**Abstract.** High concentrations of nitrous acid (HONO) have been observed in the Pearl River Delta (PRD) region of China in recent years, contributing to elevated atmospheric oxidation capacity by producing OH through HONO photolysis. We have investigated budget of HONO at an urban site in Guangzhou from 27 September to 9 November 2018 using data from a comprehensive atmospheric observation campaign. During this period, HONO was measured from 0.02 to 4.43 ppbv with an average of  $0.74 \pm 0.70$  ppbv. Emission ratios (HONO/NO<sub>x</sub>) of  $0.9 \pm 0.4\%$  were derived from 11 fresh plumes. The primary emission rate of HONO at night was calculated to be between  $0.04 \pm 0.02$  ppbv h<sup>-1</sup> and  $0.30 \pm 0.15$  ppbv h<sup>-1</sup> based on a high-resolution NO<sub>x</sub> emission inventory. Heterogeneous conversion of NO<sub>2</sub> on ground surface ( $0.27 \pm 0.13$  ppbv h<sup>-1</sup>), primary emission from vehicle exhaust (between  $0.04 \pm 0.02$  ppbv h<sup>-1</sup> and  $0.30 \pm 0.15$  ppbv h<sup>-1</sup> with a middle value of  $0.16 \pm 0.07$  ppbv h<sup>-1</sup>) and the homogeneous reaction of NO + OH ( $0.14 \pm 0.30$  ppbv h<sup>-1</sup>) were found to be the three largest sources of HONO at night. Heterogeneous NO<sub>2</sub> conversion on the aerosol surfaces ( $0.03 \pm 0.02$  ppbv h<sup>-1</sup>) and soil emission ( $0.019 \pm 0.009$  ppbv h<sup>-1</sup>) were two other minor sources. Correlation analysis shows that NH<sub>3</sub> and relative humidity (RH) may have participated in the heterogeneous transformation from NO<sub>2</sub> to HONO at night. Dry deposition ( $0.41 \pm 0.31$  ppbv h<sup>-1</sup>) was the largest removal process of HONO at night, followed by dilution ( $0.18 \pm 0.16$  ppbv h<sup>-1</sup>), while HONO loss on aerosol surfaces was much slower ( $0.008 \pm 0.006$  ppbv h<sup>-1</sup>). In the daytime, the average primary emission  $P_{\text{emis}}$  was  $0.12 \pm 0.02$  ppbv h<sup>-1</sup>, and the homogeneous reaction  $P_{\text{OH+NO}}$  was  $0.79 \pm 0.61$  ppbv h<sup>-1</sup>, larger than the unknown source  $P_{\text{Unknown}}$  ( $0.65 \pm 0.46$  ppbv h<sup>-1</sup>). Similar to previous studies,  $P_{\text{Unknown}}$  appeared to be related to the photo-enhanced conversion of NO<sub>2</sub>.

Our results show that primary emissions and reaction of NO + OH can significantly affect HONO at a site with intensive emissions, both during daytime and nighttime. The impact of uncertain parameter values assumed in the calculation of HONO sources can have strong impact on the relative importance of HONO sources at night, and could be reduced by

35 improving knowledge on key parameters such as the NO<sub>2</sub> uptake coefficient. The uncertainty with estimating direct emission can be reduced by using emission data with higher resolution and quality. Our study highlights the importance of better constraining both conventional and novel HONO sources by reducing uncertainties in their key parameters in advancing our knowledge on this important source of atmospheric OH.

40 Keywords: HONO; Budget analysis; Heterogeneous reaction; Uncertainty

## 1 Introduction

Nitrous acid (HONO) is an important primary source of hydroxyl radical (OH) through photolysis (Reaction R1), contributing up to 33–92% OH at rural and urban sites (Kleffmann et al., 2005; Michoud et al., 2012; Tan et al., 2017; Xue et al., 2020; Hendrick et al., 2014). OH is the principle atmospheric oxidant that is responsible for oxidizing and removing  
45 most natural and anthropogenic trace gases. OH initiates the oxidation of the volatile organic compounds (VOC) to produce hydroperoxyl radicals (HO<sub>2</sub>) and organic peroxy radicals (RO<sub>2</sub>), which further lead to the formation of ground-level ozone (O<sub>3</sub>) in the presence of nitrogen oxides (NO<sub>x</sub> = NO + NO<sub>2</sub>) (Xue et al., 2016; Finlayson-Pitts and Pitts, 2000; Hofzumahaus et al., 2009; Lelieveld et al., 2016; Tan et al., 2018), as well as secondary organic aerosols (SOA). However, the detailed formation mechanisms of HONO are still not well understood and the observed HONO concentrations cannot be completely  
50 explained by current knowledge (Sörgel et al., 2011a; Kleffmann et al., 2005; Sarwar et al., 2008; Liu et al., 2019a; Lee et al., 2016; Liu et al., 2020b).

