40 **Abstract.** Nitrous oxide (N₂O) is both a greenhouse gas in the troposphere and an ozone depleting substance in the
 stratosphere and is rapidly increasing in the atmosphere. The spatial distribution of N₂O emissions and the sources
 leading to rising mixing ratios in the global atmosphere are highly uncertain. We measured the global distribution of
 tropospheric N₂O mixing ratios during the airborne Atmospheric Tomography (ATom) mission. ATom measured
 mixing ratios of ~300 gas species and aerosol properties in 647 vertical profiles spanning the Pacific, Atlantic, Arctic,
 and much of the Southern Ocean basins, from nearly Pole to Pole, over four seasons (2016–2018). We measured N₂O
45 mixing ratios at 1 Hz using a Quantum Cascade Laser Spectrometer and a new spectral retrieval method to account for

the pressure and temperature sensitivity of the instrument when deployed on aircraft. This retrieval strategy improved the precision of our N₂O measurements by a factor of 3, enabling us to recover the precision to that of previous missions. Most of the variance of N₂O mixing ratios in the troposphere is driven by the influence of N₂O-depleted stratospheric air, especially at mid and high latitudes. We observe the downward propagation of lower N₂O mixing ratios (compared to surface stations) that tracks the influence of stratosphere-troposphere exchange through the tropospheric column down to the surface, resulting in a seasonal minimum at the surface 2–3 months after the peak stratosphere-to-troposphere exchange in spring. The highest N₂O mixing ratios occur close to the equator, extending through the boundary layer and free troposphere. We observed influences from a complex and diverse mixture of N₂O sources, with emission source types identified using the rich suite of chemical species measured on ATom and with the geographical origin calculated using an atmospheric transport model. Although ATom flights were mostly over the oceans, the most prominent N₂O enhancements were associated with anthropogenic emissions, including industry, oil and gas, urban and biomass burning, especially in the tropical Atlantic outflow from Africa. Enhanced N₂O mixing ratios are mostly associated with pollution-related tracers arriving from the coastal area of Nigeria. Peaks of N₂O are often well-correlated with indicators of photochemical processing, suggesting possible unexpected source processes. The difficulty of separating the mixture of different sources in the atmosphere contributes to uncertainties in the N₂O global budget. The extensive data set from ATom will help improve the understanding of N₂O emission processes and their representation in global models.

1. Introduction

Nitrous oxide (N₂O) is a powerful greenhouse gas and a major contributor to both stratospheric ozone loss and to passivation of stratospheric oxy-halogen radicals (Forster et al., 2007; Ravishankara et al., 2009). The increasing rate of 0.93 nmol mol⁻¹ yr⁻¹ of atmospheric N₂O since the industrial revolution implies significant (~30%) imbalance between emission rates and destruction in the stratosphere. Seasonal cycles in tropospheric N₂O are driven by both stratosphere-to-troposphere exchange and by surface emissions (Nevison et al., 2011; Assonov et al., 2013; Thompson et al., 2014a). Most N₂O emissions are attributed to microbial nitrification and denitrification in natural and cultivated soils, freshwaters and oceans, plus emissions related to human activities such as fertilization, biomass burning and industry (Butterbach-Bahl et al., 2013; Saikawa et al., 2014; Thompson et al., 2014a; Upstill-Goddard et al., 2017; WMO, 2018).

Much effort has been made to reduce the uncertainties in the individual components of the N₂O global budget (e.g., Tian et al., 2012, 2020; Xiang et al., 2013; Thompson et al., 2014a, b; Ganesan et al., 2020; Yang et al., 2020). Recent estimates of global total N₂O emission to the atmosphere from bottom-up and top-down methods average 17 Tg N yr⁻¹ (12.2–23.5 from bottom-up analysis, and 15.9–17.7 Tg N yr⁻¹ from top-down approaches, Tian et al., 2020). The magnitude of marine N₂O emissions is subject to large uncertainty, due to spatial and temporal heterogeneity (Nevison et al., 1995, 2005; Ganesan et al., 2020; Yang et al., 2020). The most recent estimates of the global ocean emission of

80 N₂O range between 2.5 and 4.3 Tg N yr⁻¹, with the tropics, upwelling coastal areas and subpolar regions the major contributors to these fluxes (Yang et al., 2020; Tian et al., 2020). Agricultural N₂O emission estimates range between 2.5 and 5.8 Tg N yr⁻¹, and between 4.9 and 6.5 Tg N yr⁻¹ in the case of natural soils (Kort et al., 2008; 2010; Syakila and Kroeze, 2011; Tian et al., 2020). Recent estimates of N₂O emissions from fertilized tropical and subtropical agricultural systems are 3 ± 5 kg N ha⁻¹ y⁻¹ (Albanito et al., 2017). N₂O emissions from tropical river systems in Africa
85 are estimated at 3.3 ± 1.3 Tg N₂O yr⁻¹ (Valentini et al., 2014). According to Tian et al. (2020), anthropogenic sources account for 43% of the global N₂O emissions (7.3 Tg N yr⁻¹), with industry and biomass burning emissions estimated to be 1.6 to 1.9 Tg N yr⁻¹ respectively (Syakila and Kroeze, 2011; Tian et al., 2020) and the balance from agriculture. Most of these estimates are derived from short-term local-scale in-situ measurements and are difficult to extrapolate with confidence to large regions or to the globe.

90 In the atmosphere, N₂O is destroyed by oxidation and photolysis in the upper stratosphere, which makes it a good candidate for tracing the air exchange between the stratosphere and the troposphere (Hintsa et al., 1998; Nevison et al., 2011; Assonov et al., 2013; Krause et al., 2018). Atmospheric models tend to underestimate the inter-hemispheric N₂O gradient, which Thompson et al. (2014a) attribute to an overestimation of N₂O emissions in the Southern Ocean, an underestimate of the Northern Hemisphere emissions, and/or an overestimate of stratosphere-to-troposphere exchange
95 in the Northern Hemisphere. Overall, the largest uncertainties of modelled N₂O emissions are found in tropical South America and South Asia (Thompson et al., 2014b).

We present highly resolved atmospheric N₂O profiles collected during the NASA Atmospheric Tomography (ATom) mission. ATom was a global scale airborne deployment conducted over a 3-year period (2016–2018) using the
100 NASA DC-8 aircraft. In ATom, the DC-8 flew vertical profiles (0.2–13 km) nearly continuously while measuring mixing ratios of ~300 trace gases and aerosol physical and chemical properties over the Pacific and Atlantic basins from nearly Pole to Pole and during each of the four seasons. Each deployment started and ended in Palmdale (California, USA). Each deployment (1 – 4) generally consisted of a loop southward from the Arctic through the central Pacific, across the Southern Ocean to South America, northward through the Atlantic, and across Greenland and the Arctic Ocean. During ATom-3 and -4, two additional flights from Punta Arenas (Chile) sampled the Antarctic
105 troposphere and Upper Troposphere/Lower Stratosphere (UT/LS) to 80° S.

In this work we focus on the measurements taken during January–February 2017 (ATom-2), September–October 2017 (ATom-3), and April - May 2018 (ATom-4) (no QCLS N₂O data are available for ATom-1 in Aug.). The motivation for this paper is twofold. Firstly, we present a new retrieval strategy to account for the pressure and temperature dependence of laser-based instruments, specifically for the use of quantum cascade laser spectrometers on
110 aircraft. Secondly, we report on the global distribution of N₂O from the surface to 13 km, and examine the processes contributing to the variability of tropospheric N₂O based on the vertical profiles of N₂O and a broad variety of co-variate chemical species and aerosol properties.

2 Instrument specifications, spectral analysis and calibration

115 2.1 Specifications of the QCLS

We measured N₂O mixing ratios with the Harvard/NCAR/Aerodyne Research Inc. Quantum Cascade Laser Spectrometer (QCLS). This instrument was previously deployed on the NCAR/NSF Gulfstream V for the HIAPER Pole-to-Pole Observations mission (HIPPO, Wofsy et al., 2011; https://www.eol.ucar.edu/field_projects/hippo) and the O₂/N₂ Ratio and CO₂ Southern Ocean Study (ORCAS, Stephens et al., 2018; https://www.eol.ucar.edu/field_projects/orcas). Detailed information about the spectrometer configuration can be found in Jiménez et al. (2005, 2006) and Santoni et al. (2014). A brief description follows.

QCLS provides continuous (1 Hz) and highly spectrally resolved measurements of N₂O, methane (CH₄) and carbon monoxide (CO) using two thermoelectrically-cooled pulsed quantum cascade lasers, a 76 m pathlength multiple pass absorption cell (~0.5 L volume), and two liquid-nitrogen cooled solid-state HgCdTe detectors. All these components are mounted on a temperature-stabilized, vibrationally isolated optical bench. The temperature in QCLS is controlled by Peltier elements coupled with a closed-circuit recirculating fluid kept at 288.0 ± 0.1 K. QCLS measures CH₄ and N₂O by scanning the spectral interval of 1275.45 ± 0.15 cm⁻¹. A second laser is used to scan CO at 2169.15 ± 0.15 cm⁻¹. The supply currents to QCLS are ramped at a rate of 3.8 kHz to scan the laser frequency for 200 channels (steps in frequency) in laser 1 and 50 channels in laser 2, with an extra 10 channels to measure the laser shut off (zero-light level). The spectra and fit residual for CH₄, N₂O and CO are shown in Fig. S1 of the Supplement. Mixing ratios are derived at a rate of 1 Hz by a least-squares spectral fit assuming a Voigt line profile at the pressure and temperature measured inside the sample cell and using molecular line parameters from the High-resolution TRANsmission molecular absorption database (HITRAN, Rothman et al., 2005). The temperature and pressure inside the cell are monitored with a 30 kΩ thermistor and a capacitance manometer (100 Torr full scale).

