**Abstract.** We analyzed the biogenic volatile organic compounds (BVOC) emissions from rapeseed leaf litter and their potential to create secondary organic aerosols (SOA) under three different conditions, i.e., (i) in presence of UV light irradiation, (ii) in presence of ozone, and (iii) with both ozone and UV light. These experiments were performed in a controlled atmospheric simulation chamber containing leaf litter samples, where BVOC and aerosol number concentrations were measured for six days. Our results show that BVOC emission profiles were affected by UV light irradiation, which increased the summed BVOC emissions compared to the experiment with solely O<sub>3</sub>. Furthermore, the diversity of emitted VOCs from the rapeseed litter also increased in presence of UV light irradiation. SOA formation was observed when leaf litter was exposed to both UV light and O<sub>3</sub>, indicating a potentially large contribution to particle formation or growth at local scales. To our knowledge, this study investigates, for the first time, the effect of UV irradiation and O<sub>3</sub> exposure on both VOC emissions and SOA formation for leaf litter samples. A detailed discussion about the processes behind the biological production of the most important VOC is proposed.

## 1 Introduction

Nowadays, the crucial role played by Volatile Organic Compounds (VOCs) as precursors of ozone and particles within the troposphere has been established (Hatfield and Huff Hartz, 2011). Sources of VOCs are either anthropogenic, related to human activities, or biogenic. Biogenic volatile organic compounds (BVOCs) are released from living and senescent vegetation, soils and microorganisms, or oceans (Kesselmeier and Staudt, 1999; Murphy et al., 2010). Such biogenic VOCs (BVOCs) have been estimated to contribute up to 90% of the total VOC emissions (Guenther, 1995). Furthermore, the currently most accredited emission model for BVOC (MEGAN v2.1), estimates that 760 Tg C yr<sup>-1</sup> are emitted into the troposphere (Sindelarova et al., 2014). Modeling studies have highlighted the impact of BVOCs on carbon monoxide (CO), hydroxyl radical (OH), and low-level ozone; and thus, the oxidative capacity of the troposphere (Granier et al., 2000; Pfister et al., 2008; Poisson et al., 2000). It was found that products resulting from the BVOC oxidation are significant precursors of Secondary Organic Aerosols (SOA), affecting the Earth's radiative balance (Ziemann and Atkinson, 2012) and thus, the climate and the human health (De Gouw and Jimenez, 2009). In addition, between 11% and 70% of emitted BVOCs are converted into SOA, leading to a yearly production of 140–190 Tg C yr<sup>-1</sup> of particles (Hallquist et al., 2009).

Due to the growing awareness about climate change and atmospheric pollution, the number of studies focusing on BVOCs has grown almost exponentially over the past 20 years, with a strong focus on forests and plants since they are the most important sources of BVOC. However, little attention has been drawn to leaf litter and their contribution to SOA formation in the global BVOC emissions model, even though several studies reported a significant contribution to the

BVOC ~~emissions, and emissions describing~~ describing BVOCs emitted from leaf ~~ves~~ litter as potential contributors ~~of the to~~ SOA formation (Bigg, 2004; Faiola et al., 2014; Isidorov and Jdanova, 2002; Viros et al., 2020) ~~(Bigg, 2004; Faiola et al., 2014; Isidorov and Jdanova, 2002; Viros et al., 2020)~~. The annual global ~~leafves~~ leaf litter production has been estimated ~~to be~~ between 75 and 135 Pg dry matter (DM) yr<sup>-1</sup>, contributing to ~~the~~ 10% of the global annual ~~emission~~ emissions of acetone and methanol (Matthews, 1997; ~~W~~warneke et al., 1999) ~~(Matthews, 1997; Warneke et al., 1999)~~. It was found that the ~~leafves~~ leaf litter's contribution to acetone and methanol emissions is due to the degradation processes driven by microorganisms or abiotic factors (i.e., temperature, ~~radiation~~), ~~processes~~ known to release partially oxidized VOC such as acetone and methanol (Warneke et al., 1999) ~~(Warneke et al., 1999)~~.

~~Rapeseed (Brassica napus) was chosen as model plant species in this study as model plant species due to its wide geographic distribution and its importance as a crop. Rapeseed is grown to produce animal feed, edible vegetable oils, and biodiesel. Rapeseed was the third-leading source of vegetable oil in the world in 2000, after soybean and palm oil. It is the world's second-leading source of protein meal after soybean. France is the fifth largest producer worldwide of this specific crop countries concerning the rapeseed production (Fischer et al., 2014).~~

~~The development cycle of rapeseed is divided into 3 phases: 1) the vegetative, 2) the reproduction, and 3) the maturation. For the vegetative phase, rapeseed is sown in August. This phase starts with an epigeous germination during the month of September. From September to December, the rapeseed stem will grow from 10 to 20 cm and produce about 20 leaves forming a rosette. The reproduction phase starts after the winter, i.e., between February and March. It is during this time that the rape goes up. Then we observe then the beginning of the elongation. Flowering lasts between 4 and 6 weeks, and the maturation phase is occurs when the siliques are formed (in June). In July, they are ready for the harvest. It is in this period that we collected the rapeseed litter.~~

~~Rapeseed residues are often left on the field. The incorporation of crop residues into agricultural soils improves soil structure, reduces bulk density, reduces evaporation, and decreases erosion. Rapeseed in this rotation contributes to improving the organic matter content of the soil. Organic matter, which is essential to fertility, contributes to the supply of nitrogen, to the improvement of structural stability (less sensitivity to soil compaction and erosion), and to the an increase in the storage capacity of water and mineral elements (i.e., improvement of the cation exchange capacity) (Tiefenbacher et al., 2021). Therefore, the litter associated to rapeseed is an important aspect of that process.~~

~~The volume of straw produced varies between 0.6 and 2.4 tons of dry matter per hectare. This estimate takes into account the important losses of material that occur during mowing operations, and it corresponds to the volume of harvestable straw per hectare. Only half of the total volume produced is harvested, the rest is left in the field to return to the soil (FranceAgriMer, 2016).~~

The composition and amount of BVOCs emitted from ~~leafves~~ leaf litter, alongside their associated reactivity, strongly depend on plant species, decomposition state, and environmental conditions such as temperature, ultraviolet (UV) light irradiation, and ozone concentration. Nevertheless, ozone concentration in rural areas has been estimated to be around 60 ppb, with peaks reaching 80 ppb during ~~the summer~~ (Monks et al., 2015) ~~(Monks et al., 2015)~~. This ~~affect leafves~~ affects leaf litter directly through chlorosis and cellular damage (Diaz-de Quijano et al., 2016) ~~(Diaz de Quijano et al., 2016)~~. ~~Although, Also though,~~ ozone indirectly impacts biological and chemical processes such as photosynthesis, respiration, stomatal functioning (Yendrek et al., 2017) ~~(Yendrek et al., 2017)~~, and the emissions of BVOCs (Yuan et al., 2016, 2017a, b) ~~(Yuan et al., 2016, 2017)~~.

Another important factor affecting the degradation of ~~leafves~~ leaf litter is UV light (Derendorp et al., 2011) ~~(Derendorp et al., 2011)~~, which is responsible for increased emissions of short length VOCs (i.e., C2-C5) especially in the presence of humid air (Derendorp et al., 2011) ~~(Derendorp et al., 2011)~~.

This study aims to investigate the individual and combined effects of ozone and UV light irradiation on BVOCs emission and the subsequent SOA formation from rapeseed litter, *Brassica Napus* sp. ~~The rapeseed litter was used since because it is the third most cultivated species in France after wheat and maize in France (French National Statistics, 2019) (French National~~

Code de champ modifié

Mis en forme : Français (France)

Mis en forme : Français (France)

Mis en forme : Anglais (États-Unis)

Statistics, 2019)). We investigated the VOC emission profiles of the senescent rapeseed leaves for 6 days after they were collected. The experiments ~~have been were~~ carried out in a multiphase simulation chamber ~~during which, where~~ ~~leaf~~~~ves~~~~leaf~~ litter ~~were~~~~was~~ ~~ere~~-exposed to (i) UV light (UV), (ii) ozone (O<sub>3</sub>), and (iii) a combination of both (UV\_O<sub>3</sub>).