55 So far numerous HONO sources have been found, and they can be categorized as direct emissions, homogeneous reactions and heterogeneous reactions. Fossil fuel combustion is the most important direct emission source of HONO (Kurtenbach et al., 2001; Kirchstetter et al., 1996; Rappenglück et al., 2013; Kramer et al., 2020; Xu et al., 2015; Trinh et al., 2017). In general, the emission ratios of HONO/NO<sub>x</sub> obtained from fresh air masses and vehicle exhaust (0.03%–1.7%) (Kurtenbach et al., 2001; Kirchstetter et al., 1996; Rappenglück et al., 2013; Trinh et al., 2017; Liu et al., 2017; Pitts et al., 1984;  
60 Nakashima and Kajii, 2017) are much smaller than the ratios of HONO/NO<sub>x</sub> observed in the low boundary layer (2.3%–9%) (Yang et al., 2014; Zhou et al., 2002a; Hao et al., 2020; Gu et al., 2021; Li et al., 2018a; Yu et al., 2009; Acker et al., 2006), reflecting substantial secondary formation of HONO away from direct emissions. Recent studies found that soil emission might be another major direct emission source of HONO (Su et al., 2011; Oswald et al., 2013; Weber et al., 2015; Wu et al., 2019; Porada et al., 2019; Wang et al., 2021b), although the confirmation of its atmospheric significance requires further  
65 comparisons between laboratory and field measurements. It should be noted that direct emissions may surpass secondary

sources at sampling sites with heavy emission impacts (Liu et al., 2019a; Tong et al., 2015; Zhang et al., 2019; Tong et al., 2016; Meusel et al., 2016).

70 Homogeneous gas-phase reaction between NO and OH (R2) is the most well known secondary source of HONO (Perner and Platt, 1979). HONO concentrations measured in the atmosphere cannot be explained by direct emission and this reaction alone, especially during daytime (Kleffmann et al., 2005; Lee et al., 2016) when a large source of HONO is necessary to sustain the measured level of HONO against fast photolysis. Numerous new homogeneous HONO formation mechanisms have been proposed so far to explain the gap between observed and predicted HONO, including HONO formation by photolysis of o-nitrophenol (Bejan et al., 2006; Yang et al., 2021a), homogeneous nucleation of NH<sub>3</sub>, NO<sub>2</sub> and H<sub>2</sub>O (Zhang and Tao, 2010), and the homogeneous reaction between water vapor (H<sub>2</sub>O) and electronically excited NO<sub>2</sub> ( $\lambda > 420$  nm) followed by the reaction of NO<sub>2</sub> with HO<sub>2</sub>·H<sub>2</sub>O (Li et al., 2008; Li et al., 2014b). These gas-phase reactions have yet to be confirmed to occur in the atmosphere, and are unlikely to be the main HONO source.

Heterogeneous reactions of NO<sub>2</sub> on various surfaces have drawn substantial interest due to the observed correlation between HONO and NO<sub>2</sub> during many field observations. Vertical gradient observations appear to suggest that HONO is more likely produced from the ground surface (Wong et al., 2012; Kleffmann et al., 2003; Stutz et al., 2002; VandenBoer et al., 2013; Wong et al., 2011; Villena et al., 2011), while some observations found a good correlation between HONO and aerosol surface area (Reisinger, 2000; Su et al., 2008a; Jia et al., 2020; Zheng et al., 2020; Liu et al., 2014), which can be related to the concentration and composition of particulate matter (Cui et al., 2018; Liu et al., 2014; Colussi et al., 2013; Yabushita et al., 2009; Kinugawa et al., 2011). Both laboratory studies and field observations have found that hydrolysis of NO<sub>2</sub> on wet surfaces can produce HONO (R3), and the uptake coefficient of NO<sub>2</sub> ( $\gamma$ ) can vary by several orders of magnitude (Finlayson-Pitts et al., 2003; Stutz et al., 2004; Acker et al., 2004). HONO can also be generated by NO<sub>2</sub> reduction on reductive surfaces (soot, semivolatile organic compounds, humic acid, etc.) at a much faster rate than NO<sub>2</sub> hydrolysis, but the surfaces could be inactivated in a short period of time (Ammann et al., 1998; Han et al., 2017a; Han et al., 2017b; Gerecke et al., 1998; Monge et al., 2010; Gutzwiller et al., 2002; Wall and Harris, 2017; Stemmler et al., 2006). However, irradiation could enhance the reaction and maintain the activity of the surfaces, making it possible to play an important role in HONO formation during daytime. Both laboratory and field studies found that photolysis of adsorbed HNO<sub>3</sub> and particulate nitrate (NO<sub>3</sub><sup>-</sup>) could produce HONO (Ye et al., 2016; Ye et al., 2017; Zhou et al., 2003; Zhou et al., 2002b; Zhou et al., 2011), which might be an important HONO source, at least in remote areas and polar regions. Evidence of other new pathways and mechanisms has