During sampling, the air passes through a 50-tube Nafion drier to remove the bulk water vapor. A Teflon diaphragm pump downstream of the cell reduces the air pressure to ~60 mbar. Both ambient air and calibration gases pass through a Teflon dry-ice trap to reduce the dew point to -70 °C. After ATom-1, we added a bypass between the inlet and the instrument to increase the flushing rate of the inlet and inlet tubing. The calibration sequence includes 2 minutes of Ultra-High Purity zero air, followed by 1 minute each of low- and high-mixing ratio gases every 30 minutes (see Fig. S2). During ATom-1 and -2, we measured zero air every 15 minutes, and every 30 minutes during ATom-3 and -4. A data logger (CR10X, Campbell Scientific) was used to automate the sampling sequence. The CR10X also regulated pressure and temperature and managed the data transfer.

We use gas cylinders traceable to the National Oceanic and Atmospheric Administration World Meteorological Organization scales for calibration (NOAA-WMO-X2004A scale for CH₄, WMO-X2014A for CO and NOAA-2006A for N₂O). These gas standards were recalibrated before, during and after the deployments to maintain traceability. The low-mixing ratio gas cylinder contained 298.5 ± 0.3 ppb of N₂O, 1692.4 ± 0.2 ppb of CH₄ and 119.1 ± 0.3 ppb for CO.

The high-mixing ratio gas cylinder contained 399.1 ± 0.3 ppb of N_2O , 2182.5 ± 0.3 ppb of CH_4 and 192.8 ± 0.5 ppb of CO , respectively. Detailed information on calibrations of the gas cylinders used during ATom are in Table S1 of the Supplement.

150 QCLS also measures carbon dioxide (CO_2) in a separate unit. Detailed information about QCLS CO_2 measurements can be found in Santoni et al. (2014).

2.2 Spectral analysis and calibration

155 The QCLS was damaged during shipping to the deployment site before the start of ATom-1 and the resulting alteration in the optical alignment modified the sensitivity of the instrument to temperature and pressure changes during aircraft maneuvers. At a constant altitude, instrumental precision was similar to the precision measured during HIPPO (see Allan-Werle variance analysis in Fig. 2 in Santoni et al. 2014 for HIPPO and Fig. S3 for ATom), but drifts were observed during altitude changes due to the effects of changes in cabin temperature and pressure on the spectral location of interference fringes that arise in the optical path outside the sample cell. In addition, flight altitude changes could
160 mechanically stress the optical elements surrounding the cell, further modulating fringes or changing the shape of the detected laser intensity profile. These spectral artifacts ultimately reduced the accuracy of mixing ratios retrieved from spectral fitting. The spectral artifacts most strongly affected the measurements of CH_4 and N_2O . Several post-processing methods using the TDL-Wintel software were explored to improve the precision and accuracy of ATom QCLS N_2O data, most with little success. Since the measured spectra were all saved, it is possible to re-fit the data with different
165 fit parameters. A limited number of interference fringes may be included in the set of fitting functions. However, none of the previously used full re-fitting strategies significantly improved the data accuracy.

We have achieved significant improvement in the precision and accuracy of the QCLS N_2O data using a new method dubbed the “Neptune algorithm”, developed by Aerodyne Research, Inc., and that has been further developed and applied to the data sets described here. The Neptune algorithm generates corrections to the mixing ratios retrieved
170 from the original fits by associating specific spectral features with anomalies in retrieved mixing ratios observed during calibrations, i.e. during intervals when the mixing ratios are held constant. The spectral baseline is defined as the spectral channels outside the boundaries of the spectral lines of the target gas. Fluctuations in the spectral baselines are quantified for the entire data set by means of principal component analysis (PCA). PCA provides an efficient description of the spectral fluctuations, naturally producing an ordered set from strongest to weakest of orthogonal vectors (spectral
175 forms), each with an amplitude history spanning the data set. The PCAs are defined by an optimization procedure during calibrations, when mixing ratio fluctuations are designed to be ~ 0 . The finite fluctuations in retrieved mixing ratios during calibrations are fit in the spectral space of the baseline as linear combinations of the leading PCA vector amplitudes, creating a linear combination of amplitudes of spectral fluctuations that predict errors in the mixing ratios for each gas for an entire flight. The error-producing linear combination of amplitudes of PCA spectral fluctuations
180 produces a full set of anomaly estimates, which is subtracted from the retrieved mixing ratios during the flight. The

computational time for a 10-hour long dataset is only seconds, so variations in the algorithm's parameters (i.e. how many PCAs are retained) can be optimized rapidly.

185 The Neptune-PCA analysis improved the overall precision by a factor of 4 for CH₄ and a factor of 3 in the case of N₂O with respect to the precision of the original retrievals, as measured by the standard deviation of retrieved mixing ratios during calibrations. The repeatability of the retrieved calibrations was 0.2 ppb for N₂O and 1 ppb for CH₄ (Fig. S4). The laser path of the CH₄/N₂O laser was realigned between ATom-1 and -2 and the Neptune retrieval was applied to CH₄ and N₂O measurements corresponding to the ATom-2, -3 and -4 deployments. Mixing ratios of CH₄ and N₂O could not be retrieved during ATom-1 because light levels were too low for the CH₄/N₂O laser due to the damage-induced misalignment.

190 The steps involved in the Neptune correction process were as follows.

1) We paired the mixing ratio records with the corresponding spectra (1-s resolution) for each species (CH₄ and N₂O).

2) We grouped the mixing ratios and spectra by type as calibrations (zeros, low span and high span) and air samples, and in time. The spectral data were thus arranged in an array, with point number in the spectrum as x, and spectrum number as y. We calculated an average spectrum for each group type and subtracted these from each individual spectrum within a group.

3) We zeroed-out the spectral arrays at the positions of the absorption lines to concentrate on the fluctuations observed in the baseline and to prevent the PCA from finding line-depth fluctuations as relevant vectors during the calibrations. Some degree of smoothing (in x) was applied to the subtracted spectra, so that high-frequency fluctuations, which have little influence on the mixing ratio determination, are not represented. An example of such a processed spectral array is shown in Fig. 1a.

4) We applied PCA to the whole line-zeroed spectral array to evaluate the fluctuations. PCA is applied in two steps: multiply the spectral array by its transpose, to generate an autocovariance array; and then perform singular value decomposition on the autocovariance array. The PCA generated an efficient description of how the baseline of the spectrum changed with cabin pressure and temperature. The description of spectral fluctuations is made in terms of a set of products of vectors and amplitudes.

5) We fit the spectra to the PCAs to express mixing ratio fluctuations during the set of calibrations and zeros as a linear combination of PCA vector histories. The number of vector histories that we included in the fit typically is limited to less than 30, because the weaker PCA amplitudes tend to just describe random noise.

210 The linear combination of amplitudes that links spectral fluctuations in the baseline to mixing ratio fluctuations during calibrations, was then applied to the full data set. That generated the retrieval errors for uncalibrated mixing ratios, for the whole time series. We subtracted the errors from the initial retrievals from TDLWintel-QCLS software and computed calibrated mixing ratios using the corrected retrievals for both calibrations and samples. An example of the result of the Neptune algorithm on the N₂O samples and calibrations for the ATom-4 flight on 12 May 2018 is

215 shown in Fig. 1b. The approach used here to minimize the effect of changes in pressure and temperature in optical
instruments is based on the observation of fluctuations of the baseline during calibrations. Hence, in those cases where
altitude changes occurred during sampling but not during any of the calibrations for an individual flight, this
methodology will not provide any improvement. Due to frequent calibrations, we did not observe this rare scenario in
the whole mission. To evaluate the ultimate accuracy of our measurements we compare the QCLS N₂O measurements
220 with other on-board N₂O measurements as well as with the surface N₂O measurements of stations located along the
flight tracks.

3 Accuracy of N₂O measurements from QCLS

We evaluated N₂O mixing ratios measured by QCLS against three other instruments measuring N₂O on the NASA DC-
225 8 aircraft during ATom. In addition, we compared the set of 4 airborne measurements to data from the flask sampling
network at ground stations from the NOAA Global Monitoring Laboratory (GML, <https://www.esrl.noaa.gov/gmd/>) to
evaluate the differences between the airborne data and the ground-based measurements in the NOAA reference
network.

230 3.1 Comparison between airborne N₂O measurements

Measurements of N₂O on the DC-8 were obtained by (i) the Unmanned Aircraft Systems Chromatograph for
Atmospheric Trace Species (UCATS, Hintsa et al., 2021), (ii) the PAN and other Trace Hydrohalocarbon ExpeRiment
(PANTHER; Moore et al., 2006; Wofsy et al., 2011), (iii) the Programmable Flask Package Whole Air Sampler (PFP;
Montzka et al., 2019), and (iv) our 1-Hz QCLS.

235 We compared QCLS, PANTHER and UCATS in 10s intervals as provided in the merged file,
MER10_DC8_ATOM-1.nc, available at the Oak Ridge National Laboratory Distributed Active Archive Center (ORNL-
DAAC, Wofsy et al., 2018, <https://doi.org/10.3334/ORNLDAAC/1581>). The file MER-PFP merged with the PFP
sampling interval, also available in this repository, was used to compare QCLS and PFP data. The one-to-one
comparison between these instruments showed an overall overestimation of N₂O mixing ratios from QCLS (see Fig.
240 2A1–2A3). The 95% confidence interval of the mean difference of the pairs (95% C.I.) was 0.75 ± 0.04 ppb between
QCLS and PANTHER, 1.13 ± 0.03 ppb between QCLS and UCATS, and 1.18 ± 0.09 ppb between QCLS and PFP,
respectively, for the full data set (ATom-2, -3 and -4). Information about the coefficients of the linear fit for each
instrument comparison and the 95% C.I. of the difference for each pair are shown in Table of S2. The offset that QCLS
N₂O shows against PFP N₂O coincides with the offset already reported by Santoni et al. (2014) during HIPPO in 2009-
245 2011, which may be attributed to our calibration procedure. PFP is the reference instrument on board, analyzed with
excellent precision and accuracy.

