are often spatially segregated; 2) LULCC and agriculture-related changes in surface fluxes of O₃ and
SNA precursors are not large enough to change their respective chemical production regime. At longer timescale when land
change signals are stronger, the effects of LULCC and agricultural emissions may be non-linear.

We note several important limitations and opportunities for development. We were only able to evaluate our simulation
465 extensively over Europe, North American and East Asia. In most other regions where such evaluation of SNA speciation is
not feasible, the sensitivity of SNA formation to NH₃ emissions can be a major source of uncertainty. Given the changes in
agricultural emissions have occurred in global scale, effort of monitoring SNA speciation outside North America and Europe
(e.g. Weagle et al., 2018) is necessary for understanding the sensitivity of PM_{2.5} to agricultural emissions in global extent.
470 Better understanding of both the sources and sinks of HNO₃ (e.g. Heald et al., 2012; Holmes et al., 2019; Luo et al., 2019;
Petetin et al., 2016) and nitrate partitioning (e.g. Vasilakos et al., 2018) are important for modelling SNA aerosol and its
sensitivity to NH₃ emissions. NH₃ emissions estimates also carry large uncertainty (Crippa et al., 2018). The inherent
475 inconsistency of long-term LAI time series derived from reflectance measured by different instruments (Jiang et al., 2017) and
the use of static land cover maps also introduce uncertainty in the LAI retrieval (Fang et al., 2013) and the subsequently
computed LAI changes and trends, and these have been shown to be important to changes in simulated O₃ in this study and
elsewhere (Wong et al. 2019). Though the use of PFT-based emission factors in regional and global modelling is generally
480 justifiable (Guenther et al., 2012), we cannot rule out the possibility of intra-PFT variabilities of BVOC emission factors
affecting the accuracies our results, which is exemplified by the inability of our model to capture the palm-driven isoprene
emission increase over Southeast Asia (Silva et al., 2016) as discussed in section 3. Finally, the meteorological feedbacks (e.g.
changes in sensible heat, latent heat, air temperature, boundary layer height) and the subsequent effects on atmospheric
chemistry and transport from LULCC and agricultural emissions are not considered in our study, which could potentially be
485 important (e.g. Wang et al., 2020).

Our study helps demonstrate the possible magnitudes and regional patterns of the impacts of contemporary LULCC and
agricultural emission changes on PM_{2.5} and O₃, and suggests that the combination of these factors should not be neglected in
485 the study of regional and global air quality changes over multi-decade timescales. Our results confirm the potential importance
of controlling agricultural emissions on improving PM_{2.5} air quality, which could be practical as numerous feasible options
exist for reducing agricultural emissions through optimizing livestock and crop production system (e.g. Ti et al., 2019).

Incentivizing these and other practices that improve agricultural nitrogen use efficiency (e.g. including livestock production with cropping, synchronizing nitrogen supply with crop demand) (e.g. Fageria and Baligar, 2005; Langholtz et al., 2021) can 490 be one of the keys to mitigate the air quality impacts of reactive nitrogen input without compromising agricultural productivity (e.g. Guo et al., 2020). Furthermore, as increasing reactive nitrogen input and land use change are the two of the main strategies to meet the global demand for biomass-based products in the future (Foley et al., 2011), the distinct yet significant impacts of agricultural emissions and land use change on O₃, PM_{2.5} and nitrogen deposition should be investigated as part of the overall 495 environmental impacts of land system changes, especially when tradeoff between increasing land input and cropland expansion exists (e.g. Lotze-Campen et al., 2010; Mauser et al., 2015). This could benefit agricultural policy activities by appropriately considering all in the externalities and socioeconomic costs of different options and scenarios for agricultural expansion.

Code Availability

The source code of GEOS-Chem model is publically available (<https://doi.org/10.5281/zenodo.3634864>). The GEOS-Chem model output and other source code used in the project can be obtained by contacting the corresponding author 500 (jgeddes@bu.edu).

--------	---------------	---------------	---------------	---------------

Table 4. Changes in area averaged and population-weighted (in parentheses) annual mean surface O₃ concentrations (in ppbv) due to anthropogenic emissions alone ($\Delta\text{PM}_{2.5(\text{anth})}$), LULCC ($\Delta\text{PM}_{2.5(\text{LULCC})}$), agricultural emissions ($\Delta\text{PM}_{2.5(\text{agr_emis})}$), and the combined effects of LULCC and agricultural emission ($\Delta\text{PM}_{2.5(\text{LULCC+agr_emis})}$) together. Results only from regions with population-weighted average $\Delta\text{O}_3(\text{LULCC})$, $\Delta\text{O}_3(\text{agr_emis})$ or $\Delta\text{O}_3(\text{LULCC+agr_emis}) > 0.2$ ppb are shown.

