**Abstract.** Secondary organic aerosols (SOA) are major components of atmospheric fine particulate matter, affecting climate and air quality. Mounting evidence exists that SOA can adopt glassy and viscous semisolid states, impacting formation and partitioning of SOA. In this study, we conduct explicit modeling of isoprene photooxidation and  $\alpha$ -pinene ozonolysis and subsequent SOA formation using the GECKO-A (Generator of Explicit Chemistry and Kinetics of Organics in the Atmosphere) model. Our recently-developed parameterizations to predict glass transition temperature of organic compounds are implemented into a box model with explicit gas-phase chemical mechanisms to simulate viscosity of SOA. The effects of chemical composition, relative humidity, mass loadings and mass accommodation on particle viscosity are investigated in comparison with measurements of SOA viscosity. The simulated viscosity of isoprene SOA agrees well with viscosity measurements as a function of relative humidity, while the model underestimates viscosity of  $\alpha$ -pinene SOA by a few orders of magnitude. This difference may be due to missing processes in the model including gas-phase dimerization and particle-phase reactions leading to the formation of high molar mass compounds that would increase particle viscosity. Additional simulations imply that kinetic limitations of bulk diffusion and reduction in mass accommodation coefficient may also play a role in enhancing particle viscosity by suppressing condensation of semi-volatile compounds. The developed model is a useful tool for analysis and investigation of the interplay among gas-phase reactions, particle chemical composition and SOA phase state.

## 1 Introduction

Secondary organic aerosols (SOA) are ubiquitous in the atmosphere and represent a major component of fine particulate matter, affecting air quality, climate and public health (Jimenez et al., 2009; Pöschl and Shiraiwa, 2015). Due to their complexity, SOA represent a large source of uncertainty in current understanding of global climate change and air pollution (Tsigaridis et al., 2014; Ciarelli et al., 2019). Development of SOA models represents one of the most challenging and demanding problems in atmospheric chemistry (Shrivastava et al., 2017). Formation of SOA is initiated by gas-phase oxidation of biogenic and anthropogenic volatile organic compounds (VOC) (Kroll and Seinfeld, 2008). Typically, multigenerational oxidation of VOC in the gas phase leads to the formation of a myriad of semi-volatile and low volatility compounds which can condense on pre-existing particles (Ziemann and Atkinson, 2012; Nozière et al., 2015) or contribute to nucleation and new particle formation

(Tröstl et al., 2016). As gas-phase oxidation is often regarded as the rate-limiting step of SOA formation, there is a strong need for a computational tool enabling to generate exhaustive gas-phase chemical mechanisms. The GECKO-A (Generator of Explicit Chemistry and Kinetics of Organics in the Atmosphere) model is to-date the most extensive generator of gas-phase chemical schemes; based on established reaction pathways and structure-activity relationships, it automatically generates detailed gas-phase mechanisms involving thousands-to-millions of oxidation products from a given VOC precursor (Aumont et al., 2005, 2012; Lee-Taylor et al., 2011).

Most aerosol models treat SOA particles as homogeneous and well-mixed liquids with a dynamic viscosity ( $\eta$ ) below  $10^2$  Pa s. Recent studies provide accumulating evidence that SOA can adopt glassy solid ( $\eta \geq 10^{12}$  Pa s) or amorphous semi-solid phase states ( $10^2 \leq \eta < 10^{12}$  Pa s) depending on chemical composition, relative humidity (RH), and temperature (Koop et al., 2011; Virtanen et al., 2010; Reid et al., 2018). The particle phase state is impacted by SOA chemical composition, hygroscopicity and water content. Notably, water can act as a plasticizer lowering SOA viscosity (Mikhailov et al., 2009). It has been observed that ambient SOA particles can bounce off from an impactor stage depending on ambient conditions, indicating non-liquid states of organic particles (Virtanen et al., 2011; Bateman et al., 2017; Slade et al., 2019). Measurements of the viscosity of SOA bulk materials derived from the oxidation of limonene (Hinks et al., 2016), toluene (Song et al., 2016),  $\alpha$ -pinene (Renbaum-Wolff et al., 2013; Kidd et al., 2014; Bateman et al., 2015; Zhang et al., 2015; Grayson et al., 2016; Hosny et al., 2016) and isoprene (Song et al., 2015) have confirmed that viscosity of SOA particles can vary depending on temperature and RH (Petters et al., 2019). In addition, previous studies have shown that SOA chemical composition can be affected by experimental conditions upon SOA formation such as RH and particle mass concentrations (Kidd et al., 2014; Hinks et al., 2016; Grayson et al., 2016; Jain et al., 2018). These results imply that SOA viscosity and phase state are dynamic properties in response to chemical processing of organic aerosols and variations in RH and temperature in the atmosphere.

In liquid particles, molecules diffuse fast in the particle bulk, leading to rapid establishment of gas-particle equilibrium. In glassy and viscous particles, kinetic limitations of bulk diffusion can significantly retard gas-particle partitioning, prolonging equilibration timescales (Li and Shiraiwa, 2019; Mai et al., 2015; Vaden et al., 2011), while relatively fast particle-particle mixing were observed at intermediate and high RH (Ye et al., 2016, 2018). Model simulations suggest that an assumption of instantaneous equilibrium partitioning can result in substantial overestimation of particle mass concentration and underestimation of gas-phase mass concentration (Shiraiwa et al., 2012). A proper consideration of particle phase state is essential for simulating particle size distribution dynamics in SOA growth (Shiraiwa et al., 2013; Zaveri et al., 2018, 2020). Heterogeneous and multiphase reactions (Kuwata and Martin, 2012; Shiraiwa et al., 2011; Davies and Wilson, 2015; Zhang et al., 2018; Marshall et al., 2018; Zhou et al., 2019) as well as activation to cloud droplets and ice crystals (Slade et al., 2017; Knopf et al., 2018) can also be impacted by glassy and amorphous semisolid states. Thus, it is important to consider the effects of particle phase state on SOA processes for accurate representation of the fate of SOA particles in aerosol models.

