25

26 **Abstract.** Cloud drop number concentrations (N_d) over the western North Atlantic Ocean (WNAO) are
27 generally highest during the winter (DJF) and lowest in summer (JJA), in contrast to aerosol proxy variables
28 (aerosol optical depth, aerosol index, surface aerosol mass concentrations, surface cloud condensation nuclei
29 [CCN] concentrations) that generally peak in spring (MAM) and JJA with minima in DJF. Using aircraft,
30 satellite remote sensing, ground-based in situ measurements data as well as reanalysis data, we characterize
31 factors explaining the divergent seasonal cycles and furthermore probe into factors influencing N_d on
32 seasonal time scales. The results can be summarized well by features most pronounced in DJF, including
33 features associated with cold air outbreak (CAO) conditions such as enhanced values of CAO index,
34 planetary boundary layer height (PBLH), low-level liquid cloud fraction, and cloud-top height, in addition to
35 winds aligned with continental outflow. Data sorted into high and low N_d days in each season, especially in
36 DJF, revealed that all of these conditions were enhanced on the high N_d days, including reduced sea level
37 pressure and stronger wind speeds. Although aerosols may be more abundant in MAM and JJA, the
38 conditions needed to activate those particles into cloud droplets are weaker than in colder months, which is
39 demonstrated by calculations of strongest (weakest) aerosol indirect effects in DJF (JJA) based on comparing
40 N_d to perturbations in four different aerosol proxy variables (total and sulfate aerosol optical depth, aerosol
41 index, surface mass concentration of sulfate). We used three machine learning models and up to 12 input
42 variables to infer about most influential factors related to N_d for DJF and JJA, with the best performance
43 obtained with gradient boosted regression tree (GBRT) analysis. The model results indicated that cloud
44 fraction was the most important input variable, followed by some combination (depending on season) of
45 CAO index and surface mass concentrations of sulfate and organic carbon. Future work is recommended to
46 further understand aspects uncovered here such as impacts of free tropospheric aerosol entrainment on clouds,
47 wet scavenging and giant CCN effects on aerosol- N_d relationships, updraft velocity, and vertical structure of
48 cloud properties such as adiabaticity that impact the satellite estimation of N_d .
49
50
51

52 1. Introduction

53 Aerosol indirect effects remain the dominant source of uncertainty in estimates of total anthropogenic
54 radiative forcing (Myhre et al., 2013; Boucher et al., 2013). Central to these effects is knowledge about cloud
55 drop number concentration (N_d), as it is the connection between the subset of particles that activate into drops
56 (cloud condensation nuclei, CCN) and cloud properties. It is widely accepted that warm clouds influenced
57 by higher number concentrations of aerosol particles have elevated N_d and smaller drops (all else held fixed),
58 potentially resulting in enhanced cloud albedo (Twomey, 1977), suppressed precipitation (Albrecht, 1989),
59 and increased vulnerability to overlying air resulting from enhanced cloud top entrainment (Ackerman et al.,
60 2004).

61 Reducing uncertainty in how aerosols and clouds interact within a given meteorological context
62 requires accurate estimates of N_d and aerosol concentrations and properties. Since intensive field studies
63 struggle to obtain broad spatial and temporal coverage of such data, satellite remote sensing and reanalysis
64 datasets are relied on for studies examining intra- and interannual features over large spatial areas.
65 Limitations of satellite retrievals are important to recognize. N_d is not directly retrieved but derived using
66 other parameters (e.g., cloud optical depth, cloud drop effective radius, cloud top temperature) and with
67 assumptions about cloud adiabatic growth and N_d being vertically constant (Grosvenor et al., 2018). Aerosol
68 number concentrations are usually represented by a columnar parameter such as aerosol optical depth (AOD)
69 and thus not directly below clouds, which is the aerosol layer most likely to interact with the clouds.
70 Furthermore, aerosol data are difficult to retrieve in cloudy columns. Reanalysis datasets circumvent issues
71 for the aerosol parameters as they provide vertically-resolved data (e.g., surface layer and thus below clouds)
72 and are available for cloudy columns.

73 Of special interest in this work is the western North Atlantic Ocean (WNAO) where decades of
74 extensive research have been conducted for topics largely unrelated to aerosol-cloud interactions (Sorooshian
75 et al., 2020), thereby providing opportunity for closing knowledge gaps for this area in a region with a wide
76 range of aerosol and meteorological conditions (Corral et al., 2021; Painemal et al., 2021). Past work showed
77 different seasonal cycles of AOD and N_d in this region (Sorooshian et al., 2019; Grosvenor et al., 2018),
78 which partly motivates this study to unravel why N_d behaves differently on seasonal time scales. A previous
79 study investigating seasonal cycles of N_d in the North Atlantic region found that cloud microphysical
80 properties were primarily dependent on CCN concentrations while cloud macrophysical properties were more
81 dependent on meteorological conditions (e.g., Sinclair et al., 2020). However, due to the complexity of
82 interactions involved and the co-variability between individual components, the magnitude and sign of these
83 feedbacks remain uncertain.

84 This study uses a multitude of datasets to characterize the N_d seasonal cycle and factors related to N_d
85 variability. The structure of the results and discussion are as follows: (i) case study flight highlighting the
86 wide range of N_d in wintertime and factors potentially affecting that variability; (ii) seasonal cycle of N_d and
87 aerosol concentrations based on different proxy variables; (iii) seasonal cycles of factors potentially
88 influential for N_d such as aerosol size distribution, vertical distribution of aerosol, humidity effects, and
89 aerosol-cloud interactions; (iv) composite analysis of influential factors on “high” and “low” N_d days in each
90 season; (v) modeling analysis to probe more deeply into N_d relationships with other parameters for winter
91 and summer seasons; and (vi) discussion of other factors relevant to N_d unexplored in this work.

92

93

94 2. Methods

95 2.1 Study Region

96 We focus on the WNAO, defined here as being bounded by $25^\circ - 50^\circ\text{N}$ and $60^\circ - 85^\circ\text{W}$. A subset of
97 the results focuses on 6 individual sub-domains representative of different parts of the WNAO (shown later),
98 with five just off the East Coast extending from south to north (South = S, Central-South = C-S, Central = C,
99 Central-North = C-N, North = N) and one over Bermuda.

100

101 2.2 Datasets

102 2.2.1 Satellite Observations (CERES-MODIS/CALIPSO)

103 Relevant cloud parameters were obtained from the Clouds and the Earth's Radiant Energy System
104 (CERES) edition 4 products (Minnis et al., 2011; Minnis et al., 2020), which are based on the application of
105 CERES's retrieval algorithms on the radiances measured by the MODerate resolution Imaging
106 Spectroradiometer (MODIS) instrument aboard the Aqua satellite. Level 3 daily cloud properties at $1^\circ \times 1^\circ$
107 spatial resolution (listed in Table 1) were used for the period between January 2013 and December 2017 from
108 CERES-MODIS edition 4 Single Scanning Footprint (SSF) products (Loeb et al., 2016).

109 N_d is estimated based on an adiabatic cloud model (Grosvenor et al., 2018):
110

$$111 N_d = \frac{\sqrt{5}}{2 \pi k} \left(\frac{f_{ad} C_w \tau}{Q_{ext} \rho_w r_e^5} \right)^{1/2} \quad (1)$$

112

113 where τ is cloud optical depth and r_e is cloud drop effective radius, both of which are obtained from CERES-
114 MODIS for low-level (i.e., surface to 700 hPa) liquid clouds. Q_{ext} is the unitless extinction efficiency factor,
115 assumed to be 2 for liquid cloud droplets, and ρ_w is the density of water (1 g cm^{-3}). Methods described in
116 Painemal (2018) were used to estimate parameters in Eq. 1 as follows: (i) adiabatic water lapse rate (C_w) was
117 determined using cloud top pressure and temperature provided by CERES-MODIS; (ii) the N_d estimation is
118 often corrected for the sub-adiabatic profile by applying the adiabatic value (f_{ad}), but in this work, a value of
119 $f_{ad} = 1$ was assumed due to both lack of consensus on its value and its relatively minor impact on N_d estimation
120 (Grosvenor et al., 2018); and (iii) k parameter representing the width of the droplet spectrum was assumed
121 to be 0.8 over the ocean. Statistics of N_d are often estimated after screening daily observations based on cloud
122 fractions (Wood, 2012; Grosvenor et al., 2018). The purpose of such filters is to reduce the uncertainties
123 associated with the estimation of N_d (Eq. 1) driven by the errors in the retrieval of r_e and τ from MODIS's
124 observed reflectance in a highly heterogeneous cloud field. However, this may unwantedly mask the effects
125 of cloud regime on aerosol-cloud interactions by only including certain low-level cloud types in the analyses
126 (e.g., closed-cell stratocumulus). Therefore, we use all N_d data regardless of cloud fraction with exceptions
127 being Sections 3.5 and 4.2 where a filter of low-level liquid cloud fraction (i.e., $CF_{low-liq.} \geq 0.1$) was applied.

128 The Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) instrument aboard the Cloud-
129 Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) provides data on the vertical
130 distribution of aerosols (Winker et al., 2009). Nighttime extinction profiles were acquired from Level 2
131 version 4.20 products (i.e., 5 km aerosol profile data), between January 2013 and December 2017. We
132 averaged the Level 2 daily extinctions in different $4^\circ \times 5^\circ$ sub-domains (shown later) to obtain the seasonal
133 profiles after applying the screening scheme outlined in Tackett et al. (2018).

Table 1: Summary of various data products used in this study.