also been found and their atmospheric relevance discussed (Ge et al., 2019; Wang et al., 2016; Xu et al., 2019; Li et al.,  
100 2018b; Xia et al., 2021; Zhao et al., 2021; Gen et al., 2021).

The Pearl River Delta (PRD) region is one of the biggest city clusters in the world with dense population and large anthropogenic emissions. Rapid economic development and urbanization have led to severe air pollution in this region, which has been characterized by atmospheric "compound pollution" with concurrently high fine particulate matter (PM<sub>2.5</sub>)  
105 and ozone (O<sub>3</sub>) (Tang, 2004; Chan and Yao, 2008; Yue et al., 2010; Wang et al., 2017b; Xue et al., 2014; Zheng et al., 2010). Over recent years, O<sub>3</sub> has been increasing along with reduced PM<sub>2.5</sub> in the region (Li et al., 2014a; Liao et al., 2020; Wang et al., 2009; Zhong et al., 2013; Lu et al., 2018), and has become the dominant factor of the air quality index exceeding the national standard (Feng et al., 2019), indicating the enhancement of atmospheric oxidation capacity. So far, two comprehensive atmospheric observations have been conducted in the PRD region, focusing on the balance and dynamics of  
110 OH sources and sinks (Hofzumahaus et al., 2009; Tan et al., 2019). Substantial amount of HONO was suggested to be a major source of the OH–HO<sub>2</sub>–RO<sub>2</sub> radical system in these two campaigns (Lu et al., 2012; Tan et al., 2019) as well as in other previous campaigns (Hu et al., 2002; Su et al., 2008b; Su et al., 2008a; Qin et al., 2009; Li et al., 2012; Shao et al., 2004).

115 In this work, we performed continuous measurements of HONO, along with trace gases, photolysis frequencies and meteorological conditions at an urban site in Guangzhou from 27 September to 9 November 2018, as part of the field campaign "Particles, Radicals, Intermediates from oxidation of primary Emissions in Greater Bay Area" (PRIDE-GBA2018). Benefiting from numerous prior field observational studies in the PRD region, our study stands in a strong position to ensure high quality of data acquisition and analysis of HONO, along with a full suite of other chemical species, providing a unique  
120 and valuable opportunity to refine our knowledge of HONO sources and sinks, as well as the role of HONO in the photochemistry of O<sub>3</sub> and OH in such a region with extensive air pollution as well as rigorous emission control over recent years.

Departing from the valuable knowledge and experiences gained from numerous previous HONO studies in the PRD region  
125 and around the world, we aim to draw useful and unique insights from a detailed analysis of our dataset in the context of a comprehensive review of previous data and findings, with special attention paid to reducing and/or characterizing the uncertainties in parameterizations and their implications on the relative importance of various HONO sources and sinks. Specifically, (1) a high resolution (3 km × 3 km) NO<sub>x</sub> emission inventory for the Guangzhou city (Huang et al., 2021) was used to estimate the primary emission rates of NO<sub>x</sub> and HONO, which would reduce the uncertainty of HONO primary  
130 emission rate; (2) a wide range of possible parameter values have been evaluated for each source to quantify their strengths and rank their importance; (3) uncertainties associated with each source and other possible factors are discussed in detail.

## 2 Experiment

### 2.1 Observation site

135 The sampling site (23.14° N, 113.36° E) is located in the Guangzhou Institute of Geochemistry Chinese Academy of  
Sciences (GIGCAS). The instruments were deployed in the cabin on the rooftop of a seven-story building (~ 40 m above the  
ground). The site is surrounded by residential communities and schools, with no industrial manufacturers or power plants  
around, representing a typical urban environment in the PRD region. The south China Expressway and Guangyuan  
Expressway, both with heavy traffic loading, are located at west and south of the site, with distances of about 300 m. As a  
140 result, the site often experienced local emissions from traffic. The location and surroundings of the site are shown in Fig. S1.