## 2 Materials and Methods

### 2.1 Samples collection

The leaves of ~~r~~Rapeseed (sp. *Brassica napus*) used during the experiments were collected on June 3rd, ~~2019~~~~2019~~ in the AgroParisTech field, Thiverval-Grignon (48°85'N, 1°95'E). The Thiverval-Grignon site is located about 30 km west of Paris, ~~in the~~ North of France. The soil of this site is classified as Luvisol, ~~which It~~ consists of 25% clay, 70% silt, and 5% sand. The site is 15 ha and the rapeseed leaves ~~have been were~~ collected using the random sampling method. To avoid inhomogeneous samples in terms of the decomposition stage, all ~~of~~ the leaves ~~have been were~~ cut directly from the stems. The ~~leaves~~~~leaf~~~~ves~~ samples ~~have been were~~ stored for 2 days in a refrigerated chamber at 4 °C until the ~~measurement~~~~measurements~~ started.

### 2.2 Samples preparation

The rapeseed leaves ~~have been were~~ acclimatized for about ~~2h2 h~~ hours at 20 °C before being inserted ~~in~~into the multiphase simulation chamber. In this way, leaves reached room temperature (~~20 °C~~), which corresponds to the average temperature in the ~~N~~orth of France during summertime. This was necessary for ~~the~~ reproduction of ~~the~~ real-time conditions under which the rapeseed leaves start their decomposition. Once acclimatized, leaves ~~have been were~~ weighted and spread ~~on~~out to cover the whole surface of a FEP (fluorinated ethylene propylene) film (with a surface of 0.64 m<sup>2</sup>) (**Figure 1a**). After 6 days of measurement, the surface covered by the rapeseed litter ~~has been was~~ estimated to be 0.45 m<sup>2</sup> (**Figure 1b**) using Adobe Photoshop software (V 21.1.1). Photoshop allowed the manual selection of the ~~pixel~~~~pixels~~ containing the litter, the ~~pixel~~~~pixels~~ ~~has been were~~ converted ~~in~~into surface area (m<sup>2</sup>) using the following formula:

$$A_{litter} = \frac{Px_{litter}}{Px \times m^2} \quad (\text{eq. 1})$$

where  $A_{litter}$  is the area covered by the rapeseed litter 6 days after the beginning of the experiment,  $Px_{litter}$  is the number of ~~pixel~~~~pixels~~ in the litter area, and  $Px \times m^2$  is the number of pixels per m<sup>2</sup>. The initial weight of rapeseed in the chamber ranged from 75 to 80 g. ~~Meanwhile, a~~After ~~After~~ 6 days of measurement, the weight decreased by 29-32 %. After being spread on the FEP, the samples were introduced into the multiphase simulation chamber.

### 2.3 Multiphase simulation chamber

The multiphase atmospheric simulation chamber is schematized in **Figure 2**. The atmospheric chamber has a rectangular shape with 1m length × 1m width × 2m height (total volume 2 m<sup>3</sup>). The chamber is made of FEP film. The chamber ~~has been was~~ continuously filled with 6 L min<sup>-1</sup> of purified air, where 2 L min<sup>-1</sup> of this total flow ~~have been was~~ directed inside a glass bubbler to maintain a constant relative humidity inside the chamber (RH= 50±5 %) (**Figure 2**). The overall air renewal time in the chamber was around ~~5h30~~~~5h 30~~, which allows for chemical reactions to occur. The chamber was equipped with 12 UV lamps (OSRAM lamps, Eversun L80W/79- R), 6 on the left wall and 6 on the right wall of the chamber. ~~The absolute irradiance within the chamber has been already reported by (Alpert et al., 2017). Light produced from the UV fluorescent tubes had wavelengths between 300 to 400 nm. (Alpert et al., (2017) also reported that measurements for λ < 300 nm yielded detection limit values on the order of 10<sup>-3</sup> W m<sup>-2</sup> nm<sup>-1</sup>, and thus total light output below 300 nm is negligible. The full spectrum is shown in Fig. A1 for completeness. In comparison, the solar spectrum at the eEarth's surface is shown. It was derived using the online Quick Tropospheric Ultraviolet and Visible (TUV) calculator for a solar zenith angle of 0° (available at [http://cpirm.acom.ucar.edu/Models/TUV/Interactive\\_TUV/](http://cpirm.acom.ucar.edu/Models/TUV/Interactive_TUV/)).~~

125 The spectrum of the UV lamps is reported in appendix A (Fig. A1). Temperature, relative humidity, and differential pressure  
(to ensure a slight overpressure in the chamber compared to laboratory air) have been were monitored using a combined sensor  
for temperature and relative humidity (Vaisala HUMICAP humidity, and Temperature Probe HMP110; Vaisala Differential  
Pressure Transmitter PDT101). Data about the monitored temperature are reported in Fig. A3. VOCs and particle formations  
130 were monitored using a high-resolution proton transfer reaction mass spectrometer (PTR-TOF-MS 8000, Ionicon Analytik)  
and a scanning mobility particle size spectrometer (SMPS - model 3080, TSI), respectively.

## 2.4 Experimental set-up

The rapeseed litter has been was studied within a multiphase simulation chamber, which allowed the closest representation of  
the atmospheric conditions. The rapeseed litter has been was tested under three different conditions to distinguish the potential  
factors influencing the VOC emissions and the particle formation. The chosen conditions were under (i) UV light irradiation,  
135 (ii) ozone, and (iii) ozone and UV light irradiation at the same time. The UV light irradiation has been was turned off and on  
following the night/day cycle; the UV light has been was turned on for a total of seven hours per day. The ozone has been was  
injected into the chamber once a day into the chamber, at the same time that as the UV light was turned on, with a The initial  
concentration of 80 ppb that was progressively consumed during the day. Finally, every Every sample was analysed during  
140 6 days for each of the previously mentioned conditions. Tab. 1 summarizes the different experimental runs performed in this  
study. For each of the selected conditions, blank experiments were made for 3 days under the same conditions and subtracted  
from the following experiments.

## 2.5 Particles measurementmeasurements

Particles have been were detected by means of an SMPS consisting of a differential mobility analyzeranalyser (DMA, model  
145 3085, TSI) and an ultrafine condensation particle counter (UCPC model 3776 high flow, TSI,  $d_{50} > 2.5$  nm). During the  
experiments, the scanning particle size ranged from 2.5 to 79.1 nm, and both the sheath and sample flow rates were settled at  
3 and 0.3 L min<sup>-1</sup>, respectively. The SMPS inlet was positioned at 180 cm above the rapeseed surface, to observe the particle  
formation and growth. The density of the measured particles was assumed to be 1 g cm<sup>-3</sup>. The particles loss due to the impact  
of the chamber walls has been was calculated based on data from previous experiments performed on the same multiphase  
150 simulation chamber (Alpert et al., 2017; Bernard et al., 2016). The estimation of the particlesparticle'sparticle's loss used for  
the correction of the SMPS data have been are resumed shown in Appendix A, Fig. A2.