3.2 Comparison between airborne and surface measurements of N₂O

250 We evaluate the traceability of lower-troposphere N₂O mixing ratios by ATom by comparing the four airborne instruments with the surface measurements of N₂O from the NOAA flask sampling network at common sampling locations. Information about the surface stations used here is shown in Table of S.3 of the Supplement.

255 A mean value of N₂O within a latitude range of 5 degrees north and south with respect the nearest surface station and between 1 to 4 km altitude of instrument was compared with the mean N₂O at the station located within that latitude grid and +/- 5 days of the flight (due to the non-daily frequency of flask samples). We chose this altitude range to agree with the low free troposphere conditions that characterized most of the selected ground stations. The comparison of the whole data set (ATom-2, -3, -4) shows an overall overestimation of N₂O mixing ratios by QCLS and PANTHER with respect surface data of 1.37 ± 0.35 and 0.44 ± 0.51 ppb (95% C. I.), respectively. In contrast, UCATS and PFP showed 0.27 ± 0.37 and 0.008 ± 0.34 ppb (95% C. I.), underestimation with respect to the surface data, respectively (Fig.2B1-2B4). Due to the great agreement between PFP and the surface stations and the consistent offset that QCLS shows against PFP and the stations, in the following sections, QCLS N₂O dataset is corrected by subtracting the offset with respect to the PFP data on-board in each deployment: 1.03 ± 0.13 ppb in AT-2, 1.49 ± 0.19 ppb in AT-3, and 1.18 ± 0.17 ppb in AT-4.

265 These results show the very close comparability of ATom airborne N₂O instruments (differences < 0.5 ppb, 0 ppb in the case of PFP) relative to the surface stations and demonstrate the feasibility of using ATom N₂O measurements to evaluate the impact of stratospheric air and meridional transport of N₂O emissions in N₂O tropospheric column measurements over the ocean basins. In the following section, we define the boundary conditions based on the NOAA Greenhouse Gas Marine Boundary Layer Reference from the NOAA GML Carbon Cycle Group (NOAA/ESRL GML CCGG, <https://www.esrl.noaa.gov/gmd/ccgg/mb/>) for evaluating the impact of stratospheric air and meridional transport of N₂O emissions in N₂O tropospheric column over the ocean basins. The NOAA-MBL N₂O product is synthetic latitude profile generated at 0.05 sine latitude and weekly resolution (<https://www.esrl.noaa.gov/gmd/ccgg/mb/>) from individual flask measurements of marine boundary-layer surface stations distributed along the two ocean basins, and provides the scenario to evaluate the traceability of aircraft measurements relative to ground measurements in remote sites (<https://doi.org/10.15138/53g1-x417>).

275

4. Results and Discussion

280 The vertical profiles of N₂O from ATom provide a global overview of the N₂O distribution in the troposphere with observations over the Pacific and Atlantic basins. For this study we do not include data collected over and close to land. In ATom, N₂O ranged between 280 and 335 ppb over the oceans. In each season, the lowest N₂O mixing ratios are observed at high latitudes (HL, > 60°) in the UT/LS (8–12.5 km) in air transported downward from the stratosphere.

The highest N₂O mixing ratios are found close to the equator (30° S–30° N, 326 to 335 ppb), extending along the tropospheric column up to 6 km and influenced by convective activity over the tropical regions (Kort et al., 2011; Santoni et al., 2014). At mid-latitudes (ML, 30°–60° N), tropospheric N₂O values ranged between 322 and 333 ppb. Tropospheric N₂O tends to increase towards northern latitudes as a result of higher anthropogenic emissions in the Northern Hemisphere relative to the Southern Hemisphere. More details on the variability of N₂O mixing ratios along the tropospheric column are described in Section S1.

We study the impact of N₂O sources and stratospheric air on the N₂O column based on the anomalies (enhancements and depletions) we observed in the airborne N₂O mixing ratios relative to the N₂O “background” defined here as the NOAA-MBL product. We use the NOAA-MBL product to constrain a latitudinal gradient of N₂O mixing ratios at the surface for each deployment. These data and have been widely used to estimate the N₂O background (Assonov et al., 2013; Nevison et al; 2011). More information about the NOAA-MBL product and the latitudinal gradient of their measurements is discussed in Section S2. This approach highlights the extra information that aircraft profiles can provide. Cross-sections of N₂O anomalies are shown in Fig. 3. The data describe the overall homogeneity of N₂O in the troposphere (30% of the anomalies ranged between ± 0.5 ppb). We consider the ± 0.5 ppb interval to account for the day-to-day and seasonal variability of N₂O. Episodes of N₂O depletion (< -0.5 ppb) related to the influence of stratospheric air are observed in 53.5% of the aircraft samples during ATom-2 to -4, whereas episodes of N₂O enhancement (> 0.5 ppb) related to the contribution of N₂O sources account for 16.5% of the observed anomalies.

4.1 Impact of stratospheric air on tropospheric N₂O mixing ratios during ATom

We observed a strong depletion in N₂O mixing ratios during October 2017 at high southern latitudes (SH, Fig. 3c), when the Antarctic polar vortex has broken up and the period of maximum stratosphere-to-troposphere transport was ending at Northern high latitudes. Polar vortex break-up allows depleted levels of N₂O to be distributed and to persist in the troposphere. During February 2017, 35% of the N₂O observations over the Atlantic were lower than seasonal background defined from the NOAA-MBL product (i.e., N₂O differences < -0.5 ppb) and 51% over the Pacific. During October 2017, depleted N₂O accounted for 55% of the observations over the Atlantic and 46% over the Pacific, whereas during May 2018, the percentage was 53% and 49% in the Atlantic and Pacific basins, respectively. In the Arctic, the strongest signal of N₂O depletion above the surface was observed in May. These results support previous work suggesting that downward transport of stratospheric air with low N₂O exert a strong influence on the variance of tropospheric N₂O mixing ratios (Nevison et al., 2011; Assonov et al, 2013). Bands of depleted N₂O begin to reach the surface in March-April in the Southern Hemisphere (ATom-4, Fig. 3b and e) arriving as late as August-September in the Northern Hemisphere (ATom-3 Fig. 3c and f). Surface seasonal minima therefore occur 2–4 months later than the polar vortex break-up (see Fig. S9 and S10) (*cf.* Nevison et al., 2011 and references therein).

The impact of stratosphere-to-troposphere transport can be studied by combining information on N₂O with other chemical tracers such as carbon monoxide (CO from QCLS), sulfur hexafluoride (SF₆ from PANTHER), ozone (O₃

315 from the NOAA - NO_yO_3 ; Bourgeois et al., 2020) and CFC-12 (from PANTHER), as well as meteorological parameters
such as potential vorticity, the product of absolute vorticity and thermodynamic stability (PV, generated by GEOS5-FP
for ATom). The correlation of N_2O with CO shows an L-shape curve similar to those typically observed on O_3 -CO
correlations during events of stratosphere-to-troposphere air mass mixing (Fig. 4b, Krause et al., 2018). The slightly
higher mixing ratios of CO, N_2O and SF_6 in the Northern Hemisphere are due to the larger emissions in this hemisphere.
320 Tropospheric N_2O can be identified as the horizontal band containing high N_2O (> 328 ppb) and variable CO and SF_6 ,
whereas the vertical band with variable N_2O and small changes in CO and SF_6 , shows the stratospheric influence (Fig.
4a–d). The range of N_2O -CO mixing lines are indicative of the time scales of the mixing events, where straight mixing
lines are due to fast mixing time scales (Krause et al., 2018). Episodes of fast air mass mixing were observed during all
deployments (see tracer-to-tracer correlations from the three deployments in Fig. S11). At the Pacific northern mid and
325 high latitudes (NMHL $> 30^\circ$ N), we found a consistent linear relationship between N_2O and O_3 , with a relatively constant
 $\text{N}_2\text{O}/\text{O}_3$ slope (-0.05 to -0.04) during all seasons. Linear correlations between N_2O and CFC-12 highlight the dominant
influence of stratospheric air depleted in these two substances in the range of mixing ratios observed at mid and high
latitudes.

During spring, the mid-latitudes are strongly impacted by stratospheric air due to the occurrence of tropopause
330 folds (also known as cut-off lows) to the south of the westerlies (Hu et al., 2010 and references therein). The stronger
depletion of N_2O mixing ratios observed over the Atlantic relative to the Pacific during spring is due to a greater number
of deep stratosphere-to-troposphere transport events at middle latitudes in the region between May and July (Fig. 3e;
Cuevas et al., 2013 and references therein). Anomalies in PV relative to its mean latitudinal distribution in the free
troposphere (2–8 km) highlight events of strong downward transport of stratospheric air. Negative PV, N_2O , CO, and
335 CFC-12 anomalies (positive for O_3) describe the transport of stratospheric air into the troposphere in the SH, whereas
positive PV and negative N_2O , CO, and SF_6 anomalies (positive for O_3) describe the downward transport of
stratospheric air in the NH (Fig. 4e-h). The correlations between N_2O and PV, and the similarities with CFC-12, indicate
that stratosphere-to-troposphere exchange leads to variations of tropospheric N_2O up to 10 ppb in the higher latitudes
for the altitudes covered during the flights. This influence is notably larger than the 2–4 ppb enhancements associated
340 with regional emissions (see below).