Recently, we have developed parameterizations to predict glass transition temperature ( $T_g$ ) of organic compounds based on molar mass and atomic O:C ratio (Shiraiwa et al., 2017), elemental composition (i.e., number of carbon, hydrogen, oxygen, nitrogen, and sulfur) (DeRieux et al., 2018), and volatility (Li et al., 2020).  $T_g$  is a characteristic temperature at which a phase transition from a glassy solid state to an amorphous semi-solid state occurs (Koop et al., 2011). Applying the Gordon-Taylor

mixing rule for mixtures of SOA multiple components and water, the viscosity of SOA can be estimated by the  $T_g$ -scaled Arrhenius plot of viscosity (DeRieux et al., 2018). This method has been successfully applied to estimate particle viscosity based on elemental composition obtained from high resolution mass spectrometry (Schum et al., 2018; Ditto et al., 2019; Song et al., 2019).

In this study, the  $T_g$  and viscosity prediction methods are implemented into the GECKO-A and box model. Model simulations with explicit chemical mechanisms are conducted to reproduce chamber experimental conditions for SOA generation and subsequent viscosity measurements. The effects of chemical composition and mass accommodation on SOA partitioning and viscosity are also investigated. The objective of this work is to expand our understanding on the relationship and interplay among gas-phase reactions, chemical composition and viscosity of SOA.

## 2 Methods

### 2.1 GECKO-A

GECKO-A generates detailed gas-phase chemical oxidation schemes and the associated gas-particle mass transfers for SOA formation. It produces explicit highly detailed chemical mechanisms starting from experimental data and structure-activity relationships (SARs) (Aumont et al., 2005). Implemented into a box model, these explicit chemical mechanisms simulate the oxidation of parent VOC precursors to oxidation products, their subsequent gas-phase chemistry, as well as partitioning into the particle phase based on their vapor pressures. The chemical mechanism does not account for gas-phase chemistry of species with vapor pressure below  $10^{-13}$  atm, which are assumed to be of enough low volatility to partition to the condensed phase. In our simulations, species vapor pressures are estimated via the approach by Nannoolal et al. (Nannoolal et al., 2008).

The mechanism generator follows a reduction protocol optimizing the number of generated reactions and chemical species (Valorso et al., 2011). This protocol has been established to reduce the computational cost of box-model simulations. In the gas phase, isomer substitution is not allowed for position isomers when the overall yield for the product is  $> 5\%$ ; otherwise only the highest-yield positional isomer is considered. For each reaction, pathways with branching ratios  $< 5\%$  are not accounted for and the main reaction branches are scaled proportionally (Valorso et al., 2011). The chemical mechanism accounts for chemistry of peroxy and alkoxy radicals generated during precursors oxidation. SOA chemistry is a multi-generational process and in our simulations the generated chemical schemes follow the chemistry of reaction products up to the 5th generation. The GECKO-A version used in this study has been recently enriched with SARs estimations of alkoxy radical decomposition and H-migration reaction rates (Vereecken and Peeters, 2009; La et al., 2016). Rate coefficients and branching ratios for gas-phase reactions of OH with aliphatic compounds and peroxy radicals are estimated based on recent SAR investigations (Jenkin et al., 2018a,b). Our simulations do not include autooxidation and condensed-phase chemistry, which represent limitations of GECKO-A modeling.

$\alpha$ -pinene and isoprene oxidation mechanisms have been investigated extensively both in model and experimental studies. Their oxidation mechanisms are well known, providing good estimations of resulting SOA composition. The SARs for both  $\alpha$ -pinene and isoprene oxidation are implemented into GECKO-A with state-of-the-art protocols estimating radical reactions

and respective rate constants. The base mechanism for  $\alpha$ -pinene photooxidation and ozonolysis include a detailed description of reactions with OH radicals (McVay et al., 2016), and branch reactions identified via quantum and theoretical chemical calculations (Peeters et al., 2001; Vereecken et al., 2007). Stabilized Criegee intermediates (SCIs) chemistry is not treated explicitly and stable products are directly assigned via a rule-based method. This scheme accounts for a direct reaction route to account for pinonaldehyde formation during the reaction of SCIs with water (McVay et al., 2016). The GECKO-A isoprene oxidation scheme follows the main protocol developed by Aumont et al. (Aumont et al., 2005) and branching reactions for isoprene + OH are also considered (Paulot et al., 2009). The chemical schemes for  $\alpha$ -pinene and isoprene oxidation are composed of 84,000 and 1,900 species, and of  $\sim 700,000$  and  $\sim 17,000$  reactions, respectively.