Parameter	Data Source	Spatial resolution	Vertical level	Date Range	Spatial Area	Temporal resolution
Cloud optical thickness	CERES-MODIS	1°x1°	NA	01-Jan-2013 31-Dec-2017	60°-85°W; 25°-50°N	Daily
Cloud effective radius	CERES-MODIS	1°x1°	NA	01-Jan-2013 31-Dec-2017	60°-85°W; 25°-50°N	Daily
Cloud fraction	CERES-MODIS	1°x1°	NA	01-Jan-2013 31-Dec-2017	60°-85°W; 25°-50°N	Daily
Cloud top temperature	CERES-MODIS	1°x1°	NA	01-Jan-2013 31-Dec-2017	60°-85°W; 25°-50°N	Daily
Cloud effective height	CERES-MODIS	1°x1°	NA	01-Jan-2013 31-Dec-2017	60°-85°W; 25°-50°N	Daily

135 **2.2.2 MERRA-2**

136 Aerosol data were obtained from the Modern-Era Retrospective analysis for Research and
137 Applications-Version 2 (MERRA-2) (Gelaro et al., 2017). MERRA-2 is a multidecadal reanalysis where
138 meteorological and aerosol observations are jointly assimilated into the Goddard Earth Observation System
139 version 5 (GEOS-5) data assimilation system (Randles et al., 2017; Buchard et al., 2017). Aerosols in
140 MERRA-2 are simulated with a radiatively coupled version of the Goddard Chemistry, Aerosol, Radiation,
141 and transport model (GOCART; Chin et al., 2002; Colarco et al., 2010). GOCART treats the sources, sinks,
142 and chemistry of 15 externally mixed aerosol mass mixing ratio tracers, which include sulfate, hydrophobic
143 and hydrophilic black and organic carbon, dust (five size bins), and sea salt (five size bins). MERRA-2
144 includes assimilation of bias-corrected Collection 5 MODIS AOD, bias-corrected AOD from the Advanced
145 Very High Resolution Radiometer (AVHRR) instruments, AOD retrievals from the Multiangle Imaging
146 SpectroRadiometer (MISR) over bright surfaces, and ground-based Aerosol Robotic Network (AERONET)
147 direct measurements of AOD (Gelaro et al., 2017). In this study we used total and speciated (i.e., sea-salt,
148 dust, black carbon, organic carbon, and sulfate) AOD at 550 nm between January 2013 and December 2017
149 at times relevant to Aqua's overpass time (13:30 local time). Aerosol index was calculated as the product of
150 AOD and Ångström parameter. MERRA-2 also provides surface mass concentrations of aerosol species
151 including sea-salt, dust, black carbon, organic carbon, and sulfate, which were used as a measure of aerosol
152 levels in the planetary boundary layer (PBL).

153 MERRA-2 data were also used for environmental variables including both thermodynamic (e.g.,
154 temperature and relative humidity) and dynamic parameters (e.g., sea-level pressure (SLP) and geopotential
155 heights) (Gelaro et al., 2017) listed in Table 1. Bilinear interpolation was applied to transfer all MERRA-2
156 variables (Table 1) from their original $0.5^\circ \times 0.625^\circ$ spatial resolution to the equivalent $1^\circ \times 1^\circ$ grid in
157 CERES-MODIS Level 3 data.

158

159 **2.2.3 Precipitation Data**

160 Daily precipitation data were obtained from Precipitation Estimation from Remotely Sensed
161 Information using Artificial Neural Networks–Climate Data Record (PERSIANN-CDR) data product
162 (Ashouri et al., 2015; Nguyen et al., 2018). Bilinear interpolation was applied to convert the PERSIANN-
163 CDR data from its native spatial resolution (i.e., $0.25^\circ \times 0.25^\circ$) to equivalent $1^\circ \times 1^\circ$ grids in CERES-MODIS
164 Level 3 data.

165

166 **2.2.4 Surface-based CCN Data**

167 Cloud condensation nuclei (CCN) data were obtained from the U.S. Department of Energy's Two-
168 Column Aerosol Project (TCAP) (Berg et al., 2016) to examine the seasonal variations in CCN number
169 concentration at a representative site by Cape Cod, Massachusetts (41.67°N , 70.30°W) over the U.S. East
170 Coast. TCAP was a campaign conducted between June 2012 and June 2013 to investigate aerosol optical and
171 physicochemical properties and interactions between aerosols and clouds (Liu and Li, 2019; Berg et al.,
172 2016). CCN data were available between July 2012 and May 2013 at multiple supersaturations with some
173 gaps in the data collection (i.e., November-December); for simplicity, we focused on CCN data measured at
174 a single supersaturation of 1% owing to relatively better data coverage as compared to lower supersaturations.
175 We note that this higher supersaturation is not necessarily representative of that relevant to the clouds of
176 interest, but is still insightful for understanding the seasonal cycle of CCN concentration. The qualitative
177 seasonal cycle of CCN concentration at 1% matches those at lower supersaturations (e.g., 0.15% – 0.8%).

178

179 **2.2.5 Airborne In-Situ Data**

180 We used airborne in-situ data collected during the fifth research flight (RF05) of the Aerosol Cloud
181 meTeorology Interactions oVer the western ATlantic Experiment (ACTIVATE) campaign. One flight is used
182 both for simplicity and because it embodied conditions relevant to the discussion of other results. The mission
183 concept involves joint flights between the NASA Langley UC-12 King Air and HU-25 Falcon such that the
184 former flies around 8 – 10 km and the latter flies in the boundary layer to simultaneously collect data on

185 aerosol, cloud, gas, and meteorological parameters in the same column (Sorooshian et al., 2019). The Falcon
186 flew in a systematic way to collect data at different vertical regions relative to cloud, including the following
187 of relevance to this study: BCB = below cloud base; ACB = above cloud base, BCT = below cloud top, Min.
188 Alt = minimum altitude the plane flies at (500 ft).

189 This study makes use of the HU-25 Falcon data from the following instruments: Fast Cloud Droplet
190 Probe (FCDP; $D_p \sim 3 - 50 \mu\text{m}$) (SPEC Inc.) aerosol and cloud droplet size distributions for quantification of
191 cloud liquid water content (LWC), N_d , and aerosol number concentrations with D_p exceeding $3 \mu\text{m}$ in cloud-
192 free air (termed FCDP-aerosol); Two Dimensional Stereo (2DS; $D_p \sim 28.5 - 1464.9 \mu\text{m}$) (SPEC Inc.) probe
193 for estimation of rain water content (RWC) by integrating raindrop ($D_p \geq 39.9 \mu\text{m}$) size distributions; Cloud
194 Condensation Nuclei (CCN; DMT) counter for CCN number concentrations; Laser Aerosol Spectrometer
195 (LAS; TSI Model 3340) and Condensation Particle Counter (CPC; TSI model 3772) for aerosol number
196 concentrations with D_p between $0.1 - 1 \mu\text{m}$ and above 10 nm , respectively; High-Resolution Time-of-Flight
197 Aerosol Mass Spectrometer (AMS; Aerodyne) for submicrometer non-refractory aerosol composition
198 (DeCarlo et al., 2008), operated in 1 Hz Fast-MS mode and averaged to 25-second time resolution; Turbulent
199 Air-Motion Measurement System (TAMMS) for winds and temperature (Thornhill et al., 2003).

200 CCN, LAS, CPC, and AMS data were collected downstream of an isokinetic double diffuser inlet
201 (BMI, Inc.), whereas the AMS and LAS also sampled downstream of a counterflow virtual impactor (CVI)
202 inlet (BMI, Inc.) when in cloud (Shingler et al., 2012). However, a filter was applied to remove LAS data
203 when the CVI inlet was used. Measurements from the CCN counter, LAS, CPC, and FCDP-aerosol are only
204 shown in cloud-free and rain-free conditions, distinguished by $\text{LWC} < 0.05 \text{ g m}^{-3}$ and $\text{RWC} < 0.05 \text{ g m}^{-3}$,
205 respectively, and also excluding data collected 20 seconds before and after evidence of rain or cloud.
206 Estimation of supermicrometer particles from FCDP measurements were performed after conducting the
207 following additional screening steps to minimize cloud droplet artifacts: (i) only samples with $\text{RH} < 98\%$
208 were included, (ii) data collected during ACB and BCT legs were excluded. CCN, LAS, CPC, and AMS
209 measurements are reported at standard temperature and pressure (i.e., 273 K and 760 torrs) while FCDP and
210 2DS measurements correspond to ambient conditions.

211

212 2.3 Regression Analyses

213 Regression modeling was conducted to investigate relationships between environmental variables and
214 N_d . The Gradient Boosted Regression Trees (GBRT) model, classified as a machine learning (ML) model, is
215 used, consisting of several weak learners (i.e., regression trees with a fixed size) that are designed and
216 subsequently trained to improve prediction accuracy by fitting the model's trees on residuals rather than
217 response values (Hastie et al., 2009). Desirable characteristics of the GBRT model include both its capacity
218 to capture non-linear relationships and being less vulnerable to overfitting (Persson et al., 2017; Fuchs et al.,
219 2018; Dadashazar et al., 2020). Two separate GBRT models were trained using daily CERES-MODIS N_d
220 data ($1^\circ \times 1^\circ$) in winter (DJF) and summer (JJA) to reveal potential variables impacting N_d . Winter and
221 summer are chosen as they exhibit the highest and lowest N_d concentrations, respectively, among all seasons
222 over the WNAO.

223 Many variables were picked as input parameters (Table 2) for the GBRT model, categorized as either
224 being aerosol, dynamic/thermodynamic, or cloud variables. Aerosol parameters included MERRA-2 surface
225 mass concentrations for sulfate, sea-salt, dust, and organic carbon. Black carbon concentration was removed
226 from input parameters because of its high correlation ($R^2 = 0.6$) with organic carbon. The following is the list
227 of thermodynamic/dynamic input parameters derived from MERRA-2: vertical pressure velocity at 800 hPa
228 (w_{800}), planetary boundary layer height (PBLH), cold-air outbreak (CAO) index, relative humidity (RH) in
229 the PBL and free troposphere represented by RH_{950} and RH_{800} , respectively. CAO index is defined as the
230 difference between skin potential temperature (θ_{skt}) and air potential temperature at 850 hPa (θ_{850}) (Papritz
231 et al., 2015). CERES-MODIS cloud parameters include liquid cloud fraction and cloud top height for low-
232 level clouds. In addition, PERSIANN-CDR daily precipitation (Rain) was included as a relevant cloud
233 parameter.