4.2 Impact of emissions on tropospheric N_2O mixing ratios during ATom

During ATom, episodes of N_2O positive anomalies relative to the surface station MBL reference occur close to the
equator (Fig. 3a-c), and in a few locations at mid latitudes, in both ocean basins across all seasons. We use the
345 information from the vertical profiles including back-trajectories and correlated chemical tracers to trace the origins of
these enhancements including: CO, CH_4 , and CO_2 , measured by the QCLS and NOAA Picarro 2401-m, hydrogen
cyanide (HCN), sulfur dioxide (SO_2), hydrogen peroxide (H_2O_2) and peroxyacetic acid (PAA) measured with the
Chemical Ionization Mass Spectrometer (CIT-CIMS, St. Clair et al., 2010), ammonium (NH_4^+), sulfate (SO_4^{2-}) and

350 nitrate (NO_3^-) and organic aerosols (OA) from the CU Aircraft High-Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-AMS, DeCarlo et al., 2006; Canagaratna et al., 2007; Jimenez, et al., 2019; Guo et al., 2020; Hodzic, et al., 2020), NO_y from the NOAA NO_yO_3 4-channel chemiluminescence (CL, Ryerson et al., 2019), CH_2Br_2 , CH_3CN , benzene and propane from the Trace Organic Gas Analyzer (TOGA, Apel et al., 2019) instrument, and atmospheric potential oxygen ($\text{APO} \approx \text{O}_2 + 1.1 \times \text{CO}_2$) from the NCAR Airborne Oxygen Instrument (AO2, Stephens et al., 2020).

355 Trajectories and associated surface influence functions were computed using the Traj3D model (Bowman, 1993) and wind fields from the National Center for Environmental Prediction Global Forecast System (NCEP GFS). Model trajectories were initialized at receptors spaced one minute apart along the ATom flight tracks, and followed backwards for 30 days, and reported at 3-hour resolution. From these trajectories we calculated the surface influence for each receptor point (footprints in units of $\text{ppt}/(\text{nmol m}^{-2} \text{ s}^{-1})$).

360 We calculate the correlations between N_2O and the mentioned species considering three arbitrary layers (0-2000 m, 2000-4000 m, and 4000-6000 m). Correlation coefficients in each layer for a given profile were calculated using a minimum threshold of 15 data points per layer. These profiles show that many of the most prominent enhancements of N_2O are closely associated with pollutants such as HCN, CH_3CN , H_2O_2 , and other pollutants associated with combustion and photochemical air pollution. Some profiles show peaks closely correlated with SO_2 and enhanced PM1 particles, and vertical gradients were sometimes correlated with gradients of APO and HCN.

365 The best predictors for N_2O peaks in many cases were H_2O_2 and PAA. These are both primary pollutants and the end products of atmospheric photochemistry. For the altitude range 2–4 km, regressions produced $r^2 > 0.7$ for 16 profiles of N_2O vs. H_2O_2 and 15 profiles of N_2O vs. HCN (a tracer for combustion), but only three such profiles produced these strong associations for both H_2O_2 and HCN in common. Hence, H_2O_2 appears to be an independent predictor for N_2O enhancements in polluted air encountered over the remote oceans. This result raises the question as to whether globally significant production of N_2O may be occurring in heterogeneous reactions involving HONO, NO_2 , or NO redox chemistry nearby to strong sources of reactive pollutants, as has been observed in heavily polluted atmospheres (Wang et al., 2020), or as theorized to occur in the plumes of refineries or power plants (e.g. Pires and Rossi, 1997).

375 In most of the cases, because we were sampling in the middle of the oceans and not over the source regions, the distinction between the different sources contributing to the observed N_2O enhancements is not possible. In this analysis we also observe that the impact of the different sources to N_2O mixing ratios is regionally dependent. Thus, in the following lines we describe with some examples, the sources contributing to the major enhancements of N_2O observed during ATom by oceanic regions, though we cannot pinpoint precisely the source processes.

4.2.1 N_2O enhancements over the Pacific

380 Episodes of N_2O enhancements were frequently observed at the southern Pacific Ocean mid latitudes, linked by the associated footprints to emissions over the continents. In this region, N_2O enhancements are predominantly correlated with enhancements on H_2O_2 , PAA and CO. For example, consider Fig. 5 showing data from profile 12 on 3 May 2018,

at 49.5–50° S near the Dateline. A distinct peak in N₂O of 1 ppb amplitude, at 1700 m altitude, is significantly correlated with enhancements in CH₃CN. These associations and the footprints suggest a regional contribution from fuel types
385 from the industrial zone of Australia (Fig. 5c). At higher altitudes (2.5–6 km), strong correlations between N₂O, H₂O₂, PAA, CO and HCN, but not SO₂, suggest the influence of biomass burning from central Australia (3–5 km) and from South America (6 km) (Fig. 5b and 5c middle and right panels, and Fig. S11f). The relatively low mixing ratios of short-lived trace gases, and the surface influence based on the back trajectories (Fig. S13a), indicate that most of these profiles sampled significantly aged air masses transported for extended periods over the South Pacific.

390 At the equatorial Pacific, episodes of N₂O enhancements were frequently associated with a mixture of potential marine, industrial and biomass burning emissions. Atmospheric potential oxygen (APO) is a tracer primarily of oxygen exchange with the oceans, defined as deviations in the oxygen-to-nitrogen ratio ($\delta(\text{O}_2/\text{N}_2)$) corrected for changes in O₂ due to terrestrial photosynthesis and respiration, and also mostly for influences from combustion (Stephens et al., 1998),

395
$$\delta\text{APO} = \delta(\text{O}_2/\text{N}_2) + 1.1 / X_{\text{O}_2} (X_{\text{CO}_2} - 350) \quad (1)$$

Here $\delta(\text{O}_2/\text{N}_2)$ is the deviation in O₂:N₂ ratio (per meg), 1.1 is an approximation to the O₂:CO₂ ratio for photosynthesis and respiration, X_{O₂} is the mole fraction of O₂ in dry air, and X_{CO₂} is the mole fraction of CO₂ in the air sample (dry, $\mu\text{mol mol}^{-1}$). Since APO primarily tracks oxygen exchange between the ocean and the atmosphere,
400 depletions in APO can indicate marine N₂O emissions from areas with strong upwelling (Leucker et al., 2003; Ganesan et al., 2020). However, APO is also sensitive to pollution such as biomass burning and fossil fuel combustion (Lueker et al., 2001) and because both N₂O and APO have meridional gradients resulting from many influences, correlations can result simply from sampling air transported from different latitudes. In ATom, 9 profiles showed significant correlations ($r^2 > 0.7$) between N₂O and APO (or $\delta(\text{O}_2/\text{N}_2)$, which has lower measurement noise), for altitude bins 0–2
405 km (8) and 2–4 km (1) where backtrajectories trace their origin close to the North American west coast and the Mauritanian coast, and in the equatorial Pacific. The median slope of regressions of APO vs. N₂O for these profiles in ATom was -0.04, and the mean -0.05 (± 0.04 , 1 σ) ppb per meg, very similar to the range found by Ganesan et al. (2020) and Leucker et al. (2003) in coastal areas.

An example is shown in Fig. 6 for 1 May 2018. We observed high correlation between N₂O and APO ($r^2 = 0.66$)
410 between 0 and 4 km altitude. At these altitudes we also see enhancements in dibromomethane (CH₂Br₂), a tracer of phytoplankton biomass (Liu et al., 2013 and references therein), consistent with a marine biological flux of halogenated VOCs (Asher et al., 2019), dimethyl sulfide (DMS) and methanesulfonic acid (MSA), main particulate product of DMS oxidation in the MBL. On this flight, the footprints and the surface ocean influence (Fig. S12b) indicate that this gradient represents a difference in sampling a marine air mass from the south near the surface and a more continentally influences
415 air mass from the east at 4 km (Fig. 6A–C). Thus, the N₂O:APO correlation most likely represents the latitudinal and ocean-land gradients established for a combination of reasons, with higher APO and lower N₂O from higher southern

latitudes away from continents. In this particular flight, N₂O variations were more noticeable between 4 and 6 km height, in relation to biomass burning plumes from fires occurring in Venezuela and the Caribbean, in agreement with simultaneous enhancements on CO, HCN mixing ratios (Fig. 6A, C and Fig. S12), and pollution sources near coastlines.

420

4.2.2 N₂O enhancements over the Atlantic

The Atlantic basin ATom flights saw much more continental influence than the Pacific. Around 30° N, in the North Atlantic during winter, we observe small enhancements of N₂O that contrasts with the overall influence of stratospheric air on the tropospheric column (AT-2, Fig. 3d). The contribution is much higher during the fall season (AT-3, Fig. 3f). Several episodes of N₂O enhancements are associated with enhancements of CH₄, CO, and HCN. At this altitude range, we also observe some episodes where N₂O increases while CO₂ decreases (figure not shown), which could reflect the accumulation of agricultural emissions over the summer or just greater sampling of Northern Hemisphere summer air masses, whereas increases of N₂O with CO are indicators of urban pollution and together with HCN are associated with a few episodes of biomass burning.

425

430

The influence of different regions on the N₂O mixing ratios over the Atlantic is shown on 14 May 2018 (Fig. 7). This profile shows the contribution to tropospheric N₂O from western Europe pollution transported down over the Mauritanian coast, combined with biomass burning emissions, urban and industrial emissions from southern Africa and the Middle East (between 2 and 4 km), and polluted air masses from South America and the African west coast mixed with the oceanic contribution to N₂O (~10 km, Fig. 7A–C and Fig. S13). At high altitudes, N₂O enhancements are caused by the interception of polluted airmasses from South America and the African west coast mixed with the oceanic contribution to N₂O (~10 km). The N₂O:APO correlations for the feature at 2 km most likely represent depletion of APO by industrial combustion, stoichiometrically consistent with the observed increases in CO₂ and CH₄ for this feature.