[†]The definitions and abbreviations of all regions can be found in Table S2.

Region [†]	$\Delta\text{N}_{\text{dep}}$ (TgN yr ⁻¹)	$\Delta\text{Area}_{\text{crit}}$ (1000 km ²)
FSU	-1.28	-1064
China	+1.55	+502
SAs	+1.91	0
ME	+0.29	+494
SEA	+0.61	+244
NAm	+0.66	+788
SAm	+1.24	+1467
WAf	+0.39	+487
SAf	+0.15	+363
EAf	+0.41	+364
Global	+7.20	+3673

Table 5. Changes in total nitrogen deposition ($\Delta\text{N}_{\text{dep}}$) and land area that has nitrogen deposition > 5 kgN ha⁻¹ yr⁻¹ ($\Delta\text{Area}_{\text{crit}}$), which is a proxy of potential risk of critical nitrogen deposition load exceedance. Only regions with significant $\Delta\text{N}_{\text{dep}}$ (> 0.25 TgN yr⁻¹) or $\Delta\text{Area}_{\text{crit}}$ (> 10⁵ km²) are shown.

[†]The definitions and abbreviations of all regions can be found in Table S2.

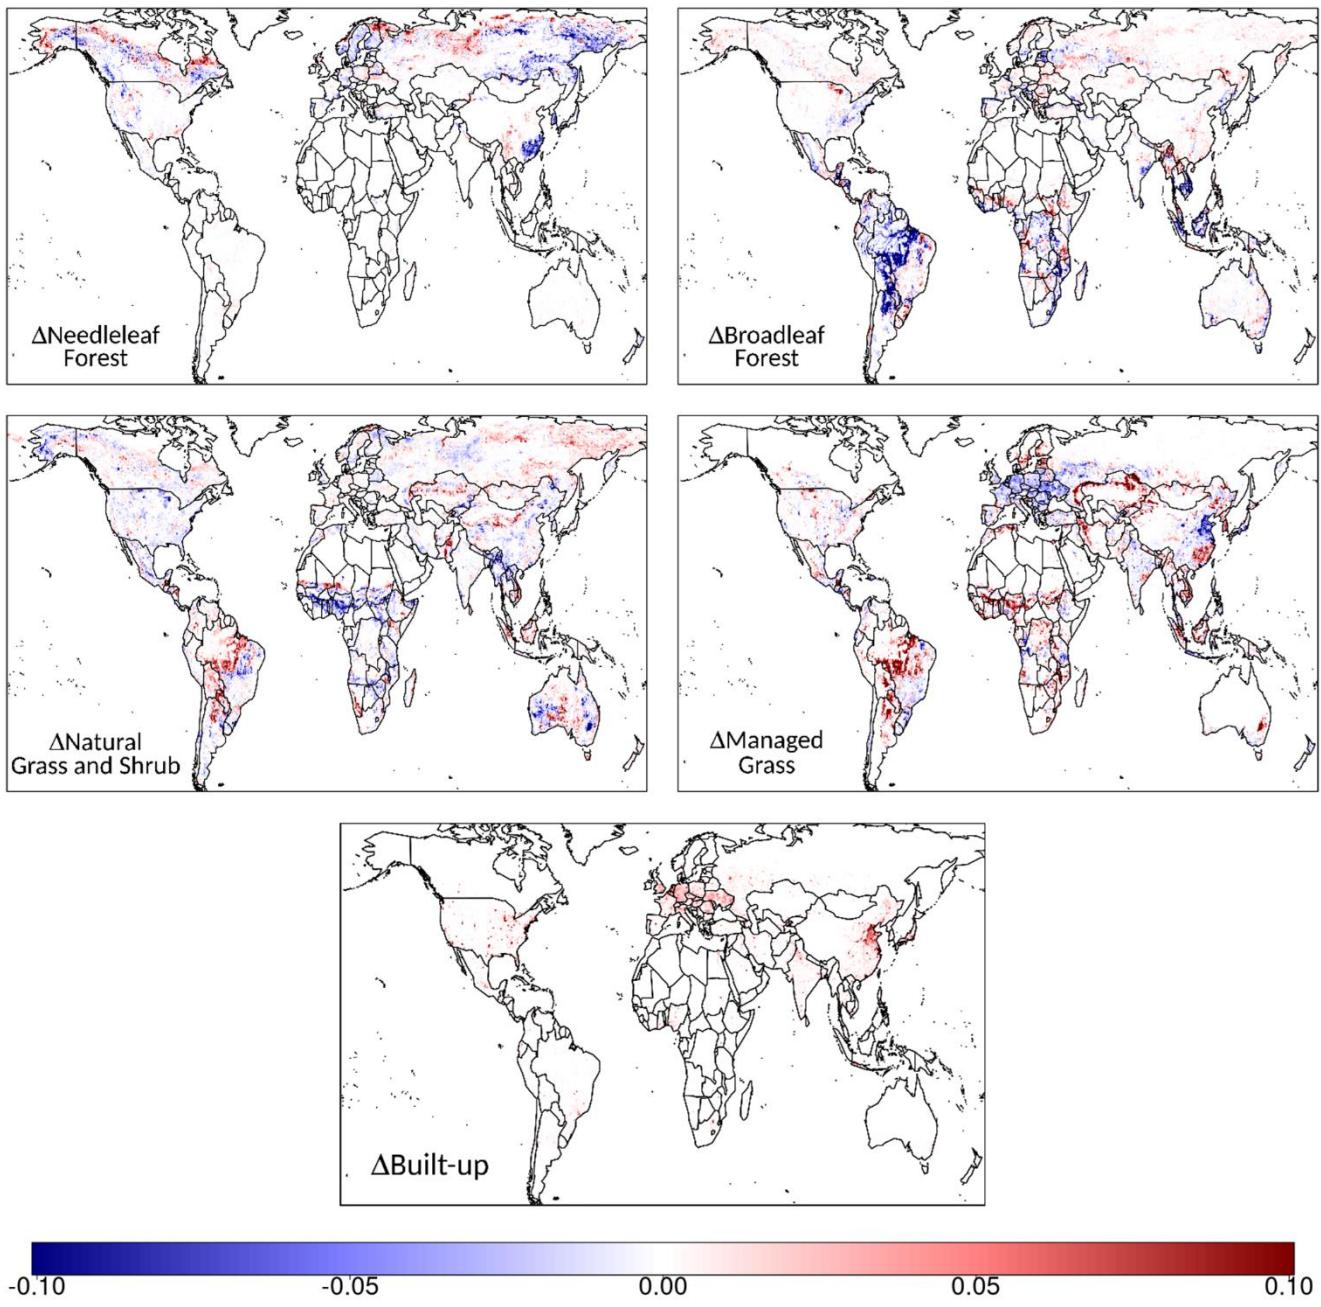

Figure 1. Global spatial patterns of 2014-1992 LULCC characterized by the changes in fractional coverages within a grid box (unitless) of major land cover types derived from the ESA CCI land cover product.