234 Data were split into two sets: training/validation (70%) and testing (30%). Five-fold cross-validation
 235 was implemented to train the GBRT model using the training/validation data. Furthermore, both performance
 236 and generalizability of the trained models were tested via the aid of the test set, which was not used in the
 237 training process. The GBRT models were performed using the scikit-learn module designed in Python
 238 (Pedregosa et al., 2011).

239

240 **Table 2: List of input parameters used as predictor variables in the GBRT and linear models. Variables**
 241 **are grouped into three general categories.**

242

Parameter	
Aerosol	Sulfate surface mass concentration (Sulfate _{sf-mass})
	Sea-salt surface mass concentration (Sea-salt _{sf-mass})
	Dust surface mass concentration (Dust _{sf-mass})
	Organic carbon surface mass concentration (OC _{sf-mass})
Cloud	Low-level liquid cloud fraction (CF _{low-liq.})
	Low-level liquid cloud-top effective height (Cloud-top _{low-liq.})
	Precipitation rate (Rain)
Dynamic/ Thermodynamic	Cold-air outbreak index (CAO _{index}): $\theta_{\text{skt}}^* - \theta_{850}$
	Relative humidity at 950 hPa (RH ₉₅₀)
	Relative humidity at 800 hPa (RH ₈₀₀)
	Vertical pressure velocity at 800 hPa (ω_{800})
	Planetary boundary layer height (PBLH)

243

244

*Skin potential temperature

245

246 The regression analyses were not performed solely to construct and provide a highly accurate model
 247 useful for prediction, but rather to disclose and examine the possible effects of the relevant input variables
 248 on N_d considering all the shortcomings of such analyses. For instance, there is some level of interdependency
 249 between input variables. To reduce unwanted consequences of correlated features, the interpretation of the
 250 results was done with the aid of accumulated local effect (ALE) plots, which are specifically designed to be
 251 unbiased to the correlated input variables (Apley and Zhu, 2020). ALE plots illustrate the influence of input
 252 variables on the response parameter in ML models. The ALE value of feature S at x_s (i.e., $f_{s,ALE}(x_s)$) can be
 253 calculated as follows:

254

$$255 \quad f_{s,ALE}(x_s) = \int_{z_{0,1}}^{x_s} \int_{x_c} f^s(z_s, x_c) P(x_c|z_s) dx_c dz_s - constant \quad (2)$$

256

257 where $f^s(z_s, x_c)$ is the gradient of model's response with respect to variable S (i.e., local effect) and $P(x_c|z_s)$
 258 is the conditional distribution of x_c (input features rather than S). $z_{0,1}$ is chosen arbitrarily below the smallest
 259 observation of feature S (Apley and Zhu, 2020). The steps in Eq. 2 can be summarized as follows (Molnar,
 260 2019; Apley and Zhu, 2020): (i) the average change in the model's prediction is calculated using the
 261 conditional distribution of features; (ii) the average change will then be accumulated by integrating it over
 262 feature S; and (iii) a constant will be subtracted to vertically center (i.e., the average of ALE becomes zero)
 263 the ALE plot. The aforementioned steps, although seemingly complex, assure the avoidance of undesired
 264 extrapolation (especially an issue for correlated variables) occurring in alternative approaches such as partial
 265 dependence (PD) plots. The value of $f_{s,ALE}(x_s)$ can be viewed as the difference between the model's

266 response at x_s and the average prediction. We used the source code available in [https://github.com/blent-](https://github.com/blent-ai/ALEPython)
267 [ai/ALEPython](https://github.com/blent-ai/ALEPython) for the calculation of ALE plots.

268

269 3. Results and Discussion

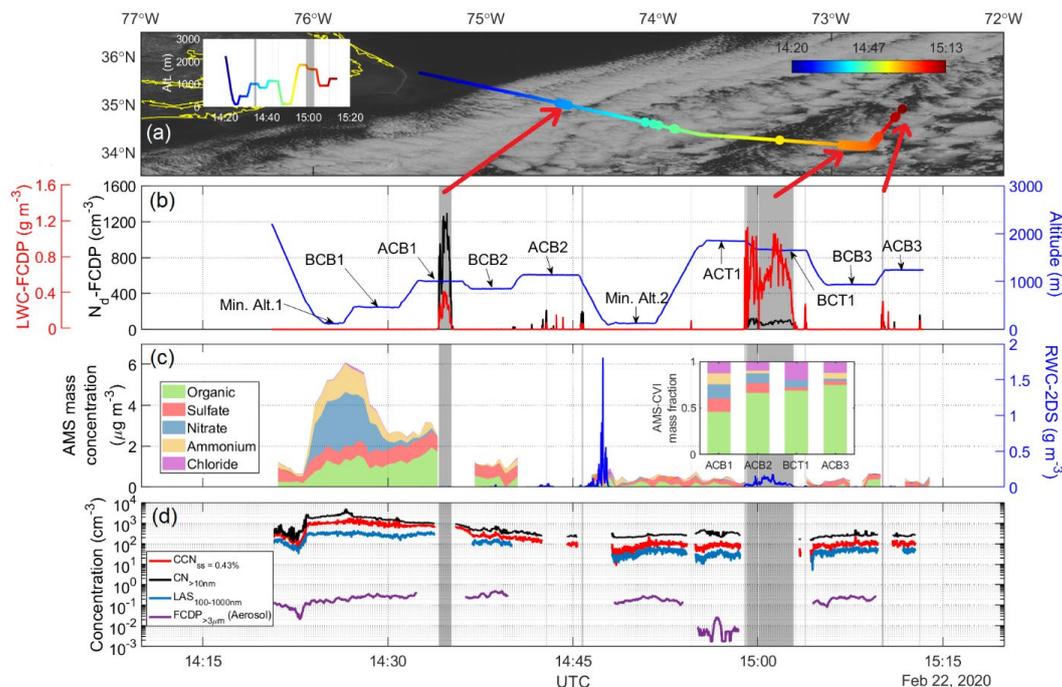

270 3.1 Aircraft Case Study of N_d Gradient

271 ACTIVATE Research Flight 5 (RF05) on 22 February 2020 demonstrates the wide range in N_d
272 offshore in the PBL (≈ 1.6 km) over the WNAO (Figure 1). On this day, the ACTIVATE study region was
273 dominated by a surface high pressure system centered over the southeastern U.S., with a significant ridge
274 axis extending from the main high to the east-northeast off the Virginia-North Carolina coast and into the
275 WNAO. Aloft, the flight region was located in northwesterly flow behind a trough offshore. This setup led
276 to subsidence in the region and generally clear skies, except where scattered to broken marine boundary layer
277 clouds formed along and east of the Gulf Stream. Two day NOAA HYSPLIT (Rolph et al., 2017; Stein et
278 al., 2015) back trajectories using the “model vertical velocity” method and “REANALYSIS” meteorology
279 data indicate air in the flight region (between 0-3 km) had wrapped around the surface high from the north
280 and left the New England coast 12-24 hours beforehand (with a descending profile). Along the flight segment
281 shown, winds were approximately 6 m s^{-1} , out of the north/northwest during the initial descent, Min. Alt. 1,
282 and BCB1 legs and primarily from the northeast for the other sections of the flight. Sea surface temperatures
283 were $6 - 9^\circ\text{C}$ near the coast during the descent and Min. Alt. 1 leg, $21 - 25^\circ\text{C}$ over the Gulf Stream during
284 the BCB1, ACB1, and BCB2 legs, and $17 - 20^\circ\text{C}$ for the remainder of the flight segment shown. The majority
285 of the segment was in or below the boundary layer clouds, with cloud base around $900 - 1100$ m and cloud
286 top around 1750 m. Note that the initial BCB1 leg was much lower at around 460 m, likely reflecting a
287 shallower marine boundary layer and cloud base near the much colder waters close to the coast. Static air
288 temperature ranged between $0 - 10^\circ\text{C}$, except for the BCT1 leg where temperatures were around -2.3°C .

289

290

291

292

293 **Figure 1: Time series of selected parameters measured by the HU-25 Falcon aircraft during a selected**
 294 **segment of RF05 on 22 February 2020: (a) overlaid flight track on GOES 16 visible imagery obtained**
 295 **at 14:55:04 UTC; (b) altitude, cloud liquid water content (LWC), and N_d , with the latter two obtained**
 296 **from the FCDP; (c) rain water content (RWC) measured by 2DS probe, AMS speciated mass**
 297 **concentration in cloud/rain-free air, and AMS mass fractions for droplet residual particles in cloud as**
 298 **measured downstream of a CVI inlet; (d) number concentrations for CCN at 0.43% supersaturation**
 299 **and particles for three diameter ranges: above 10 nm (CPC), 100-1000 nm (LAS), and above 3 μm**
 300 **(FCDP). Shaded gray areas in (b)-(d) highlight cloudy periods identified as having $\text{LWC} \geq 0.05 \text{ g m}^{-3}$.**
 301 **Locations of the cloudy regions are pointed to with red arrows in the satellite imagery. Level legs**
 302 **are defined as follows: BCB = below cloud base, ACB = above cloud base, Min. Alt. = minimum altitude**
 303 **the plane flies at (500 ft), ACT = above cloud top, BCT = below cloud top.**

304

305 N_d values from the FCDP ranged a maximum value of 1298 cm^{-3} closer to the coast during the ACB1
 306 leg (35.00° N , 74.55° W) to a minimum of 19 cm^{-3} farther away in the BCT1 leg (34.32° N , 72.73° W). The
 307 minimum N_d value in the ACB3 leg was 85 cm^{-3} (34.11° N , 72.80° W), which is a fairer comparison with
 308 the ACB1 leg in terms of being closer to cloud base. The mean N_d values (cm^{-3}) in the cloudy portions of the
 309 ACB1, BCT1, and ACB3 legs were as follows: 849, 77, 143.