435

440

During ATom, we observed large contributions to tropospheric N₂O over the Atlantic Ocean from Africa, with some influence from Europe and South America. In the subtropical and tropical regions over the Atlantic during AT-2, we found strong correlations between N₂O and H₂O₂ and PAA, HCN, CO, CO₂, SO₂, OA, NH₄⁺ and SO₄²⁻ between 2 and 4 km, representing the combined influence of photochemistry ($r_{\text{N}_2\text{OvsPAA}}^2 = 0.94$), biomass burning events from the Congo region ($r_{\text{N}_2\text{OvsHCN}}^2 = 0.95$) and industrial production of N₂O from oil and gas emissions from the Niger River Delta in Africa ($r_{\text{N}_2\text{OvsSO}_2}^2 = 0.84$). An example is shown in Fig 8 for 15 February 2017 (Fig. S12 and land contribution in Fig. S13).

445

To evaluate the origin of these enhancements, we combined the calculated surface influence with the monthly mean estimates of the global anthropogenic emission inventory from the Emissions Database for Global Atmospheric Research (EDGAR, <http://edgar.jrc.ec.europa.eu/>). By using a profile specific background, we can calculate the N₂O enhancement for a given profile. When the N₂O enhancement from the African outflow shown in Figure 8 is compared with the emission inventory (Figure 9, bars represent the range of N₂O expected from variations in the background

450

choice), we see the largest influence from African agriculture (peaking at 2 ppb at 2 km), with smaller but significant influence from Asia and Europe (0.5 ppb each at 2-4 km). Not forgetting that we are comparing a single aircraft pass with a monthly mean estimate from the inventory, and the strong impact of the latitudinal gradient we observed on the N₂O data for this particular profile, the overall expected atmospheric enhancement of N₂O calculated from EDGAR for the African region is in the order of magnitude than that observed in the atmosphere (if the error in our measurements is taken into account). EDGAR major contributions to these enhancements are agriculture soil emissions and industrial chemical processes (Fig. S14). High correlations between N₂O and HCN ($r^2 = 0.95$), CO and CH₃CN suggest a source of N₂O from burning emissions also contribute to the N₂O enhancement (Fig. 8 and Fig. S12). However, when these contributions are compared with the monthly mean fire contributions from the Global Fire Emissions Database (GFED, <https://www.globalfire.org>), the GFED wildfire contributions are minimal (~0.2 ppb), suggesting fires of anthropogenic origin might be the source of that contribution (Fig. 8A–C, 9, and S11, and S13).

5. Conclusions

Highly resolved N₂O mixing ratios were obtained during the NASA ATom airborne program by applying a new spectral retrieval method to account for the pressure and temperature sensitivity of quantum cascade laser spectrometers when deployed on aircraft. This method improved the precision of our N₂O measurements by a factor of 3, allowing us to recover the precision of N₂O measurements to the level shown in previous aircraft missions.

The N₂O altitude profiles observed during ATom show that tropospheric N₂O variability is strongly driven by the influence of stratospheric air depleted in N₂O, especially at middle and high latitudes. At high latitudes, our profiles showed a strong depleted N₂O signal around the time of the vortex break-up season, persisting for several months. Combining the information from N₂O profiles and other chemical tracers such as CO, SF₆, O₃ and CFC-12 we traced the propagation of stratospheric air along the tropospheric column down to the surface. This transport dominates the N₂O seasonal cycle and creates the seasonal surface minima 2–3 months after the peak stratosphere-troposphere exchange in spring.

The high resolution of this data set (10 s) allowed us to study the factors influencing the enhancements in the N₂O tropospheric mixing ratios associated with biomass burning, human activities such as urban and industrial emissions. The highest N₂O mixing ratios are close to the Equator, extending through the tropospheric column. Episodes of the strongest N₂O enhancements were observed close to the Equator and also in a number of locations at mid-latitudes. We use the information given by the vertical profiles of N₂O and a variety of chemical tracers together with footprints computed every 60 s along the flight track to identify and trace the sources of these N₂O enhancements. N₂O enhancement events were more frequent in the Atlantic than in the Pacific.

Over the Atlantic, excess N₂O together with the co-occurrence of other pollutants suggested that industrial and urban N₂O emissions originated in distant locations such as western and southern Africa, the Middle East, Europe and

485 South America may be significantly greater than the emissions from biomass burning in Africa. This view is supported by our observations of a strong contribution to N₂O from oil and gas emissions from the Niger River Delta in Africa. Possibly the correlations observed between N₂O and SO₂ ($r^2 = 0.90$) could be used to estimate N₂O emissions from oil and gas.

490 Over the southern Pacific Ocean and the tropical Atlantic Ocean, we observed a significant number (>12) of profiles where peaks in N₂O correlated very closely with H₂O₂ and PAA, and notably less well with HCN or CO. Since H₂O₂ and PAA are endpoint products of photochemical pollution, this observation raised the question as to whether significant N₂O may be produced by heterogenous processes involving HONO or NO_x reactions in acidic aerosols close to sources, or in very heavily polluted areas. It is hard to make a definite conclusion based on measurements so far from the most active regions. Studies directed at understanding this question would have to be carried out directly in the polluted areas. Because agricultural activities do not have unique tracer signatures, we were not able to distinguish contributions from cultivated and natural soils to N₂O emissions from the ATom data. Previous airborne studies have observed these inputs, using flights in the main agricultural areas (Kort et al, 2008), and at towers in these regions (e.g., Nevison et al, 2017; Miller et al., 2008).

500 Our study shows that airborne campaigns such as ATom can help trace the origins of biomass burning and industrial emissions and investigate their impact on the variability of tropospheric N₂O, providing unique signatures in vertical profiles and with covariate tracers. We hope that the information provided by the global, highly resolved N₂O profiles from the ATom mission will help better diagnose and reduce uncertainties of atmospheric chemical transport models for constraining the N₂O global budget.

795

800

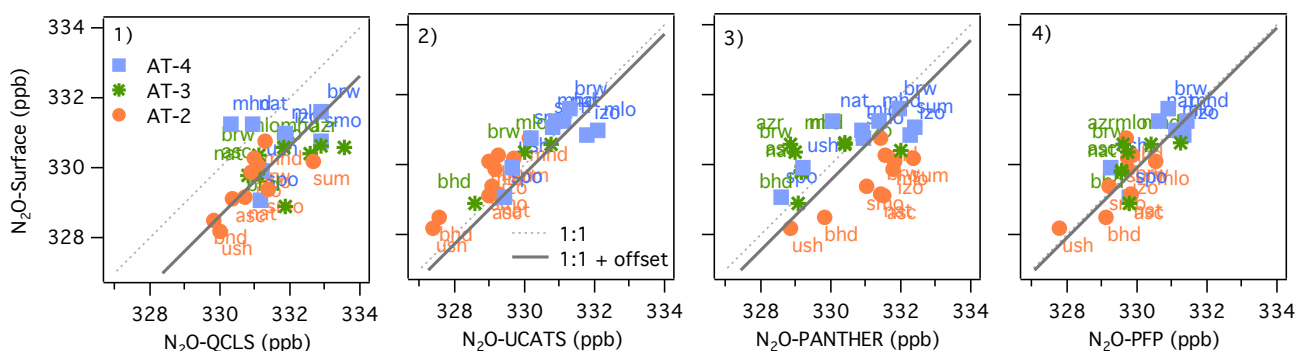

Figure 1: (a) A processed spectral array from the ATom-4 flight on 12 May 2018. “Channel” represents a point number in the spectra. Spectra have been grouped by type (i.e., calibration, ambient), with averages subtracted, absorption lines zeroed out (near channels 75, 140, and 225), and smoothed to close to the linewidth. Shifts in fringe phases during altitude changes are apparent. (b) Time series of ambient air samples, high-span, low-span, and zeros for the same flight as (a). Green dots are the original N_2O data record. Black dots are the N_2O data corrected with Neptune (no calibration applied at this point).