## 2.6 VOCs measurement

VOCs have been were detected using the PTR-TOF-MS technique, which has been already described in detail by Müller et al.,  
(2014). Ionization of the VOCs has been was carried out using the H<sub>3</sub>O<sup>+</sup> mode. The pressure and voltage of the drift tube have  
155 been were respectively set to 2.2 mbar and 500 V with a temperature of 80 °C. Consequently, the E/N ratio was about 123 Td  
(1 Td=10<sup>-17</sup> V cm<sup>2</sup>). These parameters have been were maintained constant during the whole experiment to avoid different  
ionization conditions of the VOCs within the drift tube. The sample inlet of the PTR-TOF-MS has been was constantly heated  
at 60 °C to avoid product loss by absorption in the inlet tube. The instrument sampled every 30 seconds with a flow rate of  
100 mL/min, and the raw data has been was recorded using the ToFDAQ software (Tofwerk AG, Switzerland). The PTR-TOF-  
160 MS has a mass resolution of 4500 m/Δm. The PTR-TOF-MS has a mass resolution of 4500 m/Δm. A calibration gas standard  
(TO-14A Aromatic Mix, Restek Corporation, Bellefonte, USA) containing 14 VOCs at a concentration of 100 ± 10 ppb in  
nitrogen was used to calibrate and regularly assess the instrument performance, including mass resolution, mass accuracy,  
sensitivity, and relative mass-dependent transmission efficiency. The sensitivity of these compounds ranged between 15 and  
70 cps/ppb, depending on the actual mass. However, since it was not possible to calculate the exact sensitivity for all the

165 detected compounds, we assumed that the proton reaction constant was always equal to  $2 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$  (Cappellin et al., 2011; Kalalian et al., 2020). and thus the average sensitivity of 30 cps/ppb was applied for all the compounds.

Mis en forme : Anglais (Royaume-Uni)

Mis en forme : Espace Avant : 6 pt, Après : 6 pt

Moreover, the calibration of the spectra has been performed via both an oxygen isotope of the ion source  $\text{H}_3^{18}\text{O}^+$  (21.022 m/z) and an ionized acetone molecule  $\text{C}_3\text{H}_7\text{O}^+$ , (59.0449 m/z) as described by Cappellin et al. (Cappellin et al., 2011). Those compounds have been chosen for the calibration because their identification was straightforward for all the kinds of samples kinds-used in this study.

Mis en forme

After calibrating the spectra, a peak table was created including the largest number of detected compounds. The threshold for the automatic research feature of the peak has been settled at 0.1 counts per second. Even if the peaks have been automatically identified, a manual readjustment of every peak has been performed to reduce the bias of the automatic peak research. The range of the detected masses was between 31 m/z and 164 m/z. Masses deriving from the water cluster, such as 37.03 m/z, 38.03 m/z, 39.03 m/z, and 55.03 m/z, were not taken into account during the analysis of the dataset.

Mis en forme

Furthermore, the mixing ratio (ppb) has been calculated using the PTR-viewer software (V3.2.8, Ionicon, Analytik GmbH) which used the equation described in Cappellin et al., (2011); and the VOC emissions fluxes ( $E_{\text{VOC}}$ ) in  $\mu\text{g m}^{-2} \text{ h}^{-1}$  have been calculated as follow: Furthermore, the mixing ratio (ppb) has been calculated using the PTR-viewer software (V3.2.8, Ionicon, Analytik GmbH) which used the equation described in Cappellin et al., (2011); and the VOC emissions fluxes ( $E_{\text{VOC}}$ ) in  $\mu\text{g m}^{-2} \text{ h}^{-1}$  have been calculated as follows:

$$E_{\text{VOC}} = \frac{F_{\text{air}} \times ([\text{VOC}]_{\text{litter}} - [\text{VOC}]_{\text{blank}}) \times M_{\text{VOC}}}{V_{\text{mol}} \times ((S_{\text{litter}} - S) + S_{\text{litter}} - E) / 2 \times 1000 \text{ (ng/}\mu\text{g)}} \quad (\text{eq. 2})$$

## 2.6.1 Peaks identification method

The spectra have been analyzed using the Spectra Analyser tool of the PTR viewer software (Version 3.2.8, Ionicon). This tool allowed the identification of the compounds corresponding to each peak among in the spectra; by searching for the possible combinations of elements leading to the closest molecular weight. This identification of the VOC has been also double-checked with literature reviews. Even if this method accounted for the most precise identification of the VOCs, it does not provide a certain identification of the compounds since, (1) it is not possible to distinguish between two ion masses that are closer than the PTR-TOF-MS mass resolution, and (2) the PTR-TOF-MS does not distinguish between isomers (VOCs having the same molecular mass). The PTR-TOF-MS has a mass resolution of  $4500 \text{ m/A}$ .

Mis en forme : Anglais (Royaume-Uni)

Mis en forme

## 2.6.2 Data analysis

The database was filled with 217 variables corresponding to the number of detected masses for the three different conditions UV,  $\text{O}_3$ , and  $\text{UV}_3\text{O}_3$  (as mentioned previously). The statistical analysis of the entire dataset has been performed using the R software (Version 1.2.5019- ©2009–2019 RStudio). At first, we selected the variables that were normally distributed by the Shapiro-Wilk test ( $W > 0.9$ ). Secondly, we tested the homogeneity of the variance by the Levene-test to perform the Analysis of Variance (ANOVA) test followed by the Tukey post-hoc test. Furthermore, we tested the differences between the conditions using the Principal Component Analysis (PCA – package *FactomineR*). The PCA allowed a graphical representation of the whole dataset differentiating the VOCs emission profiles for the different tested conditions without bias. A table with the 30 most emitted compounds and their relative abundance at the three different conditions is presented in Table 1. Finally, the

Mis en forme

205 calculation of the Shannon index was performed. The Shannon index is a quantitative measure reflecting how many different VOCs were emitted from each sample. It was calculated with the diversity function of the vegan package (version 2.4-3) in the R software (version 3.2.3). The diversity index was calculated as  $H = \sum_{VOC} E_{VOC} \log(E_{VOC})$ , where the sum is over all VOCs recorded in the mass table.

210 The correlation between the VOC and particles formation has been calculated using the basic package STAT of R studio. The Spearman correlation was chosen as method since the distribution of the dataset was not normal. Finally, VOC compounds with a correlation level lower than -0.6 have been discussed.

### 3 Results

#### 3.1 Ozone and UV light irradiation effect on the average VOC concentrations

215 VOC emissions have been measured for 6 days for each condition. The summed VOC emissions from the different conditions showed a statistical difference for every day of measurement. Under UV irradiation (the first condition), the summed VOC emissions kept increasing until the 5<sup>th</sup> day of measurement, while during the last day it statistically decreased (Figure 3a). Whereas, for the conditions O<sub>3</sub> and UV\_O<sub>3</sub> (second and third conditions), the summed VOC emissions increased the 2<sup>nd</sup> day; and then slowly decreased from the third to the 6<sup>th</sup> day of measurement (Figure 3b and 3c).

220 Furthermore, the ANOVA test confirmed a difference between the averages of the summed VOC emissions per day. These results highlight a statistical increase of the summed VOC emissions under UV irradiation (first condition) and a statistical decrease of the summed VOC emissions among over time for the O<sub>3</sub> and the UV\_O<sub>3</sub> condition. The summed VOC emissions were higher for the UV condition than for the UV\_O<sub>3</sub> condition. The condition with the lowest VOC emission rate was with ozone.

225 The VOC emission profiles of the different conditions are compared in Figure 4. The PCA shows that the VOC profiles emitted during the UV condition were strongly different from the VOC profiles emitted from the UV\_O<sub>3</sub> and O<sub>3</sub> conditions. Meanwhile the UV\_O<sub>3</sub> and the O<sub>3</sub> conditions had very similar profiles since their ellipses are superposed (Figure 4). The major differences in the emission profiles were led by the different concentrations of 10 compounds at the following m/z: 45.03, 45.99, 46.03, 47.02, 49.99, 59.049, 60.05, 73.03, 108.95, and 125.95. Those compounds are also among the 30 most emitted compounds throughout all three conditions (Table 1). The identification of the 30 most emitted compounds for the three different conditions are listed in Appendix A, Table A1.