## 2.2 Box model and simulations setup

Each chemical mechanism is coupled to a box model representing SOA formation from  $\alpha$ -pinene or isoprene oxidation in specific chamber experiments. The time evolution of species concentration is computed through a two-step method that explicitly solves stiff ordinary differential equations (Verwer, 1994; Verwer et al., 1996). The experimental conditions are summarized in Table 1. All laboratory experiments were performed in absence of seed particles, but the box model used in our simulations does not treat nucleation. Thus, in our simulations the first steps of nucleation are approximated by the addition of seed particles with a particle radius of 5 nm and a concentration of  $10^4$  particles  $\text{cm}^{-3}$  (McVay et al., 2016). It is assumed that the density of SOA particles is  $1.2 \text{ g cm}^{-3}$  (Kuwata and Martin, 2012). The particle number concentration is also assumed to remain constant during simulations, while the particle radius evolves following the partitioning of organics. All simulations are conducted with a NO<sub>x</sub> mixing ratio of 3 ppt to reflect low NO<sub>x</sub> conditions of chamber and flow tube experiments. For all simulations we consider reversible gas-wall partitioning of organic species with the vapor wall loss rate of  $10^{-3} \text{ s}^{-1}$  based on experimental observations (Lim and Ziemann, 2009; McVay et al., 2016). Photolysis rates are computed using the cross-sections and the quantum yields from Aumont et al. (Aumont et al., 2005). Photolysis conditions are set to average daylight conditions of a mid-latitude spring day for isoprene photooxidation simulations and to zero for  $\alpha$ -pinene dark ozonolysis experiments, coherent with the experimental conditions.

For continuous flow reactor experiments, the concentrations of VOC precursors and oxidants were stable by continuous inflow and outflow of gases from the tube reactor; in the box model simulations precursor concentrations are fixed at steady state values as measured in corresponding experiments. In chamber batch experiments, the reactants were injected once at the beginning of the experiment and the concentrations evolved; in box model simulations the VOC precursor and ozone concentrations are initially set to the respective experimental values and species concentrations evolve due to gas oxidation, gas-particle partitioning, and wall deposition. SOA particles were formed under dry conditions and then SOA were exposed to water vapor at different RH for viscosity measurements. For each set of simulations, the measured RH and temperature were used to constrain the simulation conditions. Note that partitioning of water is not considered in the box model as particle water uptake should be very minor under the very low RH values at which SOA particles were formed.

The box model treats the mass transfer of gaseous organic species to particles and to chamber walls. Gas-particle partitioning is assumed to follow Raoult's law at equilibrium (La et al., 2016) (i.e., depending on the saturation vapor pressure of the

organic compounds assuming ideal mixing). Gas to particle partitioning is described in the box model using the gas-particle mass transfer coefficient of a compound ( $k_{gp}$ , in  $s^{-1}$ ) with the Fuchs-Sutugin approach in the transition regime as (Seinfeld and Pandis, 2016):

$$k_{gp} = 4\pi D_g r_p N_p \beta \quad (1)$$

$$\beta = \frac{0.75\alpha(1 + K_n)}{K_n^2 + K_n + 0.283K_n\alpha + 0.75\alpha} \quad (2)$$

where  $D_g$  ( $cm^2 s^{-1}$ ) is the gas diffusivity,  $r_p$  (cm) is the particle radius,  $N_p$  ( $cm^{-3}$ ) is the particle number concentration,  $K_n$  is the Knudsen number, and  $\alpha$  is the mass accommodation coefficient.  $\alpha$ , also termed as the bulk accommodation coefficient, represents the probability for a gas molecule colliding with surface to enter the bulk of the particle. Based on recent experiments and molecular dynamics simulations  $\alpha$  is assumed to be unity for the base case scenario of our simulations (Liu et al., 2019; Julin et al., 2014). This approach does not account for potential kinetic limitations caused by bulk diffusion in viscous particles.

A recent study has introduced an effective mass accommodation coefficient  $\alpha_{eff}$ , which effectively considers the kinetics of accommodation at the surface, transfer across the gas-particle interface, and further transport into the particle bulk (Shiraiwa and Pöschl, 2021):

$$\alpha_{eff} = \alpha_s \frac{1}{1 + \frac{\alpha_s \omega C_0}{4D_b \rho_p} \cdot \frac{r_p}{5} 10^{-12} \frac{g \cdot cm^{-3}}{\mu g \cdot m^{-3}}} \quad (3)$$

140 where  $\alpha_s$  is the surface accommodation coefficient (i.e., the probability for a gas molecule colliding with surface to adsorb on the particle surface),  $\omega$  ( $\text{cm s}^{-1}$ ) is the mean thermal velocity of the organic compound in the gas phase,  $D_b$  ( $\text{cm}^2 \text{s}^{-1}$ ) is diffusivity in the condensed phase,  $\rho_p$  ( $\text{g cm}^{-3}$ ) is the particle density, and  $C_0$  ( $\mu\text{g m}^{-3}$ ) is the pure compound saturation mass concentration. Application of  $\alpha_{\text{eff}}$  in the Fuchs-Sutugin approach (e.g.,  $\alpha = \alpha_{\text{eff}}$ ) yields SOA partitioning with effective consideration of kinetic limitations induced by slow bulk diffusion in viscous particles. This approach can yield consistent results with a detailed kinetic multilayer model (KM-GAP, Shiraiwa et al., 2012) and two-film model solutions (Zaveri et al., 2014). We implement this method to explore the effects of mass accommodation and kinetic partitioning on predicted viscosity by comparing with the base case scenario (e.g.,  $\alpha$  fixed to 1).