310 Based on the nearest BCB legs adjacent to the maximum and minimum N_d values (BCB1 = 35.31° N ,
 311 74.95° W ; BCB3 = 34.41° N , 72.70° W), there was a significant offshore gradient in LAS submicrometer
 312 particle number concentration and AMS non-refractory aerosol mass, ranging from 424 cm^{-3} and $5.60 \mu\text{g m}^{-3}$
 313 (from BCB1) to 21 cm^{-3} and $0.32 \mu\text{g m}^{-3}$ (from BCB3), respectively; these values are based on times of the
 314 maximum and minimum LAS concentrations during the BCB1 and BCB3 legs, respectively. The mean
 315 values of submicrometer particle number concentration and AMS non-refractory aerosol for the two BCB
 316 legs were as follows: $277 \text{ cm}^{-3}/3.64 \mu\text{g m}^{-3}$ (BCB1) and $48 \text{ cm}^{-3}/0.42 \mu\text{g m}^{-3}$ (BCB3). The higher N_d value
 317 (1298 cm^{-3}) relative to LAS aerosol concentration (424 cm^{-3}) at the near-shore point is suggestive of aerosol
 318 smaller than $0.1 \mu\text{m}$ activating into drops. This is supported by the fact that both CCN (supersaturation =

319 0.43%) and CPC number concentrations with $D_p > 10$ nm exhibited mean values of 980 and 1723 cm^{-3} in the
320 BCB1 leg, respectively, dropping to 98 and 260 cm^{-3} in the BCB3 leg. There was a slighter gradient in particle
321 concentrations with $D_p > 3$ μm (most likely sea salt) between the same two points of maximum and minimum
322 LAS concentration in BCB1 and BCB3 legs, respectively: 0.26 cm^{-3} to 0.11 cm^{-3} . For the duration of the
323 flight portion shown in Figure 1, supermicrometer concentrations varied over two orders of magnitude: 0.002
324 – 0.51 cm^{-3} . Sea salt is not expected to follow the same offshore gradient as continentally-derived pollution
325 outflow.

326 Closer to shore during the Min. Alt. 1 leg, nitrate was the dominant aerosol species (~70% mass
327 fraction). Farther offshore during both the BCB1 leg and cloud-free portion of the ACB1 leg, organics were
328 the dominant constituent (~46% mass fraction), whereas farther during the BCB3 leg, the mean mass fraction
329 of sulfate was the highest (75%). Droplet residual particle data show a greater contribution of organics farther
330 offshore, increasing from 46% to 75% between the ACB1 and ACB3 legs, respectively. These composition
331 results, albeit limited to the non-refractory portion of submicrometer aerosol particles, reveal significant
332 changes with distance offshore indicative of varying chemical properties of particles activating into droplets.

333 The cloudy portions of ACB1 are characterized as having little or no rain with maximum RWC value
334 of 0.02 g m^{-3} and mean value of 0.003 g m^{-3} . There is a notable RWC peak at the beginning of the Min. Alt.
335 2 leg, reaching as high as 1.81 g m^{-3} associated with clouds aloft. The precipitation occurrence was also
336 evident in a subsequent BCT1 leg where RWC reached as high as 0.18 g m^{-3} . GOES satellite imagery of the
337 study region (Fig. 1) also reflects the effect of precipitation on cloud morphology where clouds farther
338 offshore resemble open-cell structures. Associated scavenging of particles through the washout process is
339 presumed to contribute to the decline in aerosol concentrations with distance offshore.

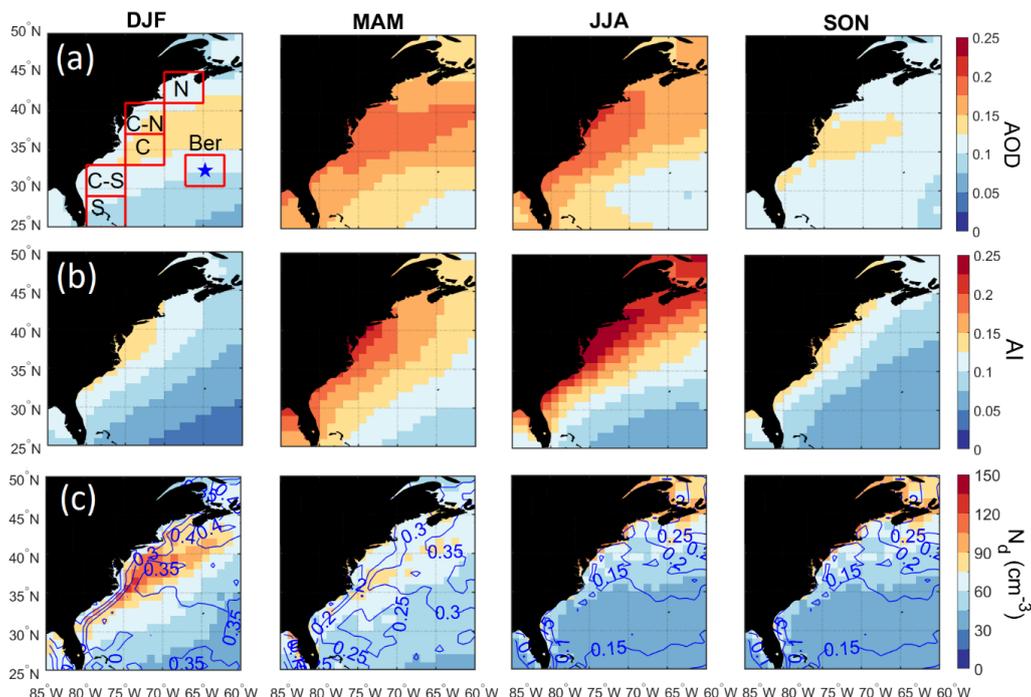

340 Figure 1 shows changes in aerosol characteristics coincident with the large gradient in N_d . While
341 ACTIVATE airborne data collection is ongoing to build flight statistics over multiple years, the wide changes
342 in microphysical properties in RF05 motivate looking at other datasets with broader spatiotemporal coverage
343 to learn about potential seasonally-dependent drivers of N_d , including meteorological parameters that vary
344 throughout the year. Furthermore, other datasets can provide insight into the source(s) of seasonal
345 discrepancy between columnar aerosol remote sensing parameters and N_d .

346

347 3.2 Seasonal Cycles of N_d and AOD

348 Figure 2 illustrates the seasonal differences in MERRA-2 AOD and CERES-MODIS N_d over the
349 WNAO that partly motivate this study. Seasonal mean values (\pm standard deviation) of AOD/ N_d (cm^{-3}) were
350 as follows for the entire WNAO: DJF = $0.11 \pm 0.03/64.1 \pm 18.0$; MAM = $0.16 \pm 0.03/60.4 \pm 13.1$; JJA = 0.15
351 $\pm 0.03/49.1 \pm 10.1$; SON = $0.11 \pm 0.03/50.3 \pm 13.9$. In contrast to AOD, N_d values and low-cloud fraction
352 (Figure 2c) were highest in DJF and lowest in JJA. DJF showed notably high N_d near the coast, qualitatively
353 consistent with the airborne data. The seasons with the greatest AOD values, accompanied by the most
354 pronounced spatial gradient offshore, were JJA and MAM. The offshore gradient owes to continental
355 pollution outflow (Corral et al., 2021 and references therein). In contrast, DJF and SON exhibited lower AOD
356 values with a distinct area of higher AOD values offshore between $\sim 35^\circ - 40^\circ$ N accounted for by sea salt.
357 MERRA-2 speciated AOD data (Figure S1) indicate that sea salt and sulfate dominate total AOD regardless
358 of season and that sulfate, organic carbon, and black carbon most closely follow the offshore gradient pattern
359 owing to continental sources. Dust and sea salt have different spatial distributions with the former derived
360 from sources such as North Africa leading to enhanced AODs $< 30^\circ$ N especially in JJA, and sea salt being
361 enhanced offshore especially in JJA.

362

363
364 **Figure 2: Seasonal spatial maps for (a) MERRA-2 aerosol optical depth (AOD), (b) MERRA-2 aerosol**
365 **index (AI), and (c) cloud drop number concentration (N_d) over the western North Atlantic Ocean**
366 **(WNAO). Contours in (c) represent low-level (cloud top pressure > 700 hPa) liquid cloud fraction**
367 **($CF_{low-liq.}$). Cloud data are based on daily Level 3 data from CERES-MODIS. The maps are based on**
368 **data between January 2013 and December 2017. The boxes in top left panel represent sub-domains**
369 **examined in more detail throughout the study, with the blue star denoting Bermuda.**
370

371 Table 3 probes deeper into individual WNAO sub-domains to compare seasonal AOD and N_d values.
372 For the six sub-domains in Figure 2, MERRA-2 AOD peaks in MAM and JJA, while N_d peaks in DJF. The
373 Bermuda sub-domain was unique in that mean N_d was slightly higher in MAM (53 cm^{-3}) as compared to DJF
374 (48 cm^{-3}). We attribute the slightly different seasonal cycle over Bermuda to its remote nature leading to
375 differences in meteorology and aerosol sources between seasons.