230 The 30 most emitted compounds represented 90-% of the summed VOC emissions for each condition. The list of the most emitted compounds between the O<sub>3</sub> condition and UV\_O<sub>3</sub> condition was similar, especially in terms of the types of emitted compounds. The three most emitted compounds for these two conditions were methanol (CH<sub>3</sub>OH<sup>+</sup>, 33.03 m/z), acetaldehyde (C<sub>2</sub>H<sub>4</sub>OH<sup>+</sup>, 45.03 m/z), and butyric acid (C<sub>4</sub>H<sub>8</sub>O<sub>2</sub>H<sup>+</sup>, 89.05 m/z). While for the UV condition, the three most emitted VOC were acetic acid (61.03 m/z), acetone (59.049 m/z), and methanol (33.03 m/z). The average contribution of the VOCs over the 6 measurement days showed a large difference for each condition. For instance, methanol contributed to 9%, 32 %, and 50%, for UV, O<sub>3</sub>, and UV\_O<sub>3</sub>, respectively.

#### 3.2 Evolution and diversity of the VOC emissions per day

240 For the UV light experiments, small changes have been observed. For example, the average contribution of acetic acid (m/z 61.03) increased between 10-15 % during days 3 to 5 compared to days 1, 2, and 6, while that of methanol (33.03 m/z) increased by 5% during days 2 and 3. However, the other most emitted VOCs contribution was constant during that time (Figure 5a). For the O<sub>3</sub> condition, the most important variation, change in the average contribution is represented by the mass 33.03 m/z, which increased by 7% between the 4<sup>th</sup> and the 6<sup>th</sup> day (Figure 5b). It is also worth mentioning that masses 42.03 m/z and 49.99 m/z contributed to less than 0.01% of the total VOC emissions during the 1<sup>st</sup> and 2<sup>nd</sup> day of measurements,

while after 3 days their contribution increased by [an 80 and 200-fold change](#), reaching 0.8% and 2% of the VOC relative abundance, respectively. The average contribution of the mass 89.06 m/z decreased over time from 5% during the first day to 0.5% during the 6<sup>th</sup> day of measurements. Similar [behavior](#) was reported for the mass 73.06 m/z, where its average contribution increased to 8% during the 2<sup>nd</sup> and 3<sup>rd</sup> measurement day and then decreased to 0.5% of the average contribution during the 6<sup>th</sup> day. [Analyzing](#) the UV\_O<sub>3</sub> condition, we noticed that the variation in the VOC contribution per day is higher than for the other conditions. In addition, [the results in Figure 5c](#) reported that the mass 71.05 m/z was strongly emitted during the 6<sup>th</sup> day of measurement (30%), whereas this VOC emission did not reach 0.01 % of the contribution in the previous days. The average contribution of the mass 33.03 m/z decreased over time, [passing from 70% on the 1<sup>st</sup> and 2<sup>nd</sup> day to 30% on the 6<sup>th</sup> day of measurements](#).

Moreover, the Shannon Index, representing the diversity of emitted VOC, ~~has been~~was calculated for ~~every~~each day of measurements to highlight an increase or a decrease of the VOC diversity with time. The VOC Shannon index showed that there ~~were~~is no statistical differences in terms of VOC diversity that were observed for the UV light condition (S.I. 3.05 – 3.28) and O<sub>3</sub> condition (p-value >0.05). ~~Concurrently~~ConcurrentlyConcurrently, the UV\_O<sub>3</sub> condition results showed a statistically significant increase of the VOC diversity with time (from 1.54 to 2.4). The Shannon index of the VOC also showed a significantly larger Shanonn index for the UV condition compared to the UV\_O<sub>3</sub> condition (3.15 compared to 2). An intermediate value of 2.35 was obtained for the O<sub>3</sub> condition.

### 3.3 Ozone and UV light irradiation effect on particle formation

Concurrently with the detection of VOC emissions, we also investigated particle formation for the three different conditions. Under UV irradiation, nucleation started 1 hour after switching on the UV light (**Figure 6a**). The initial nucleation produced a dense number of particles between  $5 \times 10^4$  and  $8 \times 10^4$  particles  $\text{cm}^{-3}$ . Then, the number of particles decreased, while their diameter increased from 2 nm to 40 nm. Likewise, under the ozone condition (**Figure 6b**), a nucleation event also started 1 h after the injection of 80 ppb of ozone. However, compared to the UV light irradiation experiment, the ozone injection led to a lower number of particles formed ( $2.5 \times 10^4$  particles  $\text{cm}^{-3}$ ) with a smaller diameter ( $< 17$  nm). Nevertheless, when the UV light irradiation was combined with ozone injection (third condition), the nucleation was stronger than the first two cases, reaching a maximum of  $3.5 \times 10^5$  particles  $\text{cm}^{-3}$  for particles diameters between 2 and 12 nm (**Figure 6c**). Ozone depletion was also faster than in the case where only  $\text{O}_3$  was used (i.e., condition two).

Furthermore, **Figure 787**, regroup the **840-8** VOC ~~negatively~~was positively correlated with ~~the temperature~~the SOA formation for the UV-O<sub>3</sub> condition. The ~~negative~~positive correlation means that VOC ~~emissions increased & decreased alongside an increase of the SOA number concentration with~~with the temperature. Those compounds have a Spearman coefficient ~~lower~~higher than -0.860.80. For the other VOC not displayed in **Figure 78**, ~~non-significant~~7, correlations ~~lower than 0.8~~7 were found. ~~along the SOA formation~~.

## 4 Discussion

#### 4.1 UV light and Ozone affect the diversity of the VOC emission profiles.

For the O<sub>3</sub> and UV\_O<sub>3</sub> experiments, the VOC diversity decreased while the methanol contribution increased. Potard et al., (2017) observed similar behaviours in their experiment, which consisted of measuring VOC emissions from soils receiving different types of amendment: the highest methanol average contribution corresponded to the lowest VOC diversity. Moreover, differentiated VOC profiles have been highlighted in the PCA (**Figure 4**) between the UV light experiment and the O<sub>3</sub> and UV\_O<sub>3</sub> experiments. Several mechanisms are regulating the VOC emissions, and thus affecting the VOC diversity. These mechanisms are discussed in detail in the following paragraphs in detail.

## 4.2 Effect of ozone and UV light irradiation on the most emitted compounds

**Acetic acid ( $C_2H_4O_2$ , 61.03 m/z) and formic acid ( $CH_2O_2$ , 47.02 m/z).** Organic acids such as acetic and formic acid are mostly emitted from living plants (Kesselmeier and Staudt, 1999); and by from the foliage of trees and crops with a flux of  $35 \mu g m^{-2} h^{-1}$  (Paulot et al., 2011). Viros et al., (2021) also detected acetic and formic acid also from senescent litter with a flux of 0.05 and  $0.98 \mu g m^{-2} h^{-1}$ , respectively. In this study, the emission rates of the two organic acids ranged from 0.76 to  $64.28 \mu g m^{-2} h^{-1}$  for acetic acid, and from 0.23 to  $9.12 \mu g m^{-2} h^{-1}$  for formic acid. Mozaffar et al., (2018) described that the acetic acid emissions were affected by temperature, as they recorded lower emissions in the early morning than during the late afternoon. This could explain the higher emissions of acetic acid observed in our study where the temperature reached  $30^\circ C$ , which is higher than the conditions encountered by Viros et al., (2021) – i.e.,  $22^\circ C$ . Mozaffar et al., (2018), while analysing BVOCs from senescent maize leaf litter, reported an acetic acid contribution to the total BVOC emission of up to 26 %. Similar results were obtained in our study, where under UV light conditions, the contribution of the acetic acid reached 20% of the total VOC emissions under UV light conditions.