### 2.2 Measurements

HONO was measured by a custom-built LOPAP (LOng Path Absorption Photometer) (Heland et al., 2001; Kleffmann et al.,  
2006). More information about our custom-built LOPAP (including principle, quality assurance/quality control, instrument  
parameters and intercomparison) are introduced in supplement information.

145  
In addition to HONO, ambient VOCs were measured using a TH-300B On-Line VOCs Monitoring System involving  
detection technology of ultralow temperature preconcentration coupled with gas chromatography-mass spectrometry  
(GC/MS) with the time resolution of 1 h. NO<sub>x</sub> (NO + NO<sub>2</sub>) was measured by a nitrogen oxides analyzer (Thermo Scientific,  
Model 42i), which used a NO-NO<sub>x</sub> chemiluminescence detector equipped with a molybdenum-based converter with the time  
150 resolution and detection limit of 1 min and 1 ppbv respectively. It should be noted that the molybdenum oxide (MoO)  
converters may also convert some NO<sub>z</sub> (= NO<sub>y</sub> - NO<sub>x</sub>) (e.g., HONO, peroxyacetyl nitrate (PAN), HNO<sub>3</sub>, and so on.) species  
to NO and hence could overestimate the ambient NO<sub>2</sub> concentrations. The degree of overestimation depends on both air  
mass age and the composition of NO<sub>y</sub>. At our site that was greatly affected by fresh emissions, the relative interferences of  
NO<sub>z</sub> to NO<sub>2</sub> have been estimated to be around 10%, which is closed to the results of Xu et al. (2013) and negligible for our  
155 discussion of HONO budget. O<sub>3</sub> was measured by an O<sub>3</sub> analyzer (Thermo Scientific, Model 49i) via ultraviolet absorption  
method with the time resolution and detection limit of 1 min and 1 ppbv respectively. SO<sub>2</sub> was measured by SO<sub>2</sub> analyzer  
(Thermo Scientific, Model 43i) via pulsed fluorescence method with the time resolution and detection limit of 1 min and 1  
ppbv respectively. CO was measured by a CO analyzer (Thermo Scientific, Model 48i) with the time resolution and  
detection limit of 1 min and 0.1 ppmv respectively. NH<sub>3</sub> was measured by laser absorption spectroscopy (PICARRO, G2508)  
160 with the time resolution and detection limit of 1 min and 1 ppbv respectively. Gaseous HNO<sub>3</sub> was detected by a Time-Of-  
Flight Chemical Ionization Mass Spectrometer (Aerodyne Research Inc., TOF-CIMS) with a time resolution of 1 min. And  
particulate nitrate (NO<sub>3</sub><sup>-</sup>) was measured by Time-Of-Flight Accelerator Mass Spectrometry (Aerodyne Research Inc., TOF-  
AMS) with a time resolution of 1 min. PM<sub>2.5</sub> was measured by a Beta Attenuation Monitor (MET One Instruments Inc.,  
BAM-1020) with the time resolution and detection limit of 1 h and 4.0 μg m<sup>-3</sup> respectively. The meteorological data,

165 including temperature (T), relative humidity (RH) and wind speed and direction (WS, WD) were recorded by Vantage Pro2  
Weather Station (Davis Instruments Inc., Vantage Pro2) with the time resolution of 1 min. Photolysis frequencies including  
J(HONO), J(NO<sub>2</sub>), J(H<sub>2</sub>O<sub>2</sub>) and J(O<sup>1</sup>D) were measured by a filter radiometry (Focused Photonics Inc., PFS-100) with a time  
resolution of 1 min.