376 One factor that could bias AOD towards higher values with disproportionately less impact on N_d is
377 aerosol hygroscopic growth in humid conditions. Table 3 summarizes mean MERRA-2 RH values in the
378 PBL and free troposphere (FT). Results show that while RH is highest in JJA (except for FT of DJF in sub-
379 domain N), differences between seasons were not very large. The maximum difference among the four
380 seasons when considering mean RH in the PBL and FT for all sub-domains ranged between 3% – 9% and
381 7% – 25%, respectively. Consequently, humidity effects on remotely sensed aerosol parameters cannot alone
382 explain the dissimilar seasonal cycle of N_d and AOD, but can plausibly contribute to some extent.
383

384 3.3 Contrasting AOD and Aerosol Index

385 While previous studies have pointed to the limitations of AOD as an aerosol proxy (e.g. Gryspeerd
386 et al., 2017; Painemal et al., 2020), the N_d -AOD anticorrelation at seasonal scale over the WNAO is at odds
387 with findings for other regions supporting the relationship between these two parameters (Quaas et al., 2008;
388 Sekiguchi et al., 2003; Nakajima et al., 2001; Quaas et al., 2006; Penner et al., 2011; Gryspeerd et al., 2016;
389 Grandey and Stier, 2010) and also that between sulfate and N_d (McCoy et al., 2017; MacDonald et al., 2020;

390 McCoy et al., 2018; Storelvmo et al., 2009; Lowenthal et al., 2004; Boucher and Lohmann, 1995). Values of
391 N_d are influenced by the number concentration of available CCN, which is determined by aerosol properties
392 (size distribution and composition) and supersaturation level. AOD is an imperfect CCN proxy variable
393 because it does not provide information about composition and size distribution, and is sensitive to relative
394 humidity. Aerosol index (AI) is more closely related to CCN as it partially accounts for the size distribution
395 of aerosols (Nakajima et al., 2001; Deuze et al., 2001; Breon et al., 2002; Hasekamp et al., 2019). The
396 sensitivity of AI to size is evident in spatial maps for each season showing more of an offshore gradient (like
397 sulfate AOD in Figure S1) in each season and lacking both the offshore peak in sea salt between $\sim 35^\circ - 40^\circ$
398 N and the maximum AOD for dust south of 30° N in JJA. However, when comparing absolute values between
399 the four seasons in Figure 2b, AI exhibits a similar seasonal cycle as AOD, thereby indicating that size
400 distribution alone cannot explain diverging seasonal cycles for N_d and AOD. We next compare N_d to aerosol
401 data in the PBL where CCN more relevant to droplet activation are confined. Size distribution effects in the
402 PBL can instead be more of a factor especially as sea salt is abundant.

403

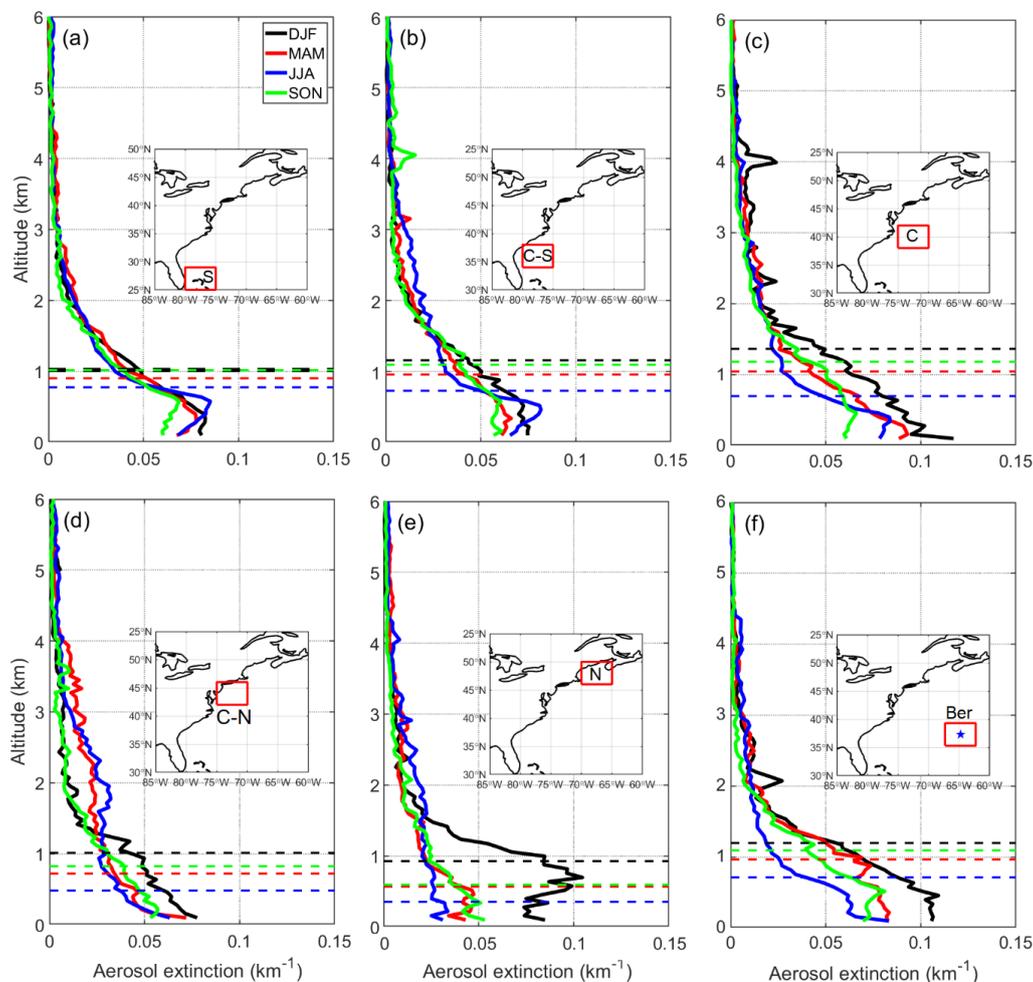

404

3.4 Aerosol Size Distribution and Vertical Aerosol Distribution

405

406 Vertical profiles of aerosol extinction coefficient estimated from CALIOP nighttime observations are
407 shown in Figure 3 for the six sub-domains. Shown also are the seasonally representative planetary boundary
408 layer heights (PBLHs) from MERRA-2, with numerical values of both PBLH and fractional AOD
409 contributions to the PBL and FT in Table 3. The CALIOP results indicate that aerosol extinction more closely
410 follows the N_d seasonal cycle with the highest (lowest) values in the PBL during DJF (JJA). However, aerosol
411 extinction coefficient is sensitive to aerosol size distribution and a plausible scenario is that DJF extinction
412 in the PBL is primarily contributed by coarse sea salt particles, which are especially hygroscopic, but do not
413 contribute significantly to number concentration as demonstrated clearly by airborne observations (Figure
414 1). This is supported in part by how DJF is marked by the highest fractional AOD contribution from the PBL
415 (59 – 72%) where sea salt is concentrated. In contrast, JJA has the lowest fractional AOD contribution from
416 the PBL (11.3 – 52.6%). Sub-domains C-N and N exhibit the greatest changes in AOD fraction in the PBL
417 between seasons with a maximum in DJF (59 – 61%) and a minimum in JJA (11 – 19%) suggesting they are
418 relatively more sensitive to the aerosol vertical distribution in leading to contrasting AOD and N_d seasonal
419 cycles. Bermuda stands out as having the highest AOD fractional contributions in the PBL in DJF (72%) and
420 SON (69%) and among the highest seasonal total AODs in those two seasons (0.14 in DJF and 0.10 in SON)
421 assisted in large part from sea salt (Figure S1) (Aldhaif et al., 2021), coincident with high seasonal wind
422 speeds (Corral et al., 2021).

422

423

424 **Figure 3: Vertical profiles of CALIPSO aerosol extinction for different seasons in (a-f) six different**
 425 **sub-domains of the WNAO. Average seasonal planetary boundary layer heights (PBLH) from**
 426 **MERRA-2 are denoted with dashed lines.**

427 To explore aerosol number concentration characteristics in the PBL in different seasons, we next discuss
 428 results from an opportune dataset over the U.S. East Coast (Cape Cod, MA) providing an annual profile of
 429 CCN concentration at 1% supersaturation (Figure 4). Cape Cod is a coastal location representative of the
 430 outflow providing an important fraction of the CCN impacting offshore low-level clouds. As the
 431 supersaturation examined is relatively high (1%), the measured CCN include smaller particles representing
 432 high number concentrations that would not appreciably contribute to the high aerosol extinctions from
 433 CALIOP in the PBL in direct contrast to sea salt (i.e., high extinction due to fewer but larger particles).
 434 Seasonal mean CCN values do not follow the seasonal cycle of N_d nor CALIOP extinction in the PBL,
 435 with values being as follows: DJF = 1436 cm^{-3} ; MAM = 1533 cm^{-3} ; JJA = 1895 cm^{-3} ; SON = 1326 cm^{-3} . These
 436 results suggest the following: (i) size distribution effects are significant in the PBL when comparing
 437 extinction to number concentration; and (ii) aerosol vertical distribution behavior cannot alone explain the
 438 divergent seasonal cycles of N_d and aerosol parameters (e.g., AOD, AI, surface number concentrations).

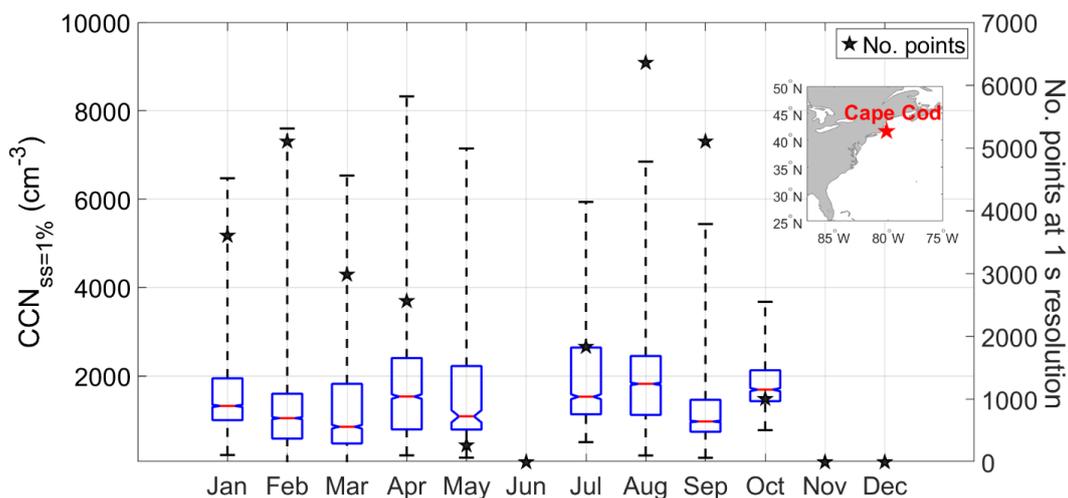

439 **Table 3: Average drop number concentration (N_d), MERRA-2 AOD, and vertically resolved AOD**
 440 **characteristics from CALIOP for each season over the sub-domains shown in Figure 2. Total CALIOP**
 441 **AOD is shown outside parentheses and numbers inside are the percent AOD fraction in the planetary**
 442 **boundary layer followed by in the free troposphere. Also shown are PBLHs (shown in Figure 3) and**
 443 **the relative humidity in the PBLH and FT.**

We next compare MERRA-2 speciated aerosol concentrations at the surface (Figure S2) to those of speciated AOD (Figure S1). Surface mass concentrations have the limitation of being biased by larger particles (similar to extinction). The seasonal cycle of mean values for speciated AOD and surface concentration for individual sub-domains generally agree with the exception that there was disagreement for sulfate in each sub-domain (see seasonal mean values in Table S1). Sulfate exhibited higher AODs in JJA but with surface concentrations usually highest in DJF or MAM; although differences in seasonal mean mass concentrations were relatively small ($< 1 \mu\text{g m}^{-3}$), a plausible explanation is enhanced secondary production of sulfate via oxidation of SO₂ or DMS convectively lifted to the free troposphere in JJA. An important result confirmed by the surface mass concentrations is that sea salt is an order of magnitude higher than the other species, supporting the previous speculation that sea salt dominates the aerosol extinction in the PBL from CALIOP.