**Methanol ( $CH_3OH$ , 33.03 m/z).** Methanol was the most emitted compound in  $O_3$  and UV- $O_3$  conditions. Methanol emission from plants is ubiquitous (Bracho-Nunez et al., 2011; Gonzaga Gomez et al., 2019; Harley et al., 2007; Wiß et al., 2017). Moreover, methanol is the most emitted VOC from crops and other plants such as *Cistus albidus*, *Coronilla valentina*, and *Prunus persica* (Harley et al., 2007), and it often contributes often to more than half of the overall VOCs emissions. Hence, in our study, the average methanol average contribution to the total VOCs emission is between 8.9 % (under UV) and 50 % (under UV and  $O_3$ ). Gonzaga Gomez et al., (2019) measured VOC emissions from rapeseed using dynamic chambers and reported that methanol contributed from 56 to 77% of the summed VOC emissions. These values are higher than in the current study. The reason behind this difference could be that Gonzaga Gomez et al., (2019) measurements were performed over the whole growing plant, while in our experiment, we only analyzed the emission from leaves the leaf litter. Furthermore, the emissions of methanol from leaves depend on the phenological stage of the plant (Wiß et al., 2017) (Wiß et al., 2017b) (Wiß et al., 2017), which could be another factor differentiating this study from that of Gonzaga Gomez et al., (2019). In fact, in this study, we measured mature leaves in the last phenological state, while Gonzaga Gomez et al., (2019) analyzed leaving plants in the flowering and grain filling stages. Mature leaves are known for emitting to emit less methanol than young ones (Harley et al., 2007). Methanol is produced via the demethylation of the pectin by the Pectin Methyl Esterase (PME) activity. This process occurs during the cell wall growth which is an intense process happening during the early stage of leaf expansion (Fall and Benson, 1996). Comparing the results obtained for the UV- $O_3$  condition with that of Harley et al., (2007), where their experimental conditions were the closest to those used here, we found that the methanol emissions were in the same range. The emission flux of methanol under the UV- $O_3$  condition in the current study is  $0.22 \pm 0.03 \mu g g^{-1} h^{-1}$ , while Harley et al., (2007) reported fluxes ranging from 0.2 to  $2.7 \mu g g^{-1} h^{-1}$  for mature leaves. Moreover, under the UV condition, our results show a higher emission rate of methanol compared to the other conditions which are, which is in line with previous studies that demonstrated how the UV light increased the methanol emissions from leaves (Derendorp et al., 2011; Harley et al., 2007). Greenberg et al., (2012) detected a methanol flux of  $1.3 \mu g m^{-2} h^{-1}$  from litter corresponding to 0.4 % of the total emission above the canopy, estimated to be  $300 \mu g m^{-2} h^{-1}$ . In this study, the methanol flux from leaf litter ranged from 4.6 to  $28.4 \mu g m^{-2} h^{-1}$  depending on the experimental conditions. Hence, our results suggest that the contribution to the total above canopy methanol emissions of the rapeseed litter could range from 2 to 10%.

**Acetaldehyde ( $C_2H_5OH$ , 45.03 m/z).** Acetaldehyde was the second most emitted compound for the  $O_3$  condition and the 3<sup>rd</sup> and the 4<sup>th</sup> most emitted for the UV- $O_3$  and UV experiments, respectively. In general, the mechanisms leading to acetaldehyde emissions are still uncertain. The most accredited hypothesis is that these emissions are correlated to with different types of stress such as ozone exposure and leaf damage (chlorosis) caused by the sunlight (Seco et al., 2007). In this study,

leaves were under high ozone concentration (60–80 ppb) and intense UV irradiation, which could have accelerated the senescence period of the rapeseed leaves inside the chamber. As a result of these stressing conditions, we obtained larger acetaldehyde emissions than in previous studies. [For instance, Greenberg et al., \(2012\) reported a VOC flux for leaf litter under the canopy of  \$0.3 \mu\text{g m}^{-2} \text{h}^{-1}\$ , corresponding to the 0.2% of the total above canopy acetaldehyde emissions, while in this study the emission flux ranged from  \$1.97 \pm 0.01 \mu\text{g m}^{-2} \text{h}^{-1}\$  for the UV- \$\text{O}\_3\$  condition to  \$26.7 \pm 0.2 \mu\text{g m}^{-2} \text{h}^{-1}\$  for the UV condition. The total above canopy acetaldehyde emissions reported by \[Greenberg et al., \\(2012\\)\]\(#\) were  \$200 \mu\text{g m}^{-2} \text{h}^{-1}\$ . As for methanol, our study suggests a higher contribution \(ranging from 2 to 13%\) to the total above canopy acetaldehyde emissions from leaf litter, ranging from 2 to 13 %.](#)

For instance, Greenberg et al., (2012) reported a VOC flux for leaves litter under the canopy of  $0.3 \mu\text{g m}^{-2} \text{h}^{-1}$ , while in this study the emission flux ranged from  $1.97 \pm 0.01 \mu\text{g m}^{-2} \text{h}^{-1}$  for the UV-O<sub>3</sub> case to  $26.7 \pm 0.2 \mu\text{g m}^{-2} \text{h}^{-1}$  for the UV one. However, Hörtnagl et al., (2014) reported a burst of  $1900 \mu\text{g m}^{-2} \text{h}^{-1}$  after a meadow cutting. Nonetheless, another pathway for the production of acetaldehyde is the ethanol oxidation at the leaf level, forming acetaldehyde (Niinemets et al., 2014; Seco et al., 2007). This process only occurs in anaerobic conditions since it is the consequence of the ethanolic fermentation pathway.

Hence, acetaldehyde can be formed in leaf tissues, but this pathway cannot be the main reason for the acetaldehyde emissions detected in this study because, since the *leaves/leaves* litter was not in an anoxic environment. The magnitude of the acetaldehyde emission rate detected is similar to the one detected by Bachy et al., (2016) from soil hosting C4 crops ( $7 \pm 9 \mu\text{g m}^{-2} \text{ soil h}^{-1}$ ). Therefore, we underline the possibility that rapeseed *leaves/leaves* litter might contribute to tropospheric acetaldehyde emissions at the same level as soil and plants under environmental stress conditions.

**Acetoin** ( $\text{C}_4\text{H}_8\text{O}_2\text{H}^+$ , 89.06 m/z). Acetoin was the second and the third most emitted compound for the conditions UV\_O<sub>3</sub> and O<sub>3</sub> respectively with an average contribution to the summed VOC emissions between 9 and 11%. This compound has already been already-reported as one of the most emitted compounds from bacteria dwelling in rapeseed samples (Wagner et al., 2018). These bacteria have been identified as *Enterobacter*, *Klebsiella*, *Serratia*, *Staphylococcus*, and *Streptomyces* (Schulz and Dickschat, 2007). The pyruvate metabolic pathway of the microorganisms just listed allows the production of the acetoin molecule by the decarboxylation of acetylactate (Schulz and Dickschat, 2007). The large production of this compound can be attributed to the presence of bacteria colonizing the 'leavesleaves' surfaces and also to the favorablefavourable conditions for the-bacteria growth, such as the optimal temperature (T= 25 °C) (Membre et al., 2005), and a humid atmosphere (RH= 50%) (Mceldowney and Fletcher, 2008) in our experiments.

**Acetone ( $\text{C}_3\text{H}_6\text{OH}^+$ , 59.049 m/z).** This compound was largely emitted from litter under UV irradiation. The average contribution of acetone was 13% under UV light, 1.64 % when influenced by both UV and ozone, and 2 % when the litter was exposed to ozone only. Acetone has been reported to be one of the most emitted compounds by plants and litter (Gonzaga Gomez et al., 2019; Greenberg et al., 2012). Greenberg et al., (2012) reported an average flux of  $0.3 \mu\text{g m}^{-2} \text{h}^{-1}$  between 11:00 and 17:00. In this study, the emissions of acetone were 10 times higher under UV irradiation. Based on (Greenberg et al., 2012), the current estimates of litter contribution to the above canopy acetone emissions is 0.1 %. However, the flux reported in Table 2 suggest that the litter contribution to acetone emission, in the absence of ozone, could be as large as 6 %.