(a) Aircraft Instrument Comparison

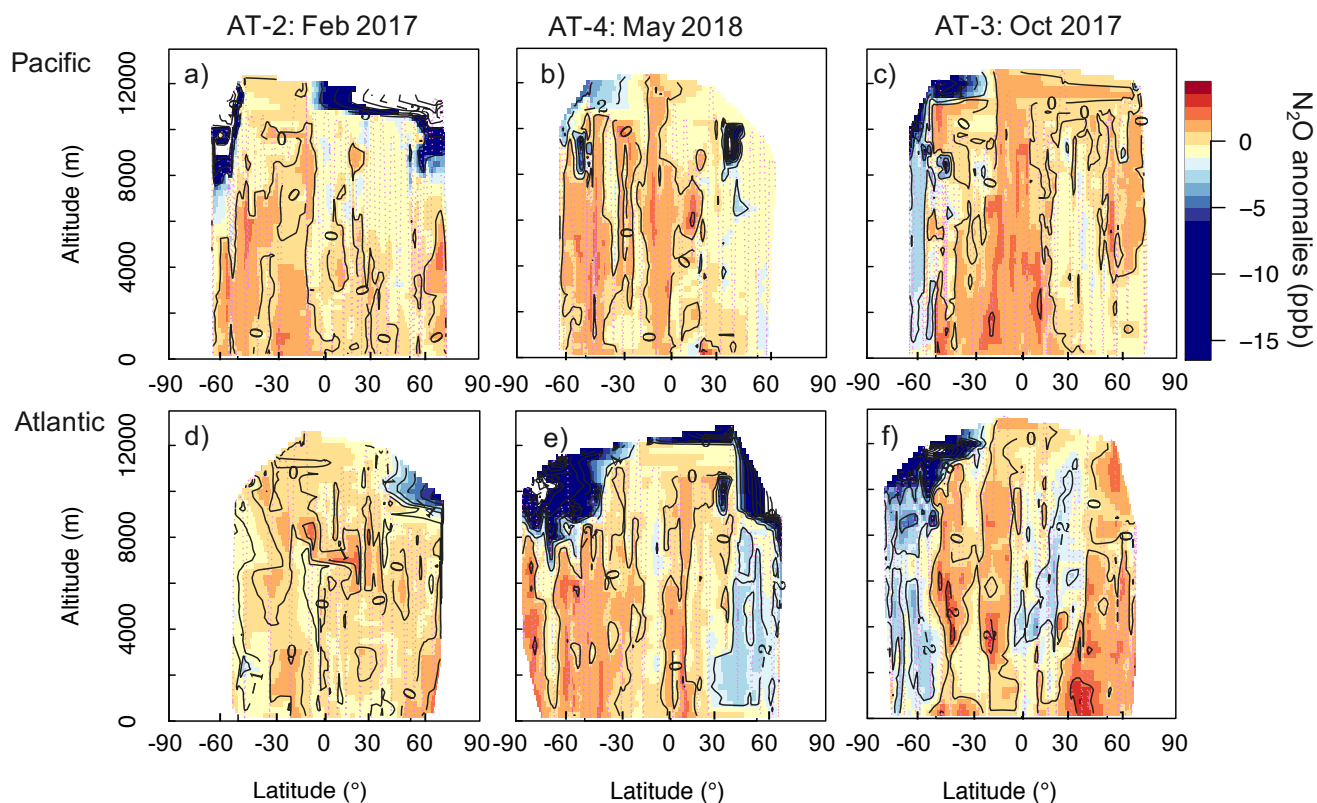

(b) Aircraft Instrument vs Surface Comparison

805

Figure 2: (a) Comparisons between Neptune-corrected QCLS N_2O and (1) UCATS N_2O , (2) PANTHER N_2O , and (3) PFP N_2O for ATom-2 (orange circles), ATom-3 (green stars), and -4 (blue squares). We used the 10s averaged merged file to compare QCLS, UCATS and PANTHER data. PFP instrument has a longer sampling time (30s to few minutes). The 1:1 line is shown as a dashed line. (b) Comparisons between NOAA N_2O surface flask measurements and Neptune-corrected and airborne data from (d) QCLS N_2O , (e) UCATS N_2O , (f) PANTHER N_2O , (g) and PFP N_2O for ATom-2, -3, and -4, similar to (a)–(c). The solid line shows the 1:1 relationship + offset. For (d)–(g) plots, the airborne data are the mean N_2O values within $\pm 5^\circ$ latitude of each surface station and between 1 and 4 km.

810

815

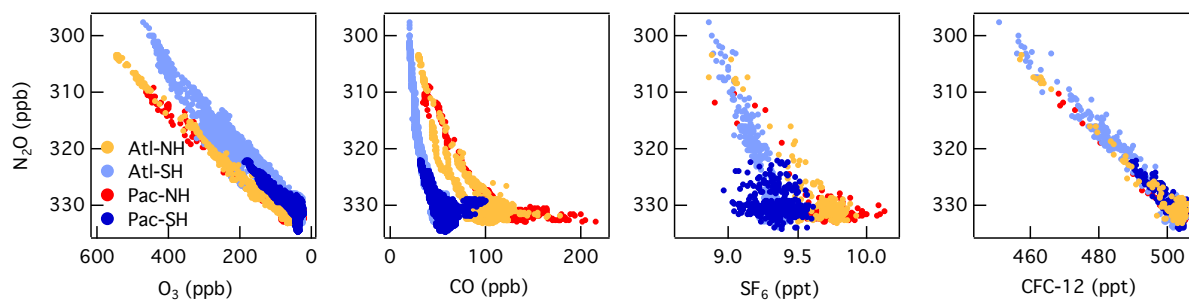

820

Figure 3: Cross-sections of N_2O anomalies (ppb), representing the differences between the airborne N_2O (10-s resolution) and the surface N_2O mixing ratios interpolated to 0.25° latitude and 250 m altitude for each deployment. Shown are the N_2O anomalies over (a)–(c) the Pacific and (d)–(f) the Atlantic, and each column represents a deployment (ordered by season, ATom-2, -4 and -3). The color-scale ranges from -15 to 5 ppb. Values between -50 and -15 ppb, observed at the highest altitudes (>10 km) are shown in white for a better visualization of small changes in positive anomalies. Lilac dashed lines represent the flight tracks. Black contours are areas of the N_2O anomalies.

825

(a) Tracer-Tracer correlations in the Northern Hemisphere Middle and High latitudes during Spring (AT-4)

(b) Pot. Vorticity vs N_2O and CFC-12 anomalies (AT-4)

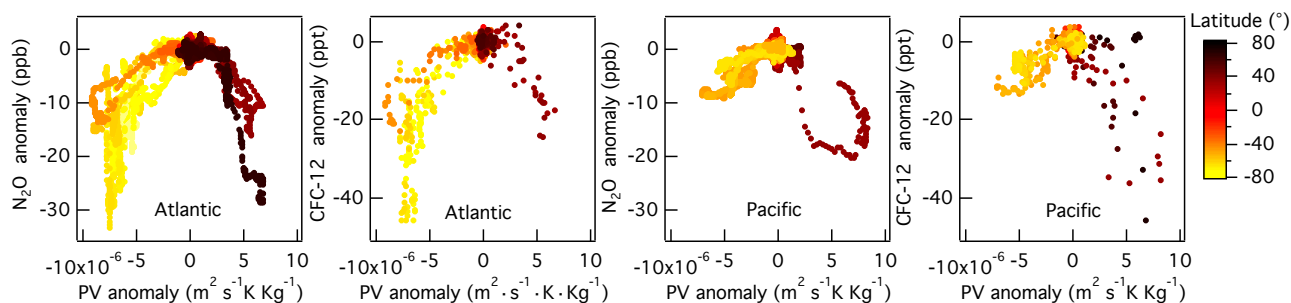

Figure 4: (a) Correlations between N_2O and (a) O_3 , (b) CO , (c) SF_6 , and (d) $CFC-12$ at mid and high latitudes (30° – 85° N) during NH spring (ATom-4). The data are colored as a function of the ocean basin and hemisphere: Pacific North Mid-High Latitudes (Pac-NH, $>30^{\circ}$ N) in red, Pacific South Mid-High Latitudes (Pac-SH, $<30^{\circ}$ S) in dark blue, Atlantic South Mid-High Latitudes (Atl-SH, $<30^{\circ}$ S) in light blue and Atlantic North Mid-High Latitudes (Atl-NH, $>30^{\circ}$ N) in orange. Note that the N_2O and O_3 axes are reversed. (b) Correlations between anomalies in potential vorticity relative to its mean latitudinal distribution in the free troposphere (2–8 km) and anomalies in N_2O and $CFC-12$ as a function of latitude during spring (ATom-4) over the Pacific and Atlantic basins. Mid-latitudes are shown in orange in the SH and clear brown in the NH.