### 3 Results and discussion

#### 170 3.1 Data overview

The time series of meteorological parameters and pollutants during the campaign are shown in Fig. 1. The HONO  
concentrations ranged from 0.02 to 4.43 ppbv with an average of  $0.74 \pm 0.70$  ppbv. Table 1 summarizes the HONO  
observations reported in PRD region since 2002. HONO appears to have shown a decreasing trend in Guangzhou, as  
improvement of air quality in Guangzhou was witnessed during the past decade. Spikes of NO occurred frequently, even up  
175 to 134.8 ppbv, as a result of traffic emissions from two major roads near the site. The concentrations of NO<sub>2</sub>, SO<sub>2</sub>, NH<sub>3</sub> and  
PM<sub>2.5</sub> ranged from 5.4–102.0 ppbv, 0–6.3 ppbv, 2.8–7.8 ppbv and 4–109  $\mu\text{g m}^{-3}$  respectively with the average values of  $50.8$   
 $\pm 17.2$  ppbv,  $1.9 \pm 1.2$  ppbv,  $6.3 \pm 2.7$  ppbv, and  $36 \pm 16$   $\mu\text{g m}^{-3}$  respectively. The O<sub>3</sub> concentrations ranged from 0.3–149.8  
ppbv with an average peak concentration of  $73.9 \pm 28.4$  ppbv. During the observation, the temperature ranged from 17 °C to  
30 °C with an average of  $24 \pm 3$  °C, and the relative humidity ranged from 28% to 97% with an average of  $70 \pm 17\%$ . The  
180 average wind speed was  $6.8 \pm 4.5$  m s<sup>-1</sup>, while the maximum wind speed was 22.7 m s<sup>-1</sup>. There was a pollution period from  
8th to 10th October with elevated PM<sub>2.5</sub> ( $60 \pm 12$   $\mu\text{g m}^{-3}$ ) and HONO ( $0.94 \pm 0.58$  ppbv). By contrast, from 29 October to 3  
November, efficient ventilation driven by strong winds ( $> 11$  m s<sup>-1</sup>) led to low levels of most pollutants in this period, with  
average concentrations of PM<sub>2.5</sub> and HONO at  $28 \pm 11$   $\mu\text{g m}^{-3}$  and  $0.56 \pm 0.34$  ppbv, respectively.

Local time [2018-mm-dd]

185

(2017a); 7: Yang (2014); 8: Xu et al. (2015); 9: Zha et al. (2014); 10: Yue et al. (2016); 11: Liu (2017); 12: Yun et al. (2017); 13: Yun (2018).

The time series of photolysis frequencies  $J(\text{HONO})$ ,  $J(\text{O}^1\text{D})$  and  $J(\text{NO}_2)$  in the whole observation period are shown in Fig. S3. The maximum values of  $J(\text{HONO})$ ,  $J(\text{O}^1\text{D})$  and  $J(\text{NO}_2)$  are  $1.58 \times 10^{-3} \text{ s}^{-1}$ ,  $2.54 \times 10^{-5} \text{ s}^{-1}$  and  $9.31 \times 10^{-3} \text{ s}^{-1}$ , respectively. 195 These  $J$  values tracked a similar diurnal pattern, reaching a maximum at noon with high solar radiation and decreasing to zero at night.

The diurnal variations of HONO,  $\text{NO}_2$ , HONO/ $\text{NO}_2$ , and NO are shown in Fig. 2. A daytime trough and a night-time peak of HONO were observed, as typically seen at urban and rural sites (Lee et al., 2016; Xue et al., 2020; Villena et al., 2011; Yang 200 et al., 2021b). The observed high HONO concentration around 0.5 ppbv at daytime implies strong HONO production to balance its rapid loss through photolysis.  $\text{NO}_2$  showed a similar diurnal pattern. It is worth noting that the diurnal variation of NO was quite similar to that of HONO, implying the potential association between them. Additionally, the observed large amount of NO ( $10.8 \pm 17.2$  ppbv) at night indicated strong primary emission near the site. As an indicator of  $\text{NO}_2$  to HONO conversion, the ratio of HONO/ $\text{NO}_2$  rose at night and decreased after sunrise due to photolysis, ranging from 0.2% to 9.1% 205 with an average of  $2.3 \pm 1.3\%$ , which is lower than most previous field observations in the PRD region (Li et al., 2012; Qin et al., 2009; Xu et al., 2015), and is typical for relatively fresh plumes (Febo et al., 1996; Lammel and Cape, 1996; Sörgel et al., 2011b; Stutz et al., 2004; Zhou et al., 2007; Su et al., 2008a).

Figure 2. Diurnal profiles of HONO, NO<sub>2</sub>, NO and HONO/NO<sub>2</sub> during the observation period. The blue line in the box and red circle refer to the median and mean, respectively. Boxes represent 25% to 75% of the data, and whiskers 95% of the data. The box plots presented in this study is generated by an Igor Pro-based computer program, Histbox (Wu et al., 2018).

### 3.2 Nocturnal HONO sources and sinks

#### 3.2.1 Direct emissions

As noted in Sect. 1, the site was expected to receive substantial direct emission of HONO from two major roads nearby. We obtained the emitted HONO/NO<sub>x</sub> ratios in fresh plumes defined with the following criteria (Xu et al., 2015):

- (a) NO<sub>x</sub> > 49.7 ppbv (highest 25% of NO<sub>x</sub> data);
- (b) NO/NO<sub>x</sub> > 0.8;
- (c) good correlation between NO<sub>x</sub> and HONO ( $R^2 > 0.70$ ,  $P < 0.05$ );

(d) short duration of plumes (< 2 h);

(e) global radiation  $< 10 \text{ W m}^{-2}$  ( $J(\text{NO}_2) < 0.25 \times 10^{-3} \text{ s}^{-1}$ ).