**Acetone** ( $C_3H_6O$ , 59.049 m/z). This compound was largely emitted from litter under UV light. The average contribution of acetone was 13% for the UV light condition and 1.64 and 2 % for the UV<sub>3</sub> and O<sub>3</sub> conditions, respectively. Acetone has been reported as one of the most emitted compounds by plants (Gonzaga-gomez et al., 2019). For instance in [InIn](#), the study of [Gonzaga Gomez et al.,\(2019\)](#), where the VOC detection has been performed at a different phenological stage of the rapeseed plant, acetone was detected among the most emitted VOCs from leaves and was correlated with sunlight; [since because the](#) highest emission peak of acetone [occuredoccurred](#) at midday. These findings are in line with the higher emissions of acetone in the UV light experiment but not with the UV<sub>3</sub> experiment. [Furthermore](#), [Cojocariu et al., \(2005\)](#) found that under stress conditions such as [high O<sub>3</sub> concentration](#), [the](#) acetone concentration increased in *Fagus sylvatica*. [which](#) This is in contrast with the results of this study; where the O<sub>3</sub> concentration seems to reduce the acetone emissions. The biogenic nature of the

370 source of acetone cannot be confirmed since, as reported by Das et al., (2003), acetone emissions could be the result of photochemical reactions of other VOCs. Decaying and senescing plants may be another direct source of acetone (Warneke et al., 1999; Jacob et al., 2002; Karl et al., 2003).

Mis en forme

4.2.1 Other emitted compound

375 **Isoprene (C<sub>5</sub>H<sub>8</sub>H<sup>+</sup>, 69.07 m/z).** In this study, isoprene was the 30<sup>th</sup> most emitted compounds only in the experiment without O<sub>3</sub>. Its average contribution in the UV light experiment was 1% with a flux rate of 3.00±0.03 µg m<sup>-2</sup> h<sup>-1</sup> or 0.02 µg g<sup>-1</sup> h<sup>-1</sup> which is almost 20 times lower than the emissions reported by Morrison et al., (2016), where the maximum detected flux of isoprene from rapeseed was 0.35 µg g<sup>-1</sup> h<sup>-1</sup>. This difference is probably due to the different samples, indeed, indeed, Morrison et al., (2016) investigated branches, while here only the emissions from senescent leaves were considered. However, the flux rate of isoprene reported by this study is in line with those reported by Gonzaga Gomez et al., (2019), i.e., 0.035 µg g<sup>-1</sup> h<sup>-1</sup>.

Mis en forme

380 Isoprene can also be emitted from microorganisms such as bacteria and fungi. Isoprene is an intermediate product of the mevalonate pathway, which leadleads to the production of essential organic compounds within the microorganismsmicroorganism's cells (Hess et al., 2013). Isoprene is therefore a metabolite directly related to the presence of microorganisms in soil and plants (Hess et al., 2013)

4.3 Temperature effect on the BVOC emissions

395 Higher temperatures increase chemical reaction rates, cellular diffusion rates, and the vapor pressure of the VOCs, as-As a consequence, BVOC emission rates are dependent on temperature. In this study, we identified 8 VOCVOCs emitted from rapeseed litter which wereare highly correlated with temperature. Among the most correlated ones, we identified methanol and MEK, in agreement with previous reports investigating such temperature dependence from rapeseed plants (Gonzaga Gomez et al., 2019). Harley et al., (2007) detected methanol emissions from 6 different plant species. Their results reported a correlation between its emission, and, the temperature of the leaves, and stomatal conductance. The mechanisms behind this behaviorbehaviour have been explained by Niinemets and Reichstein, (2003). Methanol is produced within the cell walls, and it diffuses in the liquid phase following the diffusion gradient until it reaches the surface of the cell walls. Then, methanol diffuses in the gas phase into the substomatal cavity and is released as VOC in the ambient air through the stomata. In our study, stomata lock-open as a consequence of cellular death (Prats et al., 2006), and the increased temperature accelerated the diffusion process releasing methanol as the most emitted compound from rapeseed leaf litter.

405 4.3.4 SOA formation from leaves-leaf litter BVOC emissions

Up-to our knowledge, the-an investigation of the SOA formation from leavesleafves litter samples has only been reported by the study of Faiola et al., (2014). Faiola et al., (2014) reported the maximum peak volume of the- SOA particles obtained through the oxidation of the emitted VOCs by the injection of 130 ppb of O<sub>3</sub> under controlled atmospheric conditions. The experiment was similar to the one performed here, where only 80 ppbs of ozone were injected (O<sub>3</sub> condition). Comparing the

Mis en forme

O<sub>3</sub> experiment in this study with the experiment under ~~the~~ dry conditions of Faiola et al., (2014) (Table 2), the maximum volume of SOA particles in our study has the same order of magnitude ~~than as~~ the volume reported by Faiola et al., (2014). The most important difference between this study and the previous one is the concentration of the monoterpenes detected. In Faiola et al., (2014) monoterpenes contributed to 80% of the total VOC emissions. Monoterpenes, together with isoprene and sesquiterpenes, are considered ~~as to be~~ the three primary classes of VOCs forming SOA (Sakulyanontvittaya et al., 2008). Isoprene is the most emitted compound from vegetation (Sindelarova et al., 2014) with a relatively small aerosol yield (Henze and Seinfeld, 2006). On the other hand, monoterpenes have been known to widely contribute to SOA formation (Griffin et al., 1999). In this study, monoterpenes were found to be lower than our PTR-TOF-MS detection limit, and isoprene was only the 30<sup>th</sup> most emitted compound under UV light irradiation. ~~These findings led to the hypothesis that other mechanisms involving the VOCs negatively correlated with the SOA formation, listed in Figure 8, are efficiently operating.~~ For instance, fural have ~~has~~ been reported as a precursor of SOA formation, with an aerosol yield ranging from 0.3 to 3% depending on the ozone concentration (Colmenar et al., 2020). Acetaldehyde and acetone have been reported to be ~~uptaken up~~ into the aerosol phase and to participate ~~to in~~ the aerosol-phase reactions (Barsanti and Pankow, 2004). Those reactions generate products with a relatively low vapor pressure, which leads to an additional partitioning from the gas phase, increasing the organic particulate mass (Limbeck et al., 2003; Tong et al., 2006). In this study, acetaldehyde and acetone ~~have been were~~ found to be correlated with the SOA formation ~~from rapeseed leaf litter~~ and to be largely emitted, from 60 to 40 and from 17 to 12 ppb respectively, in the UV-O<sub>3</sub> condition, ~~from rapeseed leaves litter~~. The observed particles formation highlighted the high oxidation potential of the UV light irradiation with a volume of particle production per day higher than the one found for the O<sub>3</sub> experiment (Table 2). Moreover, the combination of the ozone and the UV light produced a larger maximum aerosol volume peak than the one reported in Faiola et al., (2014) for both dry and wet conditions and the largest aerosol volume per day compared to the O<sub>3</sub> and UV light experiments (Table 2). Furthermore, we observed particles in the range from 2.5 to 79.1 nm, while Faiola et al., (2014) detected them between 20 and 730 nm. In this study, for the O<sub>3</sub> experiment, the percentage of particles under 20 nm contributed to 38% of the total aerosol volume (Table 2). Therefore, aerosol formation from ~~leaves leafves~~ litter was certainly underestimated in this previous study due to the importance of particles below 20 nm.

#### 4.54 Atmospheric implications Conclusion 4.5 Conclusion

This study highlighted the possibility that VOC emissions from rapeseed ~~leaves leaf~~ litter, one of the three most cultivated crops in France and worldwide, ~~could~~ have been underestimated. ~~We reported a~~ substantial SOA formation for the different studied conditions. ~~Moreover, in In In~~ the experiment with UV and O<sub>3</sub>, the aerosol volume measured in the chamber was 790 µm<sup>3</sup> cm<sup>-3</sup>. It is important to stress that these results may correspond to lower limits for SOA production since (i) the UV lamps had about seven times lower light intensity at 365 nm than the actual solar radiation, and (ii) the detection of the particles ~~formation have been was~~ performed up to 79.1 nm, consequently, the formation of particles having greater diameters ~~have not been was not~~ detected. We, therefore, suggest that a SOA formation from ~~leaves leafves~~ litter may have an atmospheric impact. This study also highlights the need for further studies to quantify the possible impact of the SOA formation from ~~leaves leafves~~ litter at a larger scale.