### 2.3 Viscosity prediction implementation

The glass transition temperature of an organic compound  $i$  ( $T_{g,i}$ ) can be estimated with the following recently-developed parameterization based on its elemental composition (DeRieux et al., 2018).

$$T_{g,i} = (n_C^0 + \ln(n_C))b_C + b_H \cdot \ln(n_H) + b_{CH} \cdot \ln(n_C) \cdot \ln(n_H) + b_O \cdot \ln(n_O) + b_{CO} \cdot \ln(n_C) \cdot \ln(n_O) \quad (4)$$

Where the coefficient values for  $[n_C^0, b_C, b_H, b_{CH}, b_O, \text{ and } b_{CO}]$  are  $[1.96, 61.99, -113.33, 28.74, 0, 0]$  for CH compounds and  $[12.13, 10.95, -41.82, 21.61, 118.96, -24.38]$  for CHO compounds. We have also included the recently developed parametrization for CHON compounds by Li et al. (Li et al., 2020):

$$155 \quad T_{g,i} = (n_C^0 + \ln(n_C))b_C + \ln(n_O)b_O + \ln(n_N)b_N + \ln(n_C)\ln(n_O)b_{CO} + \ln(n_C)\ln(n_N)b_{CN} + \ln(n_O)\ln(n_N)b_{ON} \quad (5)$$

Where the coefficient values for  $[n_C^0, b_C, b_O, b_N, b_{CO}, b_{CN}, b_{ON}]$  are  $[5.34, 31.53, -7.06, 134.96, 6.54, -34.36, \text{ and } -15.35]$ . These parametrizations can predict  $T_{g,i}$  with an uncertainty of about  $\pm 30$  K; note that, however, in multicomponent SOA mixtures this uncertainty would be much smaller for ideal mixing conditions (Shiraiwa et al., 2017; DeRieux et al., 2018; Li et al., 2020). The  $T_g$  of a mixture of organic compounds (e.g. dry SOA) can be estimated using the Gordon-Taylor equation with a Gordon-Taylor constant ( $k_{GT}$ ) of 1:  $T_{g,\text{org}} = \sum_i \omega_i T_{g,i}$ , where  $\omega_i$  is the mass fraction of compound  $i$  (Dette et al., 2014).

The Gordon-Taylor equation can also be used to estimate the glass transition temperature of mixtures of organic compounds and water ( $T_g(w_{\text{org}})$ ):

$$T_g(w_{\text{org}}) = \frac{(1 - w_{\text{org}}) \cdot T_{g,w} + \frac{1}{k_{GT}} \cdot w_{\text{org}} T_{g,\text{org}}}{(1 - w_{\text{org}}) + \frac{1}{k_{GT}} \cdot w_{\text{org}}} \quad (6)$$

where  $w_{\text{org}}$  is the mass fraction of organics,  $T_{g,w}$  is the glass transition temperature of pure water (136 K), and  $k_{GT}$  is the Gordon-Taylor constant which is assumed to be 2.5 (Koop et al., 2011; Zobrist et al., 2008). The  $w_{\text{org}}$  is calculated using the

mass concentration of water ( $m_{\text{H}_2\text{O}}$ ) and of the organics in SOA ( $m_{\text{SOA}}$ ) as:  $w_{\text{org}} = m_{\text{SOA}} / (m_{\text{SOA}} + m_{\text{H}_2\text{O}})$ .  $m_{\text{H}_2\text{O}}$  can be calculated using the Kohler theory with effective hygroscopicity parameter ( $\kappa$ ) (Petters and Kreidenweis, 2013).

Once  $T_{\text{g}}(w_{\text{org}})$  has been computed, the viscosity ( $\eta$ ) can be derived with the following equation based on the Vogel-Tammann-Fulcher approach (DeRieux et al., 2018):

$$\log(\eta) = -5 + 0.434 \cdot \frac{T_0 D}{T - T_0} \quad (7)$$

$$T_0 = \frac{39.17 \cdot T_{\text{g}}(w_{\text{org}})}{D + 39.17} \quad (8)$$

where  $T_0$  is the Vogel temperature and  $D$  is the fragility parameter. The  $D$  value is assumed to be 10 based on previous studies (Shiraiwa et al., 2017; DeRieux et al., 2018).

Viscosity can then be converted into bulk diffusivity using the Stokes-Einstein equation:

$$D_{\text{b}} = \frac{kT}{6\pi a\eta} \quad (9)$$

where  $k$  is the Boltzmann constant ( $1.38 \times 10^{-23} \text{ J K}^{-1}$ ),  $T$  is the temperature (K), and  $a$  is the effective molecular radius (m). This relation, however, may not be accurate for very high viscosities and needs to be corrected with the fractional Stokes-Einstein (FSE) relation (Evoy et al., 2019):

$$D_{\text{b}} = D_{\text{b},c} \cdot \left( \frac{\eta_c}{\eta} \right)^{\xi} \quad (10)$$