459

460 **Figure 4: Monthly statistics of CCN concentration (1% supersaturation) measured at Cape Cod**
 461 **between July 2012 and May 2013. Red lines represent median, whiskers are the monthly range, and**
 462 **the top and bottom of boxes represent the 75th and 25th percentile, respectively. The notches in the box**
 463 **plots demonstrate whether medians are different with 95% confidence.**

464

465 3.5 Aerosol-Cloud Interactions

466 Studies of China's east coast have shown that the aerosol indirect effect is especially strong in
 467 wintertime, whereby pollution outflow leads to high N_d and suppressed precipitation (Berg et al., 2008;
 468 Bennartz et al., 2011). It is hypothesized that a similar effect is taking place off of North America's east coast,
 469 which could in part explain enhanced N_d without necessarily a significant jump in aerosol parameter (e.g.,
 470 AOD, AI) values. Grosvenor et al. (2018) suggested that high cloud fractions in wintertime off these east
 471 coasts relative to other seasons are coincident with strong temperature inversions usually associated with cold
 472 air outbreaks that serve to concentrate and confine surface layer aerosols. We examine the relative seasonal
 473 strength of the aerosol indirect effect via spatial maps of the following metric commonly used in aerosol-
 474 cloud interaction (ACI) studies:

475

$$476 \text{ACI} = d\ln(N_d)/d\ln(\alpha) \quad (3)$$

477

478 where α represents an aerosol proxy parameter that is represented here as AI, AOD, the speciated sulfate
 479 AOD ($\text{Sulfate}_{\text{AOD}}$), and sulfate surface mass concentration ($\text{Sulfate}_{\text{sf-mass}}$). The expected range by common
 480 convention is 0 – 1, with higher values suggestive of greater enhancement in N_d for the same increase in the
 481 aerosol proxy parameter.

482 Table 4 shows that DJF usually always exhibits the highest ACI values regardless of the aerosol proxy
 483 used, consistent with a stronger aerosol indirect effect in DJF over East Asia. The mean ACI values in DJF
 484 using AI, AOD, $\text{Sulfate}_{\text{AOD}}$, and $\text{Sulfate}_{\text{sf-mass}}$ ranged from 0.25 to 0.55, 0.28 – 0.59, 0.25 – 0.53, and 0.22 –
 485 0.47, respectively, depending on the sub-domain. Spatial maps of ACI (Figure 5) do not point to significant
 486 geographic features. Coefficients of determination (R^2) when computing seasonal ACI values were generally
 487 low (≤ 0.30), with spatial maps of R^2 and data point numbers in Figure S3. Poor correlations are suggestive
 488 of the non-linear nature aerosol-cloud interactions (e.g., Gryspeerd et al., 2017) and the influence of other
 489 likely factors such as dynamical processes and turbulence, data spatial resolution and dataset size, cloud
 490 adiabaticity, wet scavenging effects, and aerosol size distribution (McComiskey et al., 2009). The results of

491 this section suggest though that aerosol indirect effects could be strongest in DJF, meaning that N_d values
 492 increase more for the same increase in aerosol.

493

494 **Table 4: Estimated values of ACI calculated four ways ($d\log(N_d)/d\log(\text{AOD})$; $d\log(N_d)/d\log(\text{AI})$;
 495 $d\log(N_d)/d\log(\text{Sulfate}_{\text{AOD}})$; $d\log(N_d)/d\log(\text{Sulfate}_{\text{sf-mass}})$) for the sub-domains shown in Figure 2. The
 496 ACI values were obtained from log-log regression on average daily values of N_d and each of the
 497 aerosol proxy variables including only the pixels with $\text{CF}_{\text{low-liq}}$ greater than 0.1. Numbers in
 498 parentheses, in order, are R^2 and the number of points used for linear regression. Statistically
 499 insignificant ACI values with p-value greater than 0.05 are marked by bold font.**

509

510 4. Discussion of Potential Influential Factors

511 We probe deeper into factors related to the N_d seasonal cycle by using (Section 4.1) composite
512 analyses based on “high” and “low” N_d days, and (Section 4.2) advanced regression techniques tackling non-
513 linear relationships. We focus the analyses on one sub-domain (C-N) both for simplicity and intriguing
514 characteristics: (i) among the highest anthropogenic AOD values over the WNAO, (ii) significant seasonal
515 changes in fractional AOD contribution to the PBL, (iii) close to the Cape Cod site where CCN data were
516 shown, and (iv) the aerosol indirect effect (Table 4) is strongest (weakest) in DJF (JJA).

517

518 4.1 Composite Analysis

519 Discussion first addresses the behavior of different environmental parameters on days with the highest
520 and lowest N_d values. Seasonal histograms of averaged daily N_d were generated for sub-domain C-N. The
521 histograms are based on the natural logarithm of N_d to better resemble a normal distribution. Subsequently,
522 one standard deviation from both sides of the seasonal mean defined cut-off points outside of which we assign

523 values as being low and high in each season. Cut-off N_d values (cm^{-3}) are as follows (low/high): 33/153
524 (DJF), 29/118 (MAM), 38/100 (JJA), and 31/115 (SON). Next, composite maps for these groups were created
525 (Figures 6 – 10) for sea level pressure, near-surface wind, low-level cloud fraction, cold-air outbreak index,
526 and AOD. The figures contrast the low and high N_d maps with those showing mean seasonal values to
527 investigate potential factors that contribute to seasonal N_d variability. Interested readers are referred to
528 Figures S4 – S21 where similar composite map results are shown for N_d itself and other parameters including
529 those in Table 2.