#### 4.4 Conclusions

In this work, we detected the VOC from rapeseed litter samples for 6 days under three different conditions: UV light irradiation, ozone injection, and UV light combined with ozone injection. The ~~experiment was experiments were as~~ performed under controlled conditions within an atmospheric simulation chamber. The results showed that BVOC emissions from senescent rapeseed litter impact the SOA formation and that the combination of UV light irradiation and ozone injection increased the BVOC emission ~~profiles profile's~~ diversity. The UV light irradiation was found to affect the production of the SOA more than

the O<sub>3</sub> injection. In the presence of both UV light and O<sub>3</sub>, the SOA formation was 9 and 52 times higher than from solely UV light or ozone, respectively.

Low emissions of isoprene were detected, even though, the production of SOA was not negligible. ~~Other compounds, were found to be negatively correlated with the SOA formation, and thus to be possible precursors of the SOA formation from leaves litter.~~ The densest portion of particles produced by litter samples had a diameter lower than 20 nm, which might have caused the ~~an~~ underestimation of the SOA formation from litter in other studies that detected a range of particles with a diameter higher than 20 nm.

Figure 1: Example of the Rapeseed litter condition a) during the first day of the VOC and particles measurements and b) after 6 days of VOC and particles measurements.

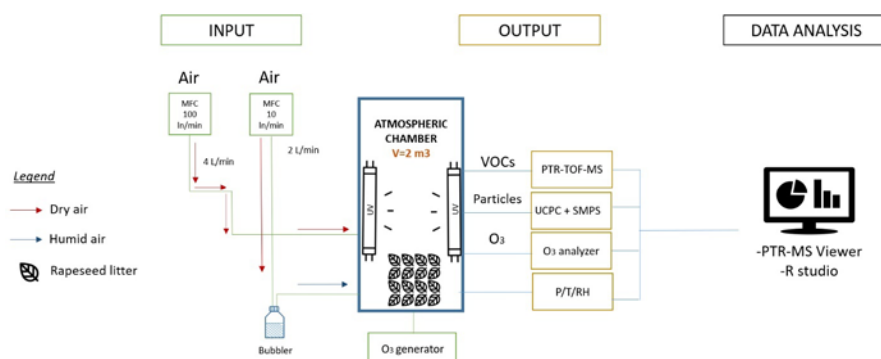

Figure 2: Scheme of the multiphase reaction chamber used for the study of the photoreactivity of the VOCs emitted from senescence rapeseed. The PTR-TOF-MS have been used for the VOCs detection, the ultrafine condensation particle counter (UCPC) and the SMPS have been used for the detection of the particle formation and measure the size particles, the O<sub>3</sub> analyzer detected the ozone inside the chamber, where P= pressure, T=temperature, and RH=relative humidity has been constantly monitored during the entire experiment.

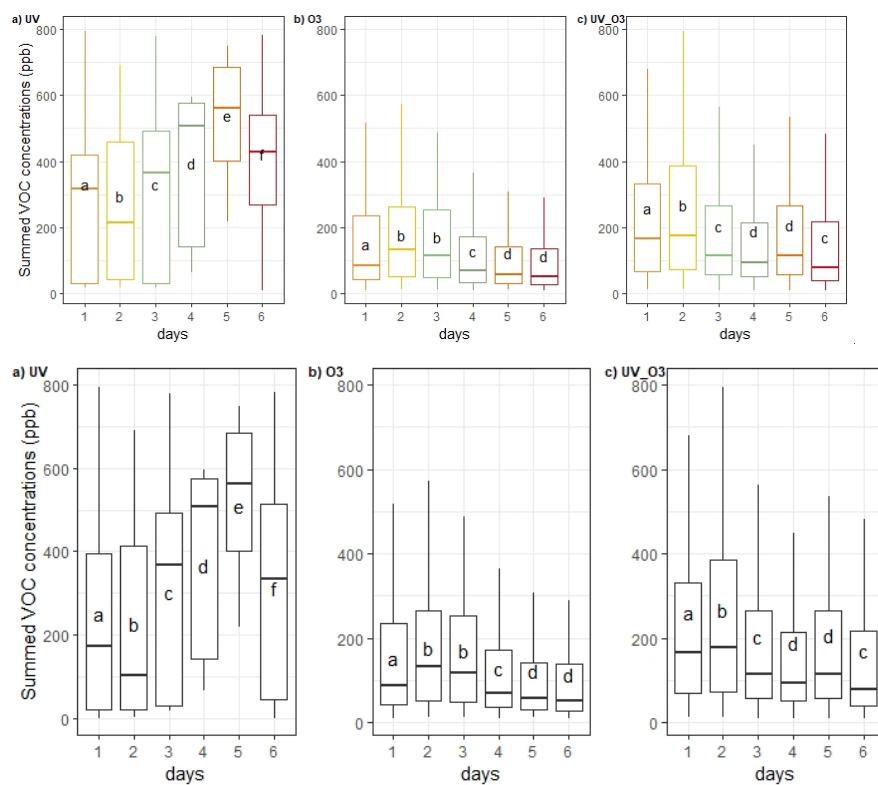

Figure 3: Summed VOC concentrations for each day (24-h period) incubation condition a) UV, b) O<sub>3</sub> and c) UV\_O<sub>3</sub>. Letters indicate the statistical difference obtained by the Tukey test.

Mis en forme : Normal

Figure 4: VOC profiles differences between UV light, UV-O<sub>3</sub>, and O<sub>3</sub> conditions, each point represent 1 day measurement. The percentage of the variance explained by the 2 first components is shown on each axis (Dim1 and Dim2).

Mis en forme : Anglais (États-Unis)

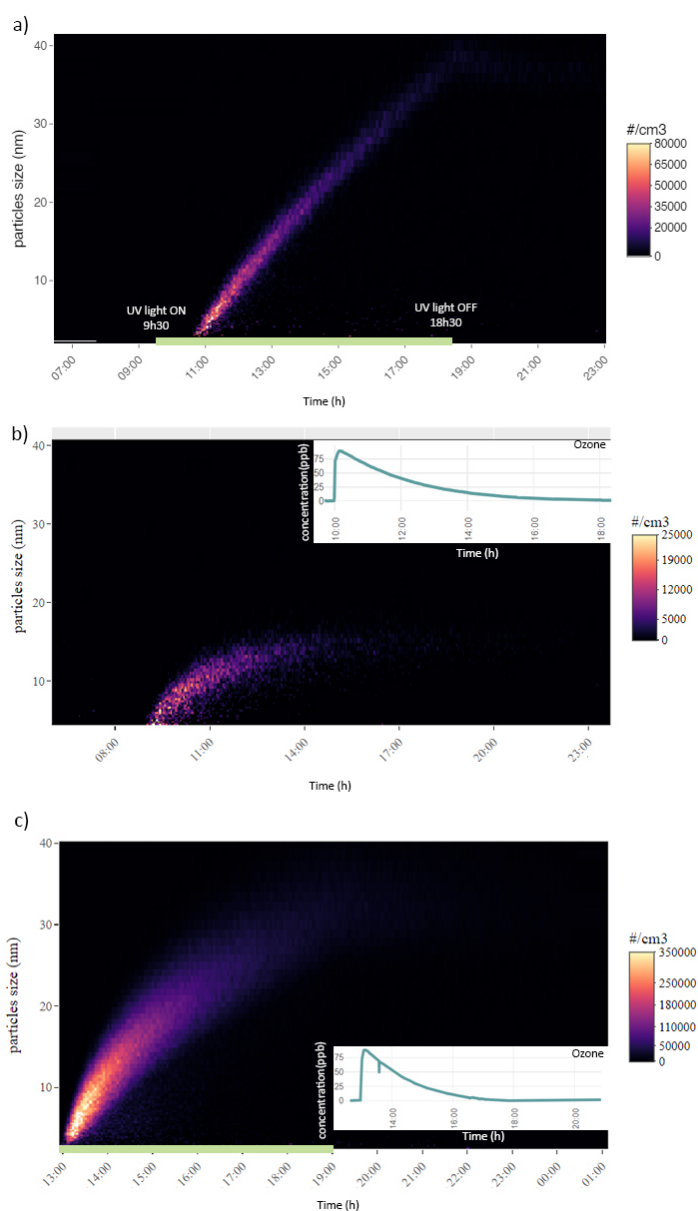

Figure 6. Temporal evolution of particle number and size distribution, ordinate represents the electrical mobility diameter (nm) and the colour scale the particle number concentration. Particle formation for the first day of measurement under a) UV light irradiation, b) Ozone injection and c) UV light irradiation and ozone injection combined. The green horizontal line represents the timeline where the UV light were switched on, for a) the UV light have been turned on at 9h30 and turned off at 18h30, for c) the UV light have been turned on at 12h30 and turned off at 19h. b) and c) also display the Ozone concentration timeline during the particle formation.