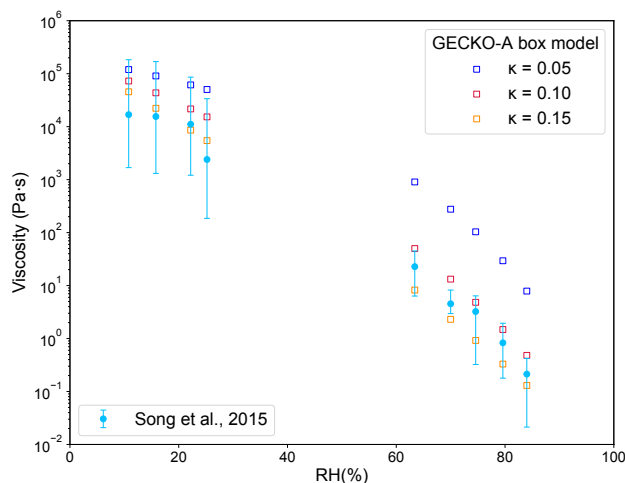

where  $\xi$  is an empirical fit parameter with the value of 0.93 (Evoy et al., 2019),  $\eta_c$  is the crossover viscosity with the value of  $10^{-3} \text{ Pa s}$ , and  $D_{\text{b},c}$  is the crossover diffusion coefficient at  $\eta_c = 10^{-3} \text{ Pa s}$  as determined by the Stokes-Einstein equation (9).

### 3 Results

#### 3.1 Viscosity predictions of isoprene and $\alpha$ -pinene SOA

Figure 1 shows the measured and simulated viscosities of isoprene SOA, showing a very good agreement with experimental observations. SOA generated by isoprene ozonolysis adopt a semi-solid state for RH < 40 % and a liquid state for RH > 60 %. The model predicted  $T_{\text{g,org}}$  is 260 K, which is in agreement with a previous estimation of 255 K (Berkemeier et al., 2014). All simulated viscosities with  $\kappa = 0.1$  fall within uncertainties of experimental measurements except at 70 % RH, which is slightly below the lower bound of the error bar of experimental measurements. The simulated O:C ratio is 1.0, which is within

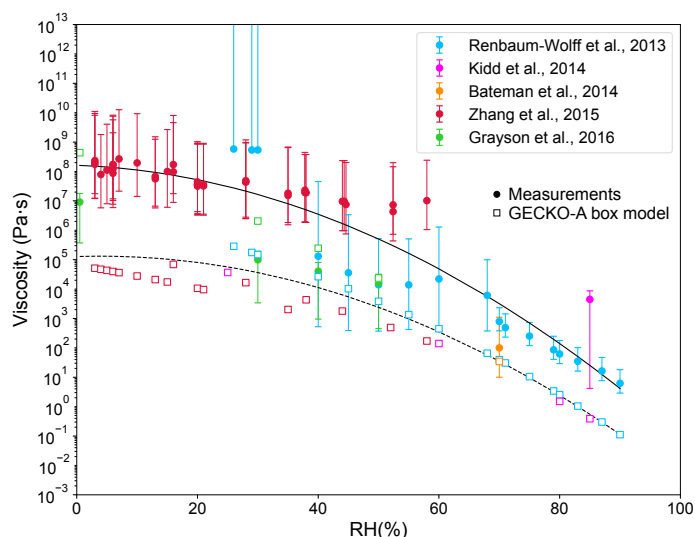

**Figure 1.** Viscosity of isoprene SOA as a function of RH. Circle markers with error bars represent measurements and associated uncertainties by Song et al. (Song et al., 2015) and square markers represent simulations with the GECKO-A box-model with different  $\kappa$  values.

190 the range of their estimation of 0.64 - 1.1 based on previous chamber experiments (Song et al., 2015). To examine the effects of  $\kappa$  on the calculated viscosity of isoprene SOA, sensitivity studies are conducted by varying  $\kappa$  within the range of 0.05–0.15, showing that lower and higher  $\kappa$  would lead to higher and lower viscosity, respectively.

Isoprene photooxidation in chamber experiments was conducted with very high precursor concentrations and a short reaction time such that a traditional gas-phase oxidation scheme dominates, which can be captured well in GECKO-A (Aumont  
 195 et al., 2005). Note that the formation of isoprene epoxydiols (IEPOX) (Paulot et al., 2009; Bates et al., 2014) and subsequent uptake of IEPOX into acidic particles followed by a series of multiphase reactions including the formation of oligomers and organosulfates (Riva et al., 2019) are found to be important in the ambient atmosphere (Wennberg et al., 2018). The uptake of IEPOX can be limited by bulk diffusion in a viscous matrix (Zhang et al., 2018) and IEPOX-SOA is reported to have high viscosity (Riva et al., 2019). For viscosity simulations of atmospherically relevant IEPOX-derived SOA, IEPOX multiphase  
 200 processes would need to be treated in future studies.

Figure 2 shows viscosity of  $\alpha$ -pinene SOA measured in a number of studies and the corresponding simulated results by the GECKO-A box model for each experimental condition. Based on previous laboratory measurements  $\kappa$  was assumed to be 0.1 (Lambe et al., 2011; Pajunoja et al., 2014; Petters et al., 2019). Overall, the model simulations can reproduce the RH-dependent viscosity of  $\alpha$ -pinene SOA, showing that  $\alpha$ -pinene SOA is semi-solid between 0–65 % RH and liquid for RH > 65 % at the room  
 205 temperature. Simulated viscosity values of  $\alpha$ -pinene SOA are by a few orders of magnitude higher than the ones simulated for isoprene SOA, which is consistent with experimental observations. Simulation results for Renbaum-Wolff's and Grayson's experiments fall within uncertainties of experimental measurements for the 40–60 % RH range. In simulations for Renbaum-Wolff's experiments at RH > 60 %, the predicted viscosity values are about one order of magnitude lower than the measured values. Larger deviations are observed for RH < 40 %, where simulated viscosities are up to four orders of magnitude lower than

**Figure 2.** Comparison of measured (solid markers) and simulated (open markers) viscosity of  $\alpha$ -pinene SOA as a function of RH. For each set of laboratory experiments the measured viscosities are reported with uncertainties. The solid and dashed lines represent the polynomial regression for measurements and model simulations, respectively, to guide eyes.