830

835

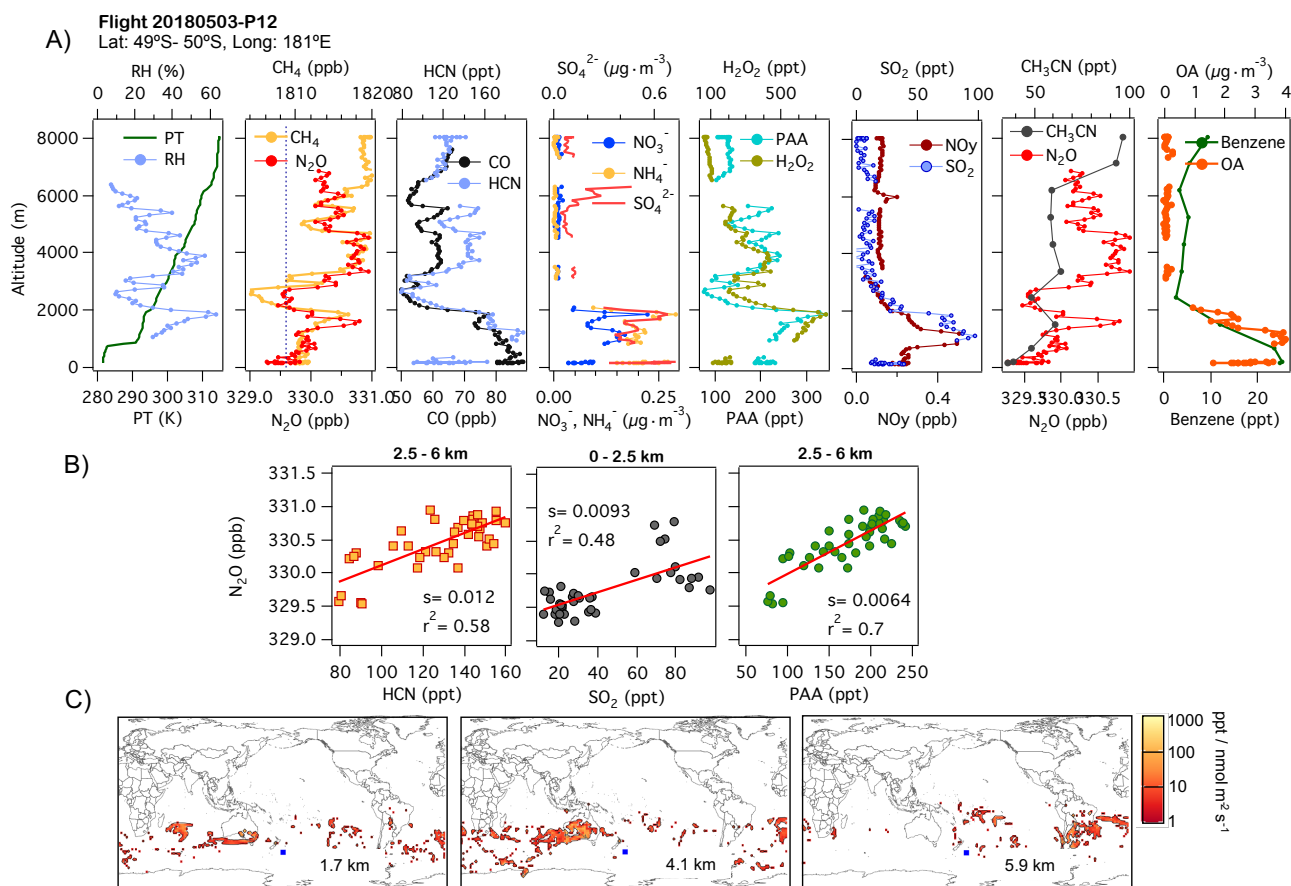

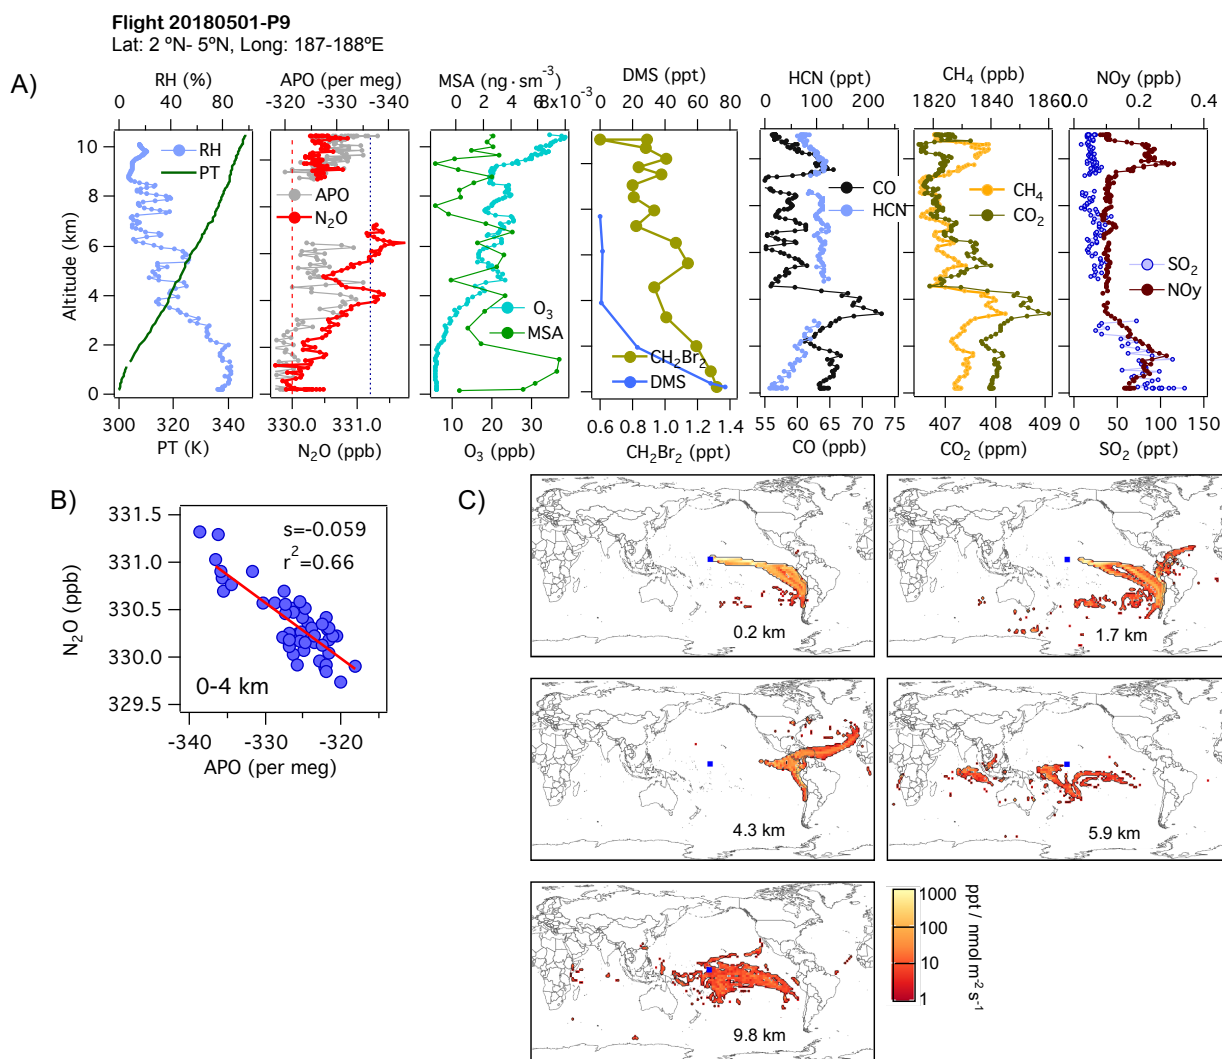

Figure 5: (a) Vertical profiles of Potential Temperature (PT), Relative Humidity (RH), N_2O , CH_4 , CO , HCN , NO_3^- , NH_4^+ , SO_4^{2-} , H_2O_2 , PAA ($\text{CH}_3\text{C}(\text{O})\text{OOH}$), SO_2 , NO_y , CH_3CN , benzene and organic aerosols (OA) from profile 12 on 3 May 2018. Dotted blue line in plot A2 represents the NOAA-MBL reference (N_2O -MBL) at the latitude of the flight. (b) Correlations between N_2O and HCN and PAA for altitudes between 2.5 and 6 km and between N_2O and SO_2 for altitudes between 0 and 2.5 km indicate an admixture of marine, biomass burning, urban sources, and oil and gas industry contributions to N_2O mixing ratios (s represents the slope of the linear fit). (c) Footprint maps tracing surface regions influencing mixing ratios measured at the altitude ranges of 1–2, 2.5–5 and 5–7 km, respectively. Blue squares show the sample locations. Values below 3 $\text{ppt} / (\text{nmol m}^{-2} \text{s}^{-1})$ are not included.