$$\Delta \text{LAI} (\text{m}^2 \text{ m}^{-2})$$

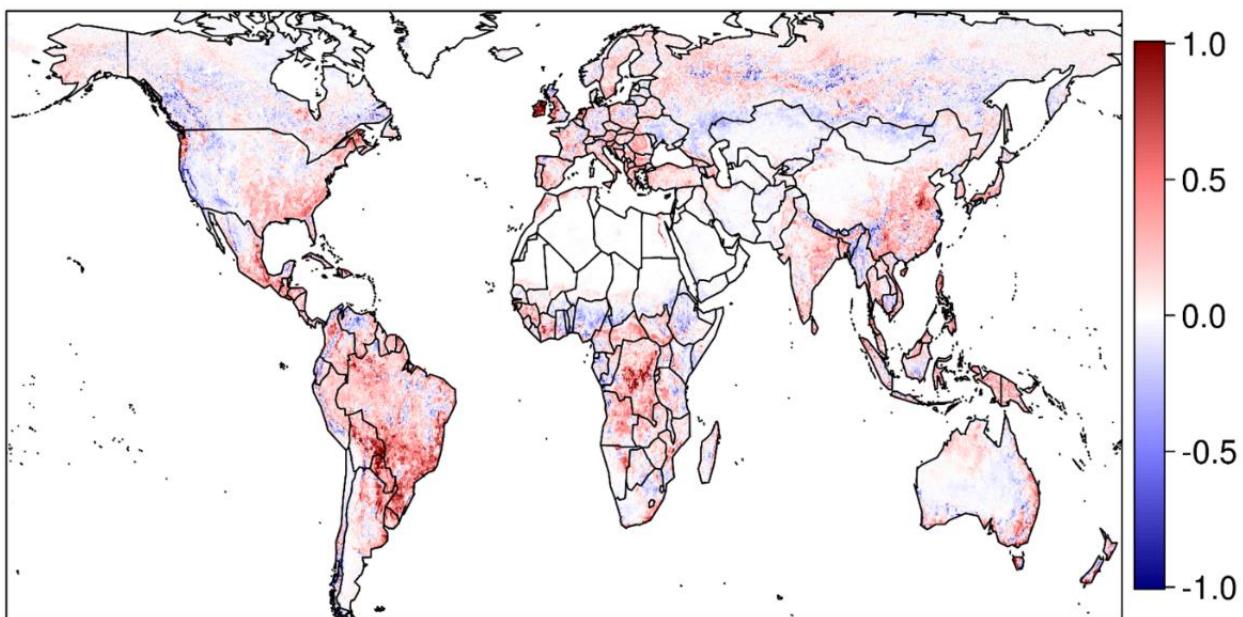

Figure 2. Global Land Surface Satellite (GLASS)-derived changes in 3-year mean annual leaf area index (LAI) (2012

825 to 2014 average minus 1991 to 1993 average).