210 experimental measurements. The simulated viscosities are about one order of magnitude higher than Grayson's measurements for  $20 < \text{RH} < 40 \%$ . The simulated viscosity for Bateman's experiment agrees well with the observed experimental value within uncertainties. Kidd et al. (Kidd et al., 2014) provided only one data point at 85 % RH, which also represents inferred viscosity based on their impactor measurement; the predicted viscosity is three orders of magnitude below the inferred value, but only one order of magnitude below its lower bound. For simulations of Zhang et al. (Zhang et al., 2015), our predictions  
 215 are about three to four orders of magnitude lower than measurements.

The simulated  $T_{g,\text{org}}$  are within 255–285 K (see Table 1), which is in good agreement with a previous estimation of 278 K (Berkemeier et al., 2014) and a measurement of 272 K (Petters et al., 2019). To assess overall performance of our viscosity predictions, measured and simulated viscosities were fitted respectively with a second-order polynomial regression. While the RH dependence of viscosity is very well captured by our simulations, the simulated values underestimate viscosity by about  
 220 two or three orders of magnitude on average. The variance of model simulations and experimental measurements is very similar ( $R^2 = 0.85$ ), indicating that the GECKO-A box model can reproduce the variability observed in experimental measurements with different experimental conditions.

Grayson et al. (Grayson et al., 2016) investigated the impact of SOA mass loadings on viscosity, observing lower viscosity with higher SOA mass concentrations in the range of  $10^2 - 10^4 \mu\text{g m}^{-3}$ . We conducted four different simulations where  
 225 precursor concentrations were varied in the range of the experimental values to match the final SOA mass loadings. As shown in Fig. 3, our simulated viscosities are within the experimental uncertainties, capturing this dependence very well. At higher mass loadings, compounds with relatively high volatility and low  $T_g$  can condense on particles, leading to a reduction of SOA

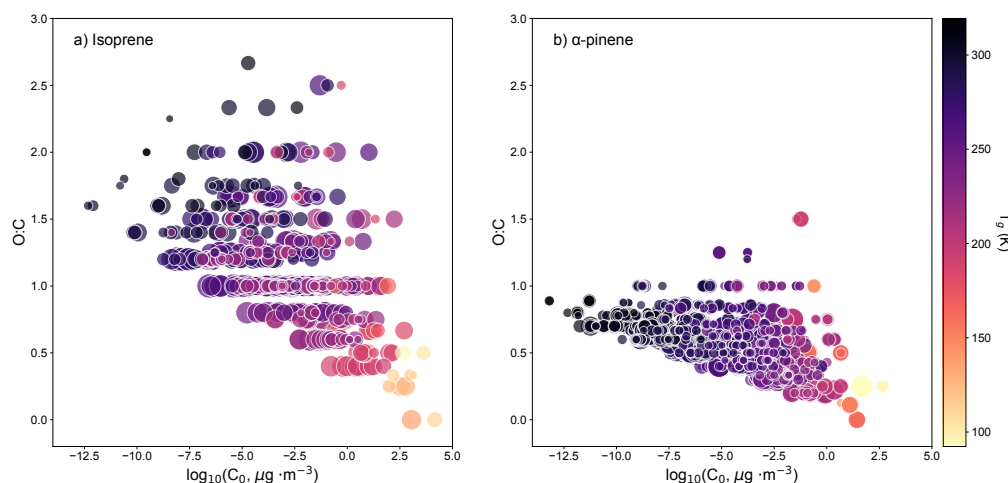

**Figure 3.** Impacts of SOA mass loadings on viscosity of  $\alpha$ -pinene SOA. The red and green lines represent the upper and lower bounds of measured viscosity in Grayson et al., 2016. Orange markers represent simulated viscosities by the GECKO-A box model.

viscosity; for lower mass loadings, condensation of lower volatility compounds with higher  $T_g$  would be dominant, resulting in higher viscosity.

### 230 3.2 Chemical composition and functional group distributions of SOA

The GECKO-A box model tracks the concentrations of species both in the gas and particle phases, while retaining information on molecular properties including molar mass, O:C ratio, vapor pressure, and volatility or pure compound saturation mass concentration ( $C_0$ ). Figure 4 shows most abundant particle-phase 500 compounds in simulated isoprene and  $\alpha$ -pinene SOA products in the 2-dimensional volatility basis set framework of O:C ratio vs.  $\log C_0$  (Donahue et al., 2011). The markers are color-coded with  $T_g$  and the marker size is scaled with particle-phase concentration in each simulation. Compounds with lower volatility tend to have higher O:C ratio and higher  $T_g$ , in good agreement with recent experimental and model studies (Zhang et al., 2019; Li et al., 2020). Isoprene oxidation products are found to have higher O:C ratio, while  $\alpha$ -pinene oxidation products have lower  $C_0$  and higher  $T_g$ . Note that, dark ozonolysis experiments of  $\alpha$ -pinene have been conducted with an OH scavenger, which may contribute to lower O:C ratios for  $\alpha$ -pinene ozonolysis products in the absence of OH oxidation. These results are in line with higher viscosity of  $\alpha$ -pinene SOA compared to isoprene SOA, as measured and modeled in Figs. 1 and 2.