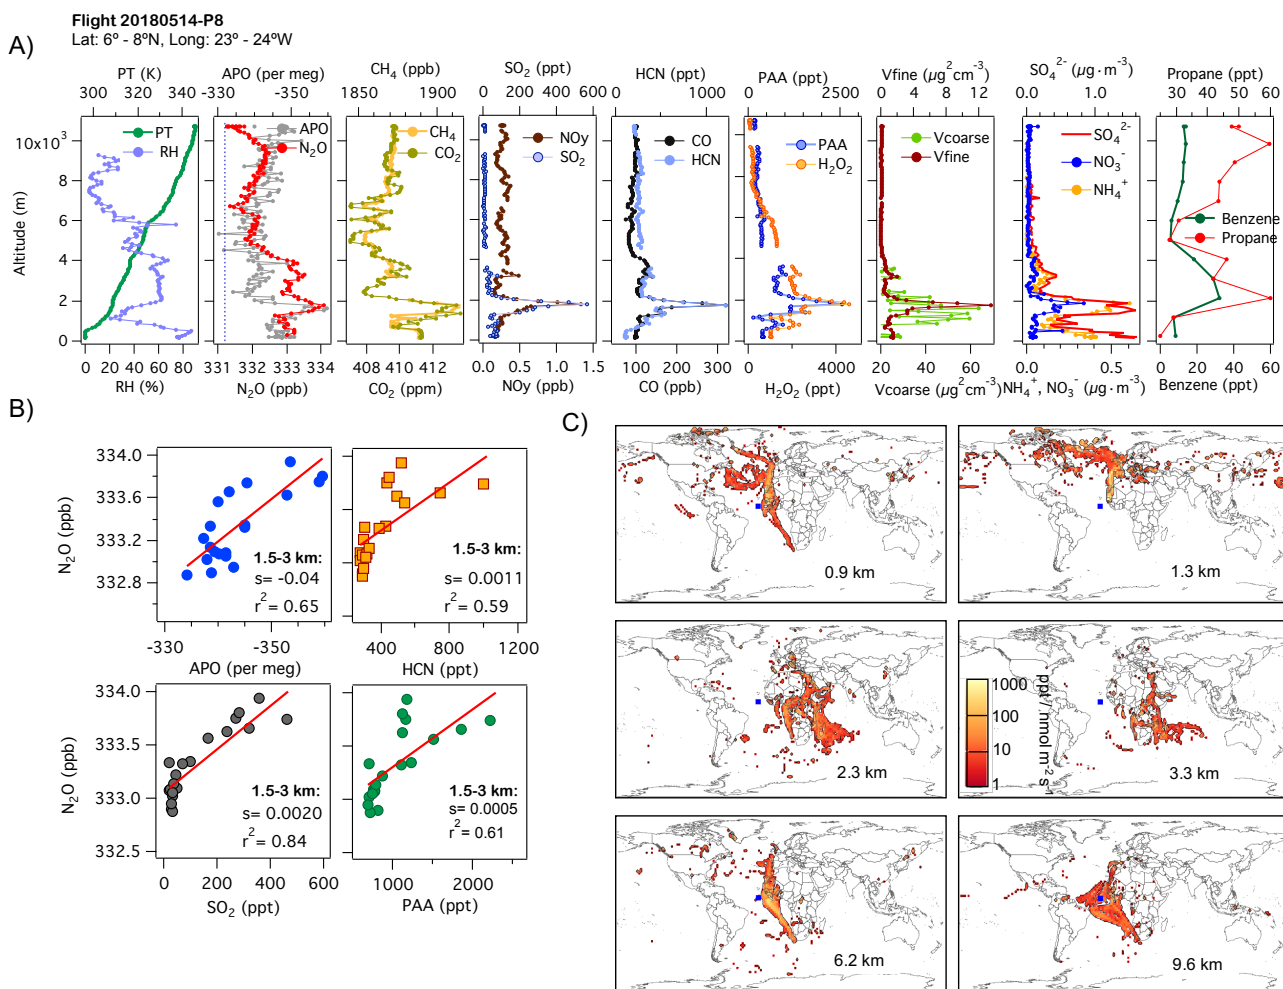

840

845

850

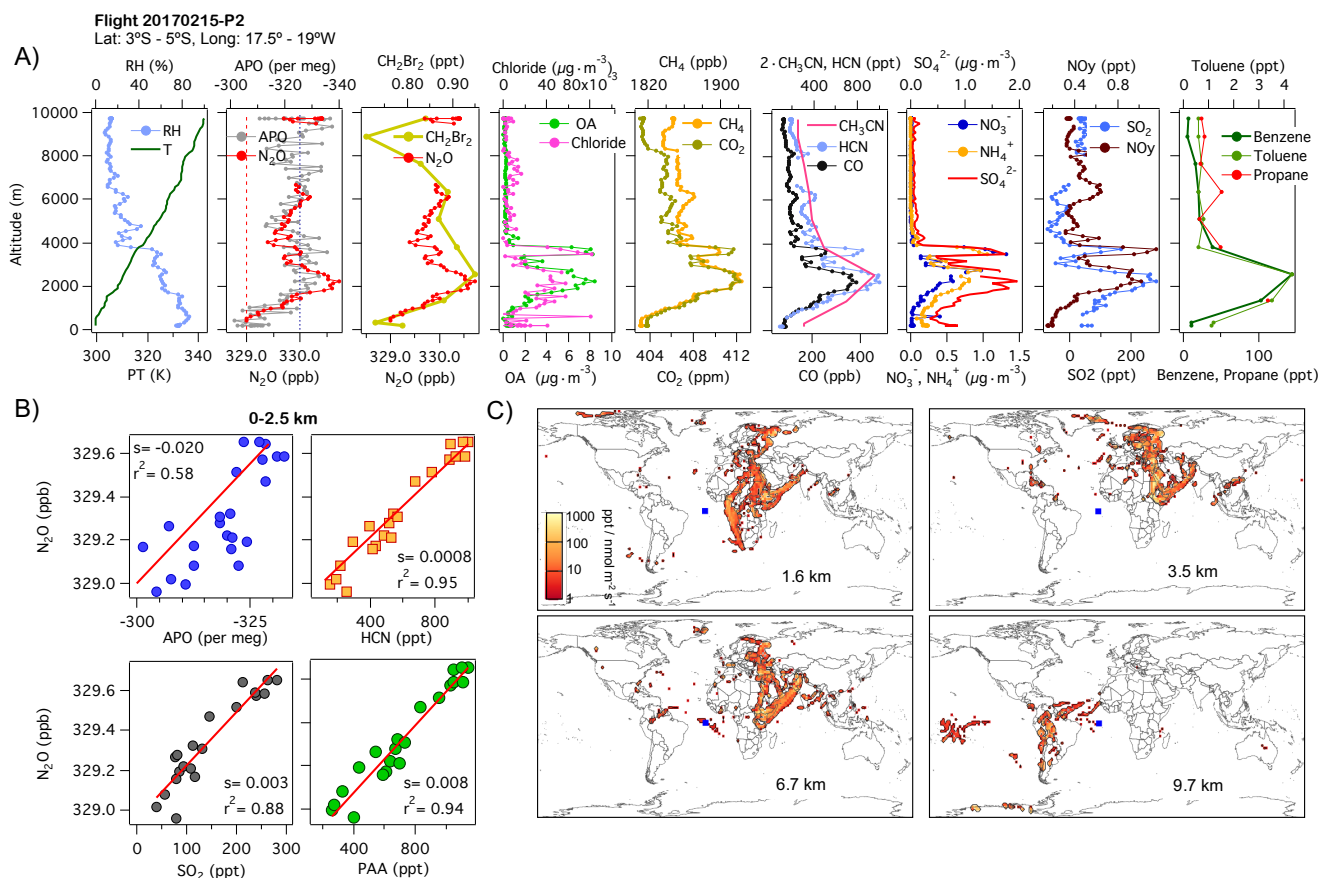

Figure 6: (a) Vertical profiles of PT and RH and tracers, N_2O , APO, O_3 , MSA, CH_2Br_2 , DMS, CO, HCN, CH_4 , CO_2 , SO_2 and NO_y , corresponding to profile 9 on 1 May 2018. Dotted blue line in plot A2 represents the NOAA-MBL reference (N_2O -MBL) at the latitude of the flight. Dashed red line shows the N_2O -MBL at the origin of the airmasses suggested by the footprints (25°S). (b) N_2O - APO correlations between 0 and 4 km possibly describing the latitudinal gradient of N_2O (s represents the slope of the linear fit). (c) Footprint maps tracing surface regions influencing mixing ratios measured at the altitude ranges of 0–2, 2–4, 3–5, 5–7 and 9–11 km, respectively. Blue squares show the sample locations. Values below 3 ppt / $\text{nmol}^{-1} \text{m}^{-2} \text{s}^{-1}$ are not included. Note that the APO axes are reversed.

Figure 7: (a) Vertical profiles of PT, RH, and tracers, N_2O , APO, organic aerosol (OA), chloride, CO_2 , CH_4 , HCN, CO, SO_2 , NO_y , NO_3^- , NH_4^+ , SO_4^{2-} , benzene and propane to profile 8 on 14 May 2018. Dotted blue line in plot A2 represents the NOAA-MBL reference (N_2O -MBL) at the latitude of the flight. (b) Correlations between N_2O and APO, HCN, SO_2 , and propane between 1 and 3 km show possible contributions from marine upwelling, biomass burning and oil and gas industry, supported by the footprints (s represents the slope of the linear fit). (c) Footprint maps tracing surface regions influencing mixing ratios measured at the altitude ranges of 0–1, 2–4, 4–5, 5–7 and 7–10 km, respectively. Blue square shows the sample point. Values below 3 ppt / $\text{nmol m}^{-2} \text{s}^{-1}$ are not included. Note that the APO axes are reversed.

865 **Figure 8: (a)** Vertical profiles of PT, RH, and tracers, N₂O, APO, CH₂Br₂, organic aerosol (OA), non-refractory chloride, CO₂, CH₄, HCN, CO, CH₃CN, NO₃⁻, NH₄⁺, SO₄²⁺, SO₂, NO_y, benzene and propane, corresponding to profile 2 on 15 February 2017. Dotted blue line in plot A2 represents the NOAA-MBL reference (N₂O-MBL) at the latitude of the flight, and red dashed line shows the NOAA-MBL at the origin of the southern airmasses shown by the footprints below 2 km (20°S). (b) Correlations between N₂O and APO, HCN and SO₂, and N₂O and PAA, indicate an admixture of marine, biomass burning, urban sources, and oil and gas industry contributions to N₂O mixing ratios (s represents the slope of the linear fit). (c) Footprint maps tracing surface regions influencing mixing ratios measured at the altitude ranges of 0–2, 2–3, 3–4 and 4–7 km, respectively. Blue squares show the sample point. Values below 3 ppt / nmol m⁻² s⁻¹ are not included in the footprint plot. Note that APO axes are reversed.

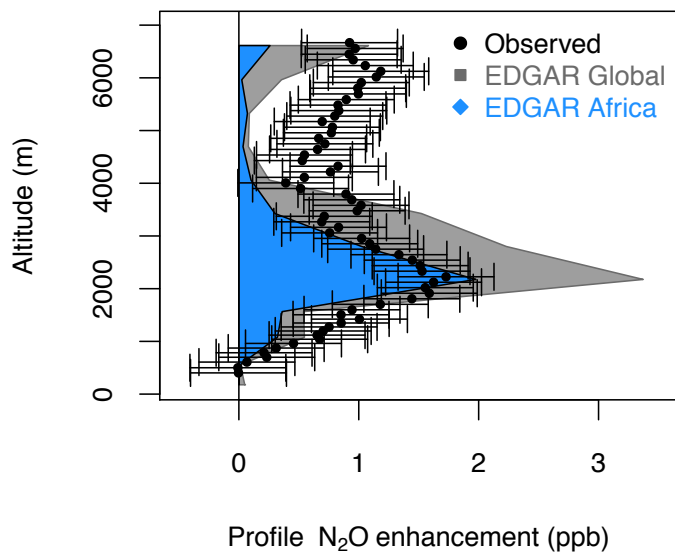

Figure 9. N₂O enhancements estimated by EDGAR for the globe (grey polygons) and for the African region (blue polygons) and the observed QCLS-N₂O enhancement relative to the NOAA-MBL N₂O reference at the origin of the southern airmasses shown by the footprints below 2 km for the profile 2017/02/15-P2 (20°S, 329 ppb).