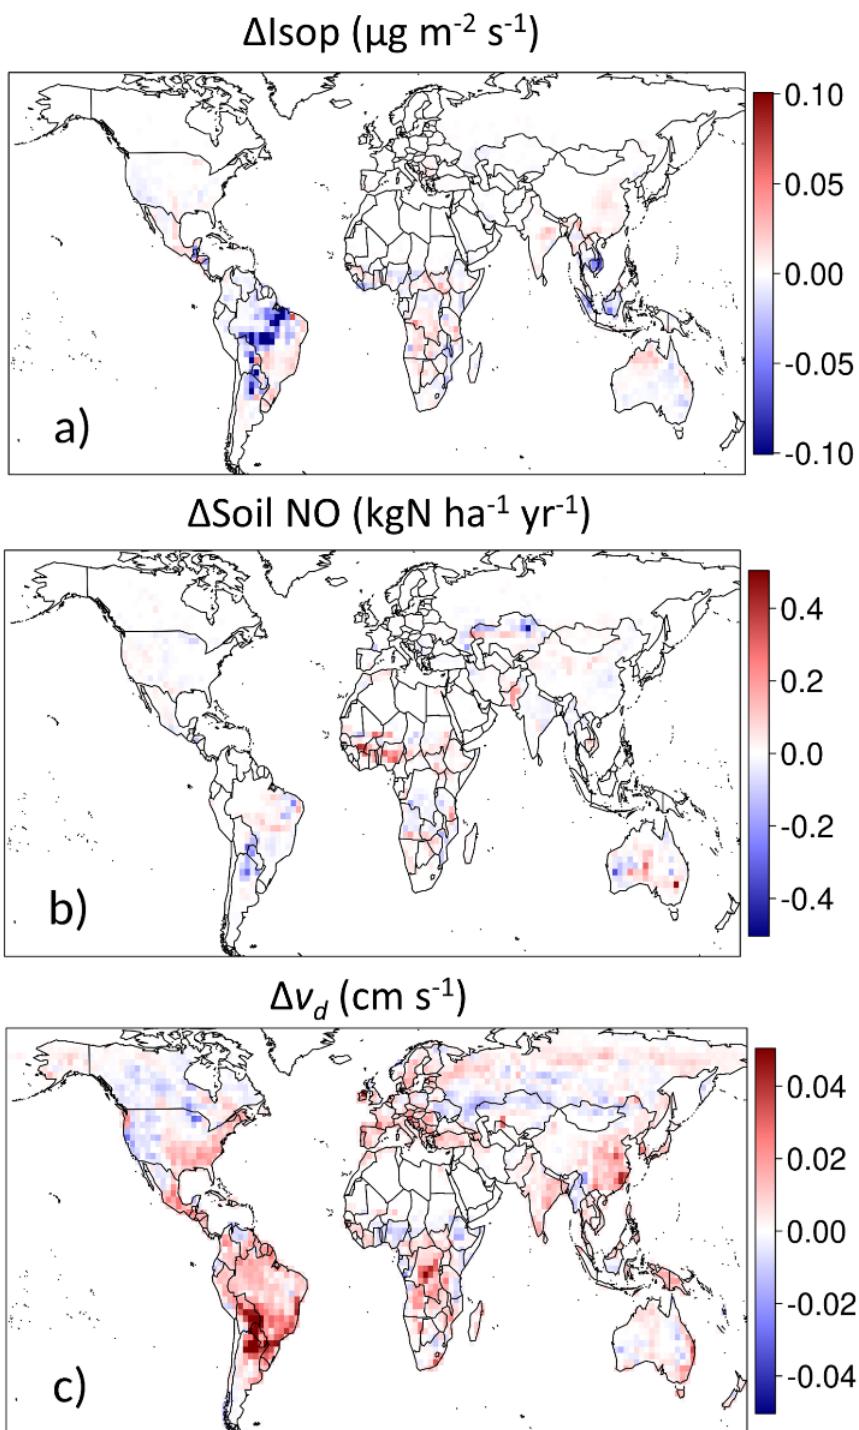

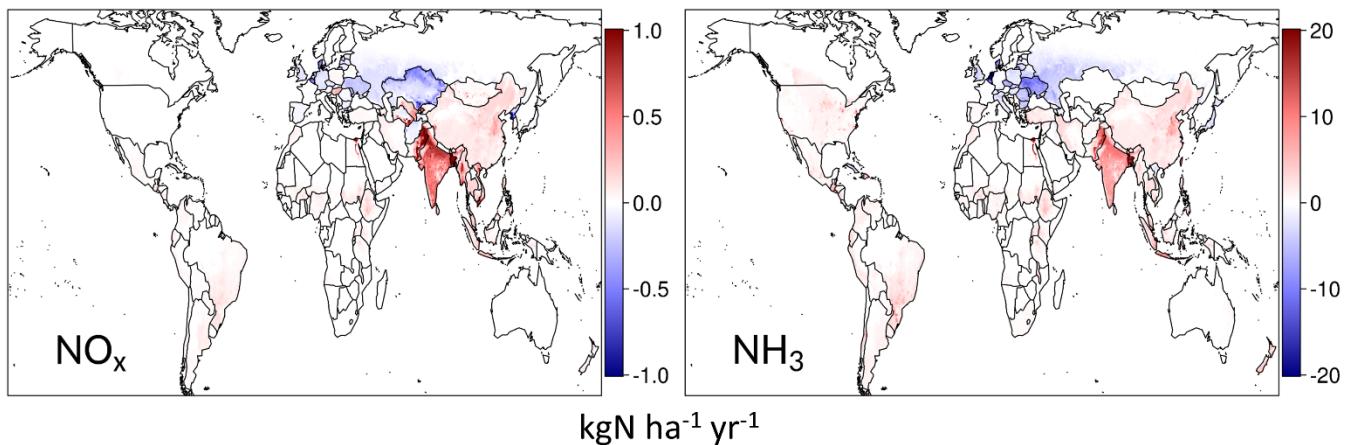

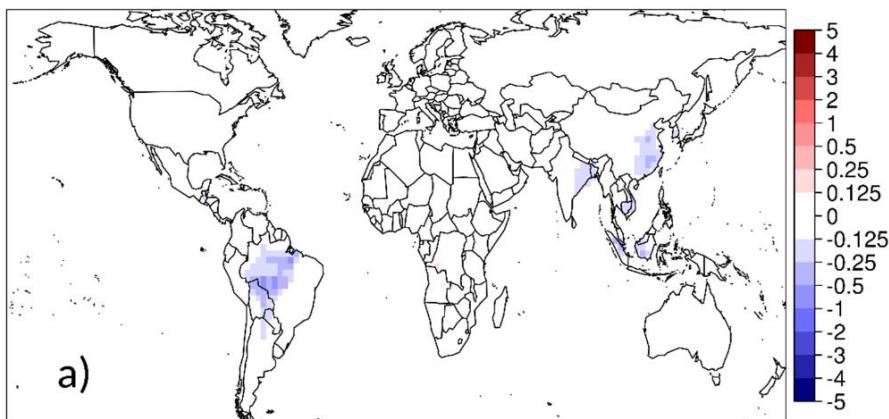

Figure 3. Changes in annual mean a) isoprene emission (ΔIsop), b) soil NO emission ($\Delta\text{Soil NO}$), and c) O_3 dry deposition velocity (Δv_d), due to LULCC over 1992 and 2014.