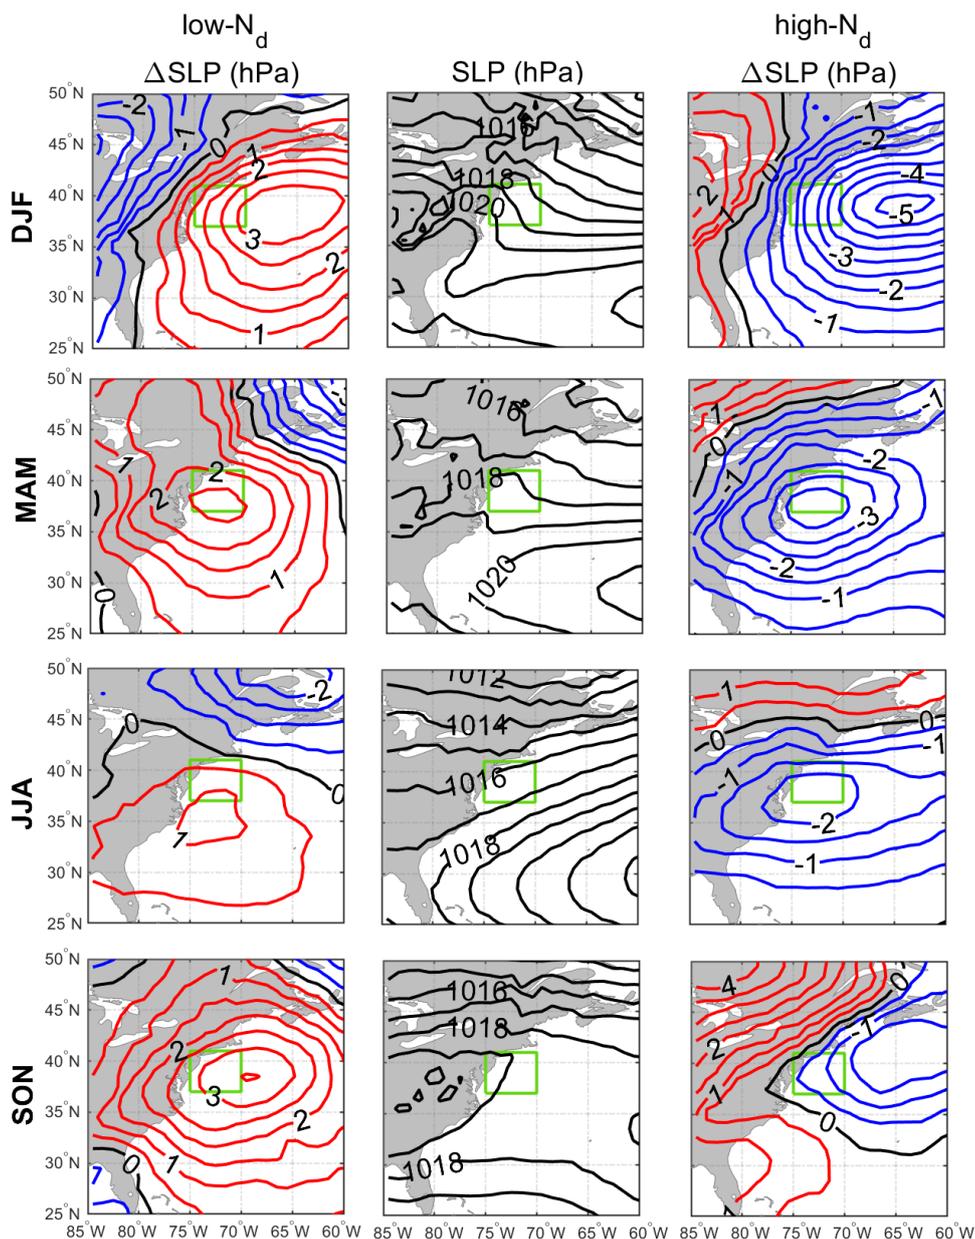

530

531 The resulting composite maps indicate high N_d days are characterized by (i) reduced SLP; (ii) more northerly-
532 northwesterly flow for all seasons (except JJA) and especially stronger winds in DJF and SON; (iii) higher
533 low-level liquid cloud fraction, especially in DJF; (iv) higher CAO index in the seasons when CAO events
534 occur more frequently (DJF, SON, MAM); and (v) enhanced AOD. Low N_d days generally exhibited opposite
535 conditions when compared to seasonal mean values: (i) enhanced SLP; (ii) wind ranging from southerly to
536 westerly without any significant wind speed enhancement; (iii) reduced low-level liquid cloud fraction,
537 especially in DJF; (iv) lower CAO index in DJF, SON, and MAM; and (v) reduced AOD in DJF and MAM,
538 enhanced AOD in JJA, and limited change in SON. Noteworthy results from Figures S4 – S21 included the
539 enhancement/reduction of PBLH on high/low N_d days (least pronounced in JJA), higher/lower RH at 950 and
540 800 hPa on high/low N_d days, and higher/lower sulfate AOD and surface concentrations on high/low N_d days
541 for DJF and MAM. Furthermore, there was a general reduction in rain on low N_d days for most seasons
542 except SON, with rain enhancement on high N_d days except for DJF (Figure S7); this was unexpected as wet
543 removal was hypothesized to be a reason for reduced N_d for at least the low N_d days. This may be attributed
544 to the rain product being for surface precipitation (and thus not capturing all drizzle) and for all cloud types,
545 including more heavily precipitating clouds deeper and higher than the low-level clouds examined for N_d .

546 The mean seasonal climatological values and anomalies suggest that high N_d cases are marked by
547 continental outflow, high cloud fractions, high PBLH, and low SLP, all of which occur most commonly in
548 DJF and are associated with cold air outbreaks. These events are marked by cold air over the warm ocean
549 leading to strong surface heat fluxes, boundary layer deepening, weakened inversion strength, in addition to
550 high and deep clouds (Kolstad et al., 2009; Fletcher et al., 2016; Abel et al., 2017; Brummer, 1996; Naud et
551 al., 2018). Coincident with these features is the Icelandic Low, which is a significant climatological feature
552 of the North Atlantic whereby subpolar low pressure builds in extratropic areas beginning in the fall with
553 westerly winds in the boundary layer that shift more to northerly in the winter (Sorooshian et al.,
554 2020; Painemal et al., 2021). This low-pressure system seems to be stronger on high N_d days resulting in more
555 continental outflow and high number concentrations of CCN; the greater CAO index values near the coast
556 promote high cloud coverage affording more opportunity for cloud processing of particles to ultimately
557 enhance droplet activation. While there can be considerable enhancement in N_d as cold air outbreak air masses
558 evolve over warmer waters, precipitation scavenging farther downwind will be an efficient method of
559 boundary layer aerosol (and N_d) removal (Abel et al., 2017; Lloyd et al., 2018), which contributes at least in
560 part to the sharp N_d gradients offshore demonstrated in Figure 1.

588 4.2 Multivariate Regression Analysis

589 Modeling analysis focuses on the two seasons (DJF and JJA) with the extremes in terms of seasonal
590 mean values for N_d and aerosol parameters. Added motivation for examining those two seasons stems from
591 spatial maps of R^2 based on ACI analysis (Figure S3). Using the surface sulfate concentration as the aerosol
592 proxy generally yielded higher R^2 values in three seasons (DJF = 0.13, MAM = 0.05, SON = 0.08) except
593 JJA (0.02) for which the choice did not matter owing to low R^2 (≤ 0.03) values for all four aerosol proxy
594 variables tested. Although the R^2 values are all generally low, DJF and JJA are the seasons when surface
595 sulfate levels are the most and least capable in explaining N_d , with R^2 among the four proxy variables
596 exhibiting the widest (DJF values: 0.07 – 0.13) and narrowest range (JJA: 0.01 – 0.03) of values. We address
597 here how much improvement is gained in modeling N_d by advancing from linear regressions based on one
598 input variable to (i) adding more input variables, and (ii) moving to a more sophisticated model (GBRT) that
599 captures non-linear relationships.

600 We show in Table 5 the performance of two linear models based on a single linear regression (with
601 sulfate mass concentration), and a multi-regression that uses 12 input variables listed in Table 2. In addition,
602 Table 5 also lists the performance of the GBRT model that ingests 12 inputs variables, similar to the linear
603 multi-regression model. The average R^2 scores of the test set for predicting N_d based on a linear regression
604 using only sulfate surface mass concentration were 0.17 and 0.09 in DJF and JJA, respectively. In contrast,
605 R^2 between the multi-regression linear model and the test dataset increased to 0.28 and 0.26 for DJF and JJA,
606 respectively. This increase in predictive capability was helpful to reduce the gap between seasons by
607 presumably accounting for factors more important in JJA aside from surface concentration of sulfate. The R^2
608 scores increased even more to 0.45 and 0.39 for DJF and JJA, respectively, for the GBRT model. Therefore,
609 accounting for non-linear relationships improved predictive capability in both seasons. It is important to note
610 that the GBRT model was robust in terms of overfitting and especially generalizability as R^2 values of the
611 test and validation sets were similar for both seasons.

612
613 **Table 5: Performance of different models in predicting N_d assessed based on average R^2 -scores on both**
614 **validation and test sets. The models were fitted separately for DJF and JJA seasons. Table 2 has the**
615 **complete list of variables used in the GBRT model.**

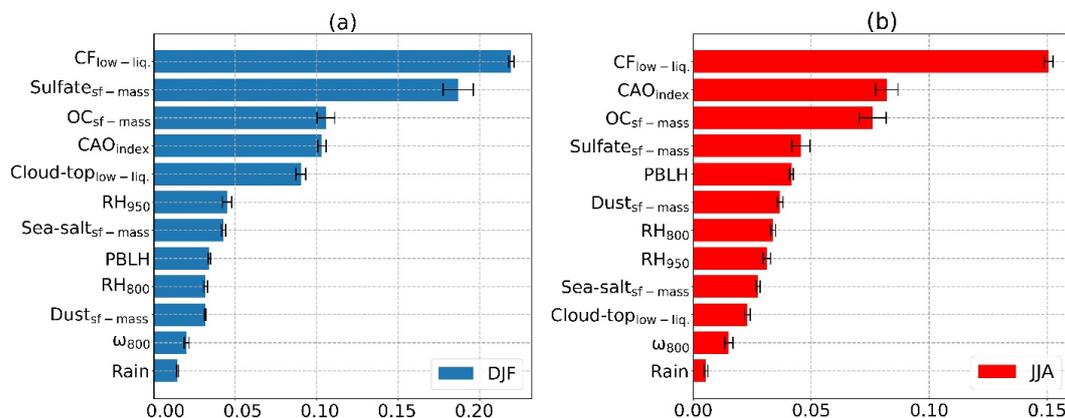

Model	Model type	Number of predictor variables	R^2 -score (DJF/JJA)	
			Validation set	Test set
$N_d \sim f(\text{Sulfate}_{\text{sf-mass}})$	Linear	1	0.17/0.10	0.17/0.09
$N_d \sim f(\text{Sulfate}_{\text{sf-mass}}, \text{CF}_{\text{low-liq}}, \dots)$	Linear	12	0.28/0.27	0.28/0.26
$N_d \sim f(\text{Sulfate}_{\text{sf-mass}}, \text{CF}_{\text{low-liq}}, \dots)$	GBRT	12	0.45/0.42	0.45/0.39

616

617

618 We next discuss the importance ranking of different parameters from Table 2 in terms of influencing
619 N_d for DJF and JJA (Figure 11). Low-level liquid cloud fraction was the most important parameter in both
620 seasons with the next three parameters being in common but in different order per season. In DJF, sulfate
621 surface mass concentrations were the second most important factor, followed by organic carbon surface
622 concentrations and the CAO index. As sulfate is secondarily produced via gas-to-particle conversion
623 processes, this result is consistent with those from Figure 1 showing the presumed strong impact of particles
624 smaller than 100 nm in impacting N_d values close to shore. In JJA, the CAO index was second most important,
625 followed by organic carbon and sulfate surface concentrations. Also, our results throughout the study and
626 supported by modeling are in agreement with Quinn et al. (2017) that sulfate particles contribute more to the
627 CCN budget than sea salt particles. In DJF and JJA, the fifth most important factor was low-level liquid
628 cloud-top effective height (10th most important in JJA) and PBLH (8th most important in DJF), respectively.

Figures 12 and 13 show accumulated local effect (ALE) plots for the various parameters ranked in Figure 11. In both seasons, but especially DJF, enhanced surface concentrations of sulfate and organic carbon coincide with higher N_d , whereas there was not any obvious positive association between N_d and either sea salt or dust (Figure 12). Dust in JJA and sea salt in DJF, seasons of which each respective aerosol type is most predominant, exhibited negative relationships with N_d . Such a negative relationship is plausibly related to differences between ACI when calculated using AOD versus AI (Painemal et al., 2021); for instance, coarse sea salt can expedite collision-coalescence and thus reduce N_d , which has the effect of reducing ACI (Eq. 3) and even possibly yielding negative values (Table 4). Negative values of other ACI constructs coincident with poor R^2 values have previously been attributed to potential effects of giant CCN (Terai et al., 2015; Dadashazar et al., 2017), but further research needs to examine this in more detail.