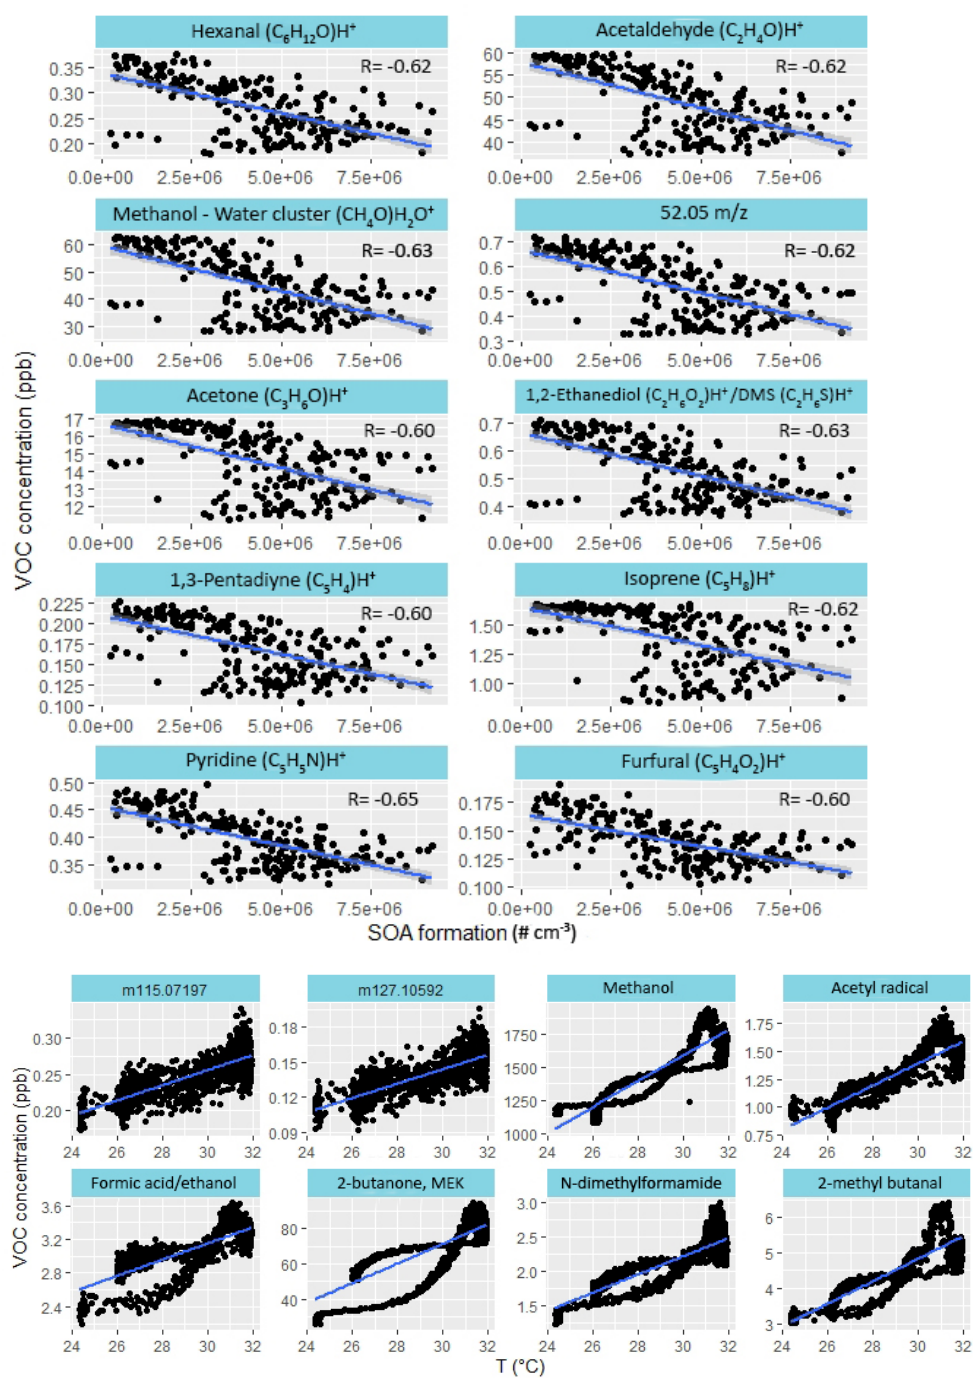

Figure 7 Correlation between VOC mixing ratios and total particles number observed under the temperature under the UV-O<sub>3</sub> condition. The 810 most correlated VOC are shown. The (Pearson correlation coefficients > 0.8), (R) are also displayed for all correlations.

Table 1. experimental conditions

	Experimental conditions	Colza weight	Surface covered	Days of VOC detection	Days of SOA detection	Blank conditions
UV light	7h per day of irradiation with UV	Initial weight: 85 g, Weight after 6 days 52 g	Initial surface covered: 0.64 m <sup>2</sup> Surface covered after 6 days: 0.45 m <sup>2</sup>	6	1	3 days averaged with 7h per day of irradiation with UV
Ozone	Initial concentration of ozone injected in the chamber: 80 ppbs	Initial weight: 80 g, Weight after 6 days 49 g	Initial surface covered: 0.64 m <sup>2</sup> Surface covered after 6 days: 0.45 m <sup>2</sup>	6	1	3 days averaged with an initial concentration of ozone injected in the chamber of 80 ppbs
UV light and ozone	Initial concentration of ozone injected in the chamber: 80 ppbs, 7h per day of irradiation with UV	Initial weight: 80.7 g, Weight after 6 days 47 g	Initial surface covered: 0.64 m <sup>2</sup> Surface covered after 6 days: 0.45 m <sup>2</sup>	6	1	3 days averaged with an initial concentration of ozone injected in the chamber of 80 ppbs and 7h per day of irradiation with UV

Table 12. The average of 30 most emitted compound during the 6 days of measurement for the three different conditions: UV light irradiation, Ozone, and UV light irradiation and ozone at the same time. The flux was calculated using the averaged surface of the leaf litter between the initial covered surface (0.64 m<sup>2</sup>) and the final covered surface (0.45 m<sup>2</sup>). Within the columns m/z, the compounds highlighted as the most differentiating between the VOC profiles by the PCA are in bold. A tentative identification of the compound here listed is reported in appendix Appendix B, Table B1.

Mis en forme : Exposant

MOST CONCENTRATED COMPOUNDS (UV)			MOST CONCENTRATED COMPOUNDS (O <sub>3</sub> )			MOST CONCENTRATED COMPOUNDS (UV-O <sub>3</sub> )		
m/z	BVOC—Flux (µg/m <sup>2</sup> /h)* ± sd	Average contribution (%)	m/z	BVOC—Flux (µg/m <sup>2</sup> /h)* ± sd	Average contribution (%)	m/z	BVOC—Flux (µg/m <sup>2</sup> /h)* ± sd	Average contribution (%)