During the campaign, 11 fresh plumes were identified to satisfy criteria (a)–(e) (see Table S2). Two cases among them are shown in Fig. S4. The HONO/NO<sub>x</sub> ratios in these selected plumes varied from 0.1% to 1.5% with an average value of  $0.9 \pm$   
225 0.4%, which is comparable to the average value of 1.2% measured in Hong Kong (Xu et al., 2015), 1.0% observed in Hong Kong (Yun et al., 2017), 0.79% measured in Nanjing (Liu et al., 2019b) and 0.69% observed in Changzhou (Shi et al., 2020). It should be noted that the emission factor derived in this study was based on field observation and the screening criterion for fresh air mass was  $\text{NO}/\text{NO}_x > 0.8$ , while the fresh air mass was characterized by  $\text{NO}/\text{NO}_x > 0.9$  in the tunnel experiments conducted by Kurtenbach et al. (2001), so the air masses we selected were still slightly aged and the emission factor derived  
230 in this study is slightly overestimated.

To quantify the primary emission rate of HONO, three methods have been used in previous studies (Liu et al., 2019b; Liu et al., 2020a; Meng et al., 2020). In method (1), the observed NO<sub>x</sub> concentration is simply assumed to represent the accumulation of emissions but ignore the sinks of NO<sub>x</sub> and HONO, as well as transport and convection. On this basis,  
235  $[\text{HONO}]_{\text{emis}}$  (the primary emission's contribution to HONO concentration) is estimated as the product of emission coefficient  $K$  and observed NO<sub>x</sub> concentration (Cui et al., 2018; Huang et al., 2017) (see Eq. (1)). Since it is difficult to determine the time of NO<sub>x</sub> emissions, method (1) can not exclude the NO<sub>x</sub> levels before emission begins. With this in mind, in method (2), primary emission rate  $P_{\text{emis}}$  is estimated as the product of emission coefficient  $K$  and  $[\Delta\text{NO}_x]/\Delta t$ , where  $[\Delta\text{NO}_x]$  is the difference between observed NO<sub>x</sub> at two time points (Liu et al., 2019b; Zheng et al., 2020) (see Eq. (2)). Obviously, it can  
240 only be used when NO<sub>x</sub> is increasing. It should be noted that any loss of NO<sub>x</sub> and HONO can be a source of error for these two methods, especially during daytime. In method (3), primary emission rate  $P_{\text{emis}}$  is equal to the product of emission coefficient  $K$  and NO<sub>x</sub><sup>\*</sup>, the NO<sub>x</sub> emission from source emission inventory (Michoud et al., 2014; Su et al., 2008b) (see Eq. (3)). This method adheres to the definition of HONO emission rate, assuming that the primary sources are evenly mixed in a specific area. It is desirable to use emission inventory data with high spatial and temporal resolution to obtain an accurate  
245 estimate.

$$[\text{HONO}]_{\text{emis}} = K \times [\text{NO}_x] \quad (1)$$

$$P_{\text{emis}} = K \times [\Delta\text{NO}_x]/\Delta t \quad (2)$$

$$P_{\text{emis}} = K \times \text{NO}_x^* \quad (3)$$

$$250 \quad P_{\text{HONO}} = \frac{[\text{HONO}]_{t_2} - [\text{HONO}]_{t_1}}{t_2 - t_1} \quad (4)$$

In this study, we first used NO<sub>x</sub> emission rate from a high-resolution emission inventory (Huang et al., 2021) to calculate emission rate of HONO  $P_{\text{emis}}$  at night (18:00–6:00). The NO<sub>x</sub> emission rate was extracted from a  $3 \text{ km} \times 3 \text{ km}$  grid cell

centred around our site. As a comparison, we also used the 2017 NO<sub>x</sub> emission inventory of Guangzhou city to repeat the  
255 calculation. The two inventories are primarily different in spatial resolution. The high-resolution 3 km × 3 km data is  
expected to better represent local traffic emissions, whereas the city-level emission inventory represents the total emission.  
Since we cannot quantify the relative contribution of the local and regional emissions to this site, two results are used to  
represent upper and lower limits of the contribution of primary emissions to HONO. The nighttime height of the boundary  
layer is assuming to 200 m according to the previous study in the PRD region in autumn by Fan et al. (2008).