Our method to estimate  $T_g$  of organic compounds and SOA viscosity are based on elemental composition without accounting for molecular structure and specific intramolecular interactions. Some organic compounds with reactive functional groups may undergo particle-phase reactions, which are not treated in our simulations. To explore these aspects, we investigate the

**Figure 4.** Chemical composition of SOA derived from oxidation of (a) isoprene and (b)  $\alpha$ -pinene of all simulated experimental conditions reported in Table 1 plotted in the 2D-VBS framework of volatility and O:C ratio. Markers represent 500 most abundant particle-phase compounds from each simulation. The markers are color-coded with  $T_g$ . The marker size is scaled with particle phase concentration in each simulation.

functional groups distributions computed by GECKO-A and box modeling. The simulated functionality group distributions of particle-phase SOA compounds are shown in Fig. 5. Most experiments led to similar chemical composition with high concentrations of ketones ( $-\text{RC}(\text{O})\text{R}$ ) and hydroperoxides ( $-\text{ROOH}$ ), followed by slightly lower concentrations of aldehydes ( $-\text{RCHO}$ ), alcohols ( $-\text{ROH}$ ) and carboxylic acids ( $-\text{RC}(\text{O})\text{OH}$ ). The simulations for Grayson's experiments are characterized by the highest concentrations of  $-\text{ROOH}$  and  $-\text{ROH}$ , and by lower fractions of  $-\text{RCHO}$ . The simulations for Kidd's experiments show the second highest abundance of  $-\text{ROH}$  and noticeable amounts of  $-\text{RC}(\text{O})\text{OR}$ . The simulation for Bateman's experiment is characterized by high  $-\text{RC}(\text{O})\text{R}$  abundance. A previous study suggested that the hydrogen-bond formation among organic compounds in the SOA organic matrix may influence the viscosity of  $\alpha$ -pinene SOA significantly (Kidd et al., 2014). It has been further shown that alcohol and carboxylic acid groups can increase viscosity due to the formation of hydrogen bonding and ionic interactions if carboxylic acids are dissociated (Grayson et al., 2016; Rothfuss and Petters, 2017). These effects are not explicitly considered in our viscosity estimation method, which may be one of the reasons for the discrepancies between measurements and simulations of SOA viscosity.

Chemical composition simulated for Zhang's experiments is characterized by the highest  $-\text{RCHO}$  fraction among all experiments, which may explain the largest difference between predicted and measured viscosities. Aldehydes are known to be highly reactive in the condensed phase by reacting with alcohols and hydroperoxides to form peroxyhemiacetals and oligomers (Ziemann and Atkinson, 2012). Such multiphase reactions could be accelerated under acidic conditions in the presence of carboxylic acids (Bakker-Arkema and Ziemann, 2020; Shiraiwa et al., 2013). In addition, the GECKO-A model treats neither

**Figure 5.** Simulated functional group distributions in particle-phase compounds derived from  $\alpha$ -pinene ozonolysis for various experiments.

autoxidation to form highly oxygenated organic molecules (HOMs) nor gas-phase dimerization reactions of peroxy radicals, which are recently found to play a significant role in SOA formation and growth (Bianchi et al., 2019). These higher molar mass compounds with very low volatility have higher  $T_g$ , hence leading to higher SOA viscosity (Koop et al., 2011; Zhang et al., 2019; Champion et al., 2019; Li et al., 2020). While the extent of effects of these processes may vary among reaction conditions applied in each experiment, the lack of treatment of these processes may be another plausible reason of lower simulated viscosity compared to experimental measurements.

### 3.3 Effects of mass accommodation

All the above simulations were conducted with mass accommodation coefficient equal to unity. Hereby, we investigate potential kinetic limitations of bulk diffusion on SOA partitioning and resulting viscosity by simulating two distinct experimental conditions of flow tube experiments by Renbaum-Wolff et al. (Renbaum-Wolff et al., 2013) and batch experiments by Kidd et al. (Kidd et al., 2014). The effective mass accommodation coefficient ( $\alpha_{\text{eff}}$ ) is computed with Eq. 3, which is implemented into Eq. 1 and 2 to simulate partitioning that effectively accounts for kinetic limitations of bulk diffusion.

Figure 6 shows the simulated viscosity estimations for SOA formation under dry conditions followed by water exposure at different RH. Final viscosity values are higher for simulations with  $\alpha_{\text{eff}}$  compared to those with  $\alpha$  fixed to 1. For simulations of Kidd's experiments, there is a large difference by several orders of magnitude in viscosity between two simulations of different

**Figure 6.** Simulated viscosities of  $\alpha$ -pinene SOA with experimental conditions of Kidd et al. (2014) (blue) and Renbaum-Wolff et al. (2013) (red). The simulations were conducted in two different scenarios:  $\alpha = 1$  (dashed lines) and  $\alpha = \alpha_{\text{eff}}$  (solid lines).