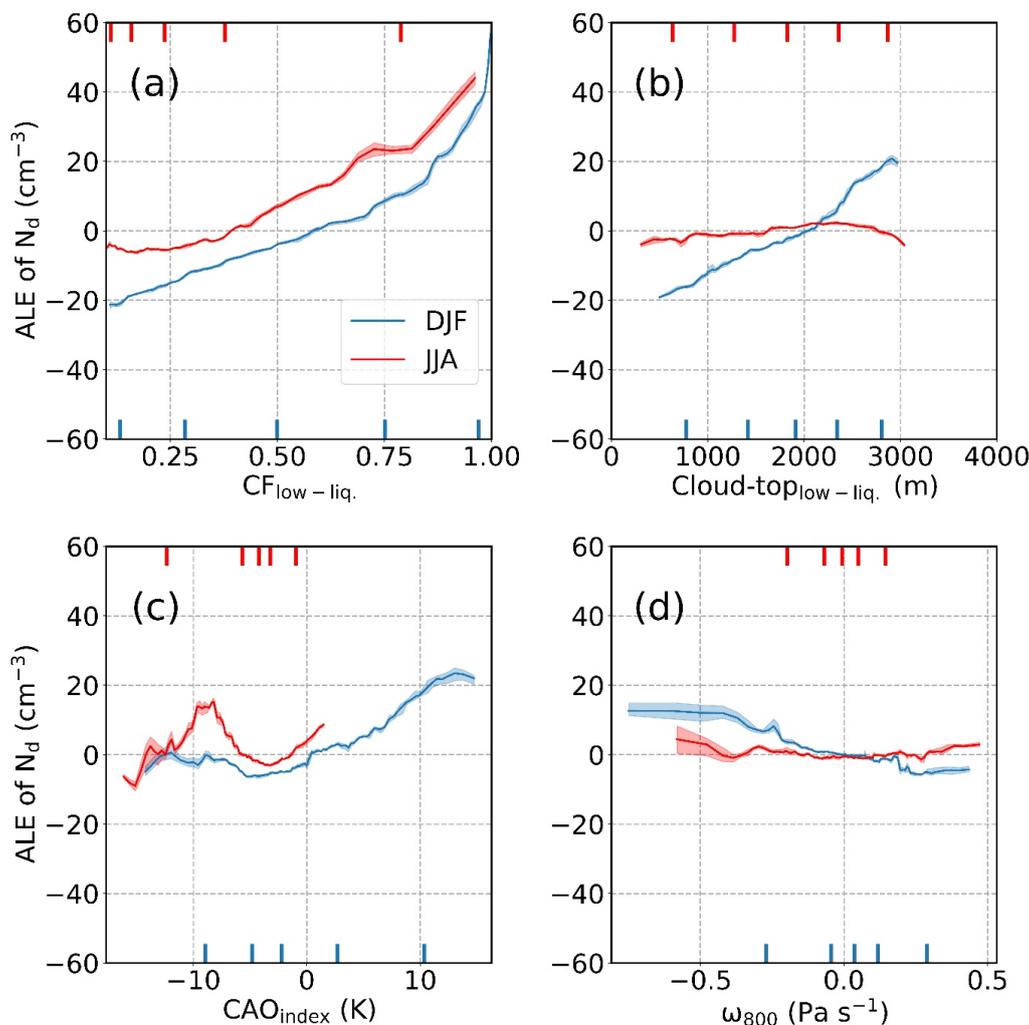

Figure 13 shows the similarity in the positive relationship between cloud fraction and N_d in both seasons. Only in DJF did cloud-top effective height exhibit a clear relationship with N_d (positive), likely linked to the common phenomenon of CAOs noted in Section 4.1 based on heightened CAO index values, deepening of the boundary layer, and weakened inversion strength. This is supported by enhanced N_d values coincident with negative values for ω_{800} (i.e., rising motion) and CAO index values above 0 in DJF without such relationships in JJA (Figure 13). The four parameters in Figure S22 (PBLH, RH₉₅₀, RH₈₀₀, Rain) did not reveal very pronounced trends with N_d in either season consistent with how they did not rank highly in importance (Figure 11).

668 **(CAO) index, and (d) vertical pressure velocity at 800 hPa (ω_{800}).**

669

670 4.3 Unexplored Factors

671 Additional factors impacting the relationship between aerosol and N_d seasonal cycles are discussed
672 here that warrant additional research with more detailed data at finer scales such as with aircraft. We are
673 cognizant that this list is not fully exhaustive. As low-level cloud fraction impacted model results of Section
674 4.2 so substantially, the dynamics of the studied clouds require further characterization. As cloud fraction
675 and CAO index are well related, especially in DJF, aerosol-cloud interactions likely are stronger than other
676 seasons (as implied by Section 3.5) due in part to enhanced surface fluxes and turbulence, and thus more
677 droplet activation with higher cloud supersaturations (Painemal et al., 2021); in contrast, the smaller shallow
678 cumulus clouds in summertime may be less favorable for droplet activation due to factors such as reduced
679 turbulence and more lateral entrainment.

680 Entrainment of free tropospheric aerosol can impact N_d values, with potentially varying degrees of
681 influence between seasons. It is presumed that with summertime convection, the more broken cumulus scenes
682 are less adiabatic through the cloudy column and more affected by entrainment and mixing; hence, N_d values
683 derived using data that remote sensors retrieve near cloud top could be considerably lower than values lower
684 by cloud base. Satellite remote sensing studies of aerosol-cloud interactions will struggle for analyzing winter
685 data as compared to summertime because of the varying degree of spatial and temporal mismatch in different
686 seasons between cloud and aerosol retrievals. More specifically, it is easier to get nearly coincidental
687 sampling in summertime due to lower cloud fractions, while in winter the frontal regions with high cloud
688 fractions make it challenging to get aerosol retrievals. There is complexity in understanding how aerosols
689 relate to N_d due to how giant CCN can reduce N_d and also since wet scavenging can remove aerosols
690 efficiently. As aircraft data are limited and difficult to use for assessing seasonal cycles, new techniques of
691 retrieving CCN and N_d from space will greatly assist such types of studies in the future.

692 693 **5. Conclusions**

694 This work investigates the seasonal cycle of N_d over the WNAO region in terms of concentration
695 statistics and with discussion of potential influential factors. The results of this work have implications for
696 increased understanding of aerosol-cloud interactions and meteorological factors influencing concentration
697 of cloud droplets in the marine boundary layer. The results and interpretations can be summarized as follows
698 in the order of how they were presented:

- 699
700 • An ACTIVATE case flight during the DJF season shows a sharp offshore N_d gradient ranging from
701 $> 1000 \text{ cm}^{-3}$ to $< 50 \text{ cm}^{-3}$ explained in part by particles smaller than 100 nm activating into drops
702 during a cold air outbreak with post-frontal clouds. There were significant changes in aerosol
703 composition in cloud-free air and also in droplet residual particles as a function of offshore distance.
- 704 • N_d is generally highest (lowest) in DJF (JJA) over the WNAO but aerosol parameters such as AOD,
705 AI, and surface-based aerosol mass concentrations and CCN concentrations (1% supersaturation) are
706 generally highest in JJA and MAM and are at (or near) their lowest values in DJF. While aerosol
707 extinction in the PBL is highest in DJF, it is driven largely by sea salt (large but few in number), and
708 thus cannot explain the N_d peak in wintertime.
- 709 • While relative humidity was generally highest in JJA across the WNAO, the differences between
710 seasons in the PBL and FT were not sufficiently large to explain the divergent seasonal cycles of
711 AOD and N_d .
- 712 • The susceptibility of N_d to aerosols (Eq. 3) was strongest in DJF using four different proxy variables
713 for aerosols, suggestive of at least one reason why N_d can be highest when aerosol proxy variables
714 for concentration are typically near or at their lowest values.
- 715 • Composite maps of high versus low N_d days across the WNAO reveal that conditions associated with
716 the highest N_d days, regardless of season (but especially DJF) are reduced sea level pressure, stronger
717 winds aligned with continental outflow, high low-level liquid cloud fraction, higher CAO index and
718 PBLH, and enhanced AOD. Cold air outbreaks are coincident with all of these conditions, especially
719 in the colder months of DJF in sharp contrast to JJA when N_d is lowest.
- 720 • Gradient boosted regression analysis shows that the most important predictors of N_d in DJF and JJA
721 vary to some extent, but with cloud fraction being the most important parameter, followed by either
722 (for DJF) surface mass concentrations of sulfate and organic carbon and CAO index or (for JJA) CAO
723 index, surface mass concentrations of organic carbon, and sulfate concentrations. Accumulated local
724 effect plots confirm that sulfate and organics help drive the high N_d values via continental outflow,
725 which is assisted in large part by CAO type of conditions such as high cloud fraction and high CAO
726 index.

727 Therefore, the combination of continental pollution outflow and turbulence changes contributed by
728 surface fluxes (manifested in strongest CAO index values in DJF and weakest in JJA) markedly influence
729 the N_d cycle, leading to differing annual cycles in cloud microphysics and aerosols. More detailed data such
730 as from aircraft and modeling can help extend this line of research to confirm these findings and speculations
731 such as how (i) the aerosol indirect effect is strongest in DJF due to boundary layer dynamics such as with
732 more turbulence and mixing than other seasons (Painemal et al., 2021); (ii) enhanced giant CCN in forms
733 such as sea salt and dust can reduce N_d via expediting the collision-coalescence process; and (iii) substantial
734 aerosol removal can occur far offshore as postfrontal clouds associated with CAOs build and then begin to
735 precipitate. The latter hypothesis may help explain why Bermuda (> 1000 km offshore the U.S. East Coast)
736 was the only selected sub-domain in this study to not have a seasonal N_d peak in DJF.