260

The observed HONO accumulation rate P<sub>HONO</sub> is calculated by Eq. (4), where [HONO]<sub>t<sub>1</sub></sub> and [HONO]<sub>t<sub>2</sub></sub> represent the HONO  
concentration at 18:00 and 6:00 Local Time, respectively. Then an average P<sub>HONO</sub> of 0.02 ± 0.06 ppbv h<sup>-1</sup> can be derived.  
Hourly HONO primary emission rates calculated with the two inventories are shown in Fig. 5 (a). P<sub>emis</sub> calculated with the  
high-resolution emission data (3 km × 3 km) shows a steep downward trend from 18:00 (0.56 ppbv h<sup>-1</sup>) to 4:00 (0.14 ppbv  
265 h<sup>-1</sup>), followed by an upward trend from 4:00 (0.14 ppbv h<sup>-1</sup>) to 6:00 (0.25 ppbv h<sup>-1</sup>) with the average of 0.30 ± 0.15 ppbv h<sup>-1</sup>.  
By contrast, P<sub>emis</sub> with the city level emission data (Guangzhou) is much lower (0.04 ± 0.02 ppbv h<sup>-1</sup>) and varied smoothly  
throughout the night. Similar results have been obtained at urban sites (Liu et al., 2020a; Liu et al., 2020b; Gu et al., 2021)  
and a suburban site (Michoud et al., 2014), while the result at a rural site is much lower (Su et al., 2008b) in the PRD region.  
The uncertainty of P<sub>emis</sub> stems from the uncertainty of the inventories (-25%–28%) (Huang et al., 2021). Regardless, direct  
270 emission of HONO represents a large HONO source at night along with other sources of HONO that remain to be considered.

We also calculated the primary emission's contribution to HONO ([HONO]<sub>emis</sub>/[HONO]) using Method (1) and made  
comparisons against [HONO]<sub>emis</sub>/[HONO] ratios obtained previously from urban sites in China (Table S3). The values varied  
widely from 12% to 52%, with seasonal difference of more than a factor of 2 for the same site, reflecting large variability of  
275 HONO emissions spatially and temporally. In comparison, the ratio of [HONO]<sub>emis</sub>/[HONO] at our site is relatively high at  
47%, as can be expected from the relatively strong vehicle exhaust emissions near our site.

In addition to traffic emissions, we also estimated the HONO emission rate from soil P<sub>soil</sub> (ppbv h<sup>-1</sup>) according to Eq. (5):

$$P_{\text{soil}} = \frac{\alpha F_{\text{soil}}}{H} \quad (5)$$

280 where F<sub>soil</sub> is the emission flux (g m<sup>-2</sup> s<sup>-1</sup>); H is the height of boundary layer (H, m) and was assumed to be 200 m (Fan et al.,  
2008); α is the conversion factor ( $\alpha = \frac{1 \times 10^9 \times 3600 \times R \times T}{M \times P} = \frac{2.99 \times 10^{13} \times T}{M \times P}$ ); T is the temperature (K); M is the molecular weight (g  
mol<sup>-1</sup>) and P is the atmospheric pressure (Pa). HONO emission flux from soil depends on the temperature, water content and  
nitrogen nutrient content of soil, which have been considered according to the parameters reported in the literature (Oswald  
et al., 2013). Since grassland, coniferous forest and tropical rain forest are the typical plants in Guangzhou city area (Wu et  
285 al., 2015) and their emission fluxes are comparable (Oswald et al., 2013), emission flux from grassland was adopted to  
represent the soil HONO emission in Guangzhou. The average nighttime P<sub>soil</sub> varied from 0.011 to 0.035 ppbv h<sup>-1</sup>, with a

mean value of  $0.019 \pm 0.009$  ppbv  $\text{h}^{-1}$ . The HONO emission rate from soil at our site is slightly larger than the result reported in Shijiangzhuang urban area (Liu et al., 2020a) and comparable to that in Beijing urban area (Liu et al., 2020b). A caveat is that the calculation relies on laboratory results and is therefore prone to errors due to any possible inconsistency between laboratory simulations and field observations. Overall, soil emission is a minor source compared to other sources.

### 3.2.2 NO + OH homogeneous reaction

The reaction between NO and OH acts as the most well known principle homogenous HONO source. It can contribute a substantial fraction to HONO formation when NO and OH concentrations are high (Alicke et al., 2003; Liu et al., 2019b; Wong et al., 2011; Tong et al., 2015; Zhang et al., 2019). Taking the homogeneous Reactions R2 and R5 into account, the net HONO homogeneous production rate can be calculated following Eq. (6):

$$P_{\text{OH}+\text{NO}}^{\text{net}} = k_{\text{NO}+\text{OH}}[\text{NO}][\text{OH}] - k_{\text{HONO}+\text{OH}}[\text{HONO}][\text{OH}] \quad (6)$$