$\alpha$  when  $\text{RH} < 40\%$ ; for example, at  $40\%$  RH the simulated SOA viscosity is  $\sim 10^4$  Pa s with  $\alpha = 1$ , while it is  $\sim 10^8$  Pa s with  $\alpha = \alpha_{\text{eff}}$ . This large difference stems from a stark reduction of  $\alpha_{\text{eff}}$  for semivolatile compounds in a glassy solid matrix, which would prevent condensation of semi-volatile compounds with relatively low  $T_g$ ;  $\alpha_{\text{eff}}$  for low volatile compounds with higher  $T_g$  remains still close to unity allowing condensation, resulting in solidification of SOA particles.

280 This effect is reflected on the low simulated SOA mass loading of Kidd's experiments. When  $\alpha = \alpha_{\text{eff}}$  the simulated SOA mass loading is  $15 \mu\text{g m}^{-3}$ , which is much lower than the simulation with  $\alpha = 1$  (i.e.  $7000 \mu\text{g m}^{-3}$ ), where higher volatility compounds would condense without kinetic limitations, resulting in lower viscosity. The observed mass loadings during Kidd et al. (Kidd et al., 2014) chamber experiments were approximately  $\sim 1000 \mu\text{g m}^{-3}$ . This indicates that particle viscosity and resulting kinetic limitations may be overestimated in  $\alpha_{\text{eff}}$  simulations or particle-phase reactions contribute substantially on

285 SOA formation, as discussed in Sect. 3.2. The predicted viscosities for the two scenarios for Renbaum-Wolff's experiments are very similar. In both scenarios, particles are liquid for  $\text{RH} > 65\%$  and semi-solid at  $\text{RH} < 65\%$ . The mass loadings simulated for Renbaum-Wolff's experiments are on the same order being 15 and  $79 \mu\text{g m}^{-3}$  for simulations with  $\alpha_{\text{eff}}$  and  $\alpha = 1$ , respectively. Both results are close with the experimental measurement value of  $\sim 50 \mu\text{g m}^{-3}$ . Kidd et al. (Kidd et al., 2014) applied higher oxidant and precursor concentrations (Table 1), resulting in larger effects of mass loadings and hence mass accommodation.

290 As viscosity measurements were not conducted at lower RH in Kidd et al. (Kidd et al., 2014) and time evolution of SOA mass concentrations and viscosity are unavailable for both studies, it is hard to fully resolve impacts of mass accommodation in this study; we intend to investigate this aspect in a follow-up study.

#### 4 Conclusions

We applied the  $T_g$  parameterizations and viscosity prediction method in the GECKO-A box model to simulate the evolution of viscosity and composition of SOA generated via  $\alpha$ -pinene and isoprene oxidation. A range of simulations were performed with experimental conditions applied for viscosity measurements in order to explore various effects such as chemical composition, relative humidity, mass loadings, and mass accommodation coefficient on SOA viscosity. Simulated viscosities are consistent with the observed RH-dependence of viscosity for  $\alpha$ -pinene and isoprene SOA, demonstrating the robustness of our viscosity prediction method. Simulated viscosity values for isoprene SOA are in good agreement with measurements, while those for  $\alpha$ -pinene SOA were by a few orders of magnitude lower than experimental measurements. The simulated chemical composition and functional group distributions indicate that  $\alpha$ -pinene SOA contain substantial amounts of aldehydes, ketones, and carboxylic acids. These compounds are reactive and may undergo dimerization and oligomerization reactions. In addition, GECKO-A does not treat detailed chemistry involving stabilized Criegee intermediates, autoxidation and gas-phase dimerization by peroxy radicals. These processes are known to lead to the formation of high molecular mass compounds that would increase viscosity of SOA. Moreover, the model assumes that gas-particle partitioning of organics follows Raoult's law with ideal mixing conditions. The implementation of these processes are warranted in future studies for better representation of SOA chemical composition and viscosity.

Experiments were conducted to form SOA under dry conditions followed by water exposure for viscosity measurements and it was unnecessary to consider uptake of water into the condensed phase upon SOA formation. Previous studies have suggested that water vapor can significantly affect the composition of SOA. At higher RH water vapor interacts with Criegee intermediates, leading to production of carboxylic acids or aldehydes and ketones via decomposition routes (Kristensen et al., 2014). Kidd et al. (Kidd et al., 2014) have reported that as the RH at which the SOA is formed increases, there is a decrease in viscosity, accompanied by an increasing contribution from carboxylic acids and a decreasing contribution from higher molecular mass products. These aspects including chemistry of Criegee intermediates and water uptake should be a subject of future studies for simulating particle viscosity under humid conditions.

We have also explored the effects of kinetic partitioning by accounting for reduction of mass accommodation coefficient in a semisolid or viscous phase. The simulation results suggest that kinetic limitations in the particle phase would result in a decrease in SOA mass loading and an increase in viscosity due to suppression of condensation of semi-volatile compounds. It is still challenging to accurately assess the extent of this effect on viscosity due to the lack of experimental data for comparison and to the absence of some chemical processes in our modeling method. Future experiments with simultaneous measurements of chemical composition in the gas and particle phases as well as particle viscosity under different RH conditions will be enormously helpful to further improve and constrain the model. While this study simulated viscosity of pure organic particles, future studies should also investigate viscosity of inorganic-organic particles and effects of non-ideal interactions including phase separation (Zuend and Seinfeld, 2012; You et al., 2014) and gel formation (Richards et al., 2020). The developed model in this study is a useful tool for further exploration of phase state of atmospherically relevant SOA and it should also be useful in refining the representation of SOA chemical evolution and phase state in regional and global air quality models.