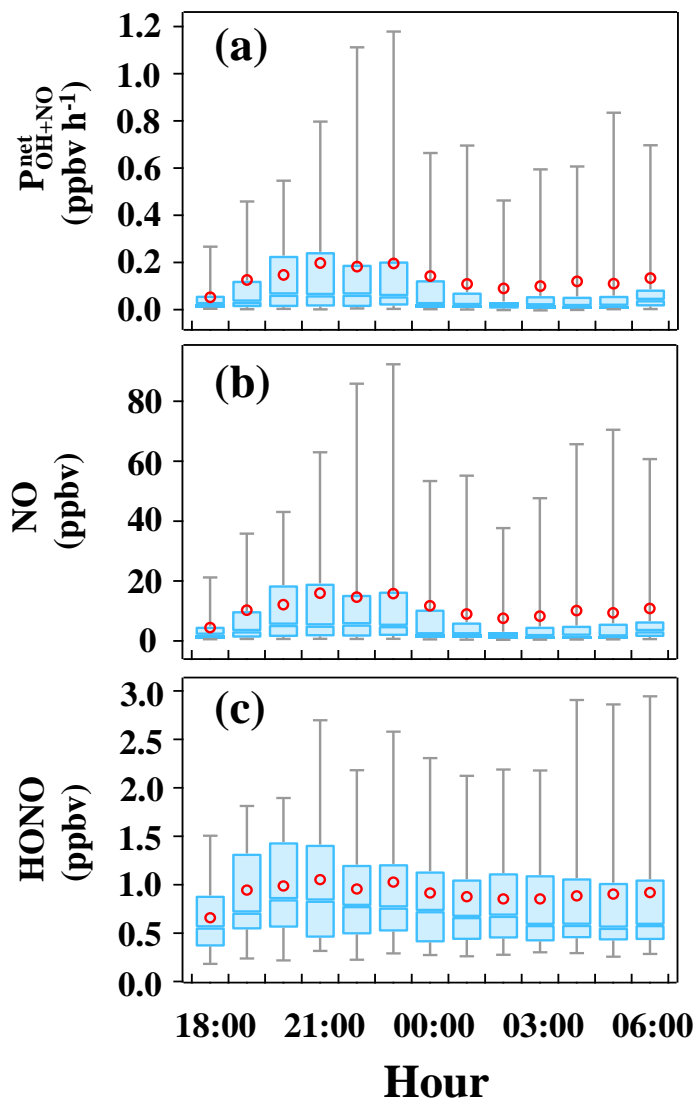

300

In Eq. (6),  $k_{\text{NO}+\text{OH}}$  ( $7.2 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1}$ ) and  $k_{\text{HONO}+\text{OH}}$  ( $5.0 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1}$ ) are the reaction rate constants of the Reactions R2 and R5 at 298 K, respectively (Li et al., 2012). Since the OH concentration was not measured, an average nighttime value of  $0.5 \times 10^6 \text{ cm}^{-3}$  measured in Heshan in the PRD region in autumn of 2014 was assumed (Tan et al., 2019). As shown in Fig. 3, the variation of  $P_{\text{OH}+\text{NO}}^{\text{net}}$  largely followed that of NO, since the concentration of NO was 10 times larger than HONO. And the average value of  $P_{\text{OH}+\text{NO}}^{\text{net}}$  is  $0.13 \pm 0.30$  ppbv  $\text{h}^{-1}$ , leading to a cumulative HONO contribution of 1.62 ppbv. The obtained  $P_{\text{OH}+\text{NO}}^{\text{net}}$  is similar to previous studies, such as 0.12 ppbv  $\text{h}^{-1}$  in Xianyang (Li et al., 2021), 0.13 ppbv  $\text{h}^{-1}$  in Zhengzhou (Hao et al., 2020), 0.26 ppbv  $\text{h}^{-1}$  in Xi'an (Huang et al., 2017) and 0.28 ppbv  $\text{h}^{-1}$  in Guangzhou Back Garden (Li et al., 2012). We note that the measured HONO only increased 0.26 ppbv in this period, much smaller than the cumulative production of HONO by the reaction between NO and OH, indicating a large sink to balance this source and other sources that will be discussed below.

310

Since OH was not measured in our study, we carried out sensitivity tests using one fifth and twice of assumed OH concentration ( $0.5 \times 10^6 \text{ cm}^{-3}$ ) (Lou et al., 2010). As shown in Table S4, within the range of nighttime OH concentration, the cumulative production of the homogeneous reaction of NO + OH in this study are always large enough to surpass the average measured accumulation of HONO, indicating that the NO + OH source is a major source term regardless of uncertainties in OH concentrations.

315

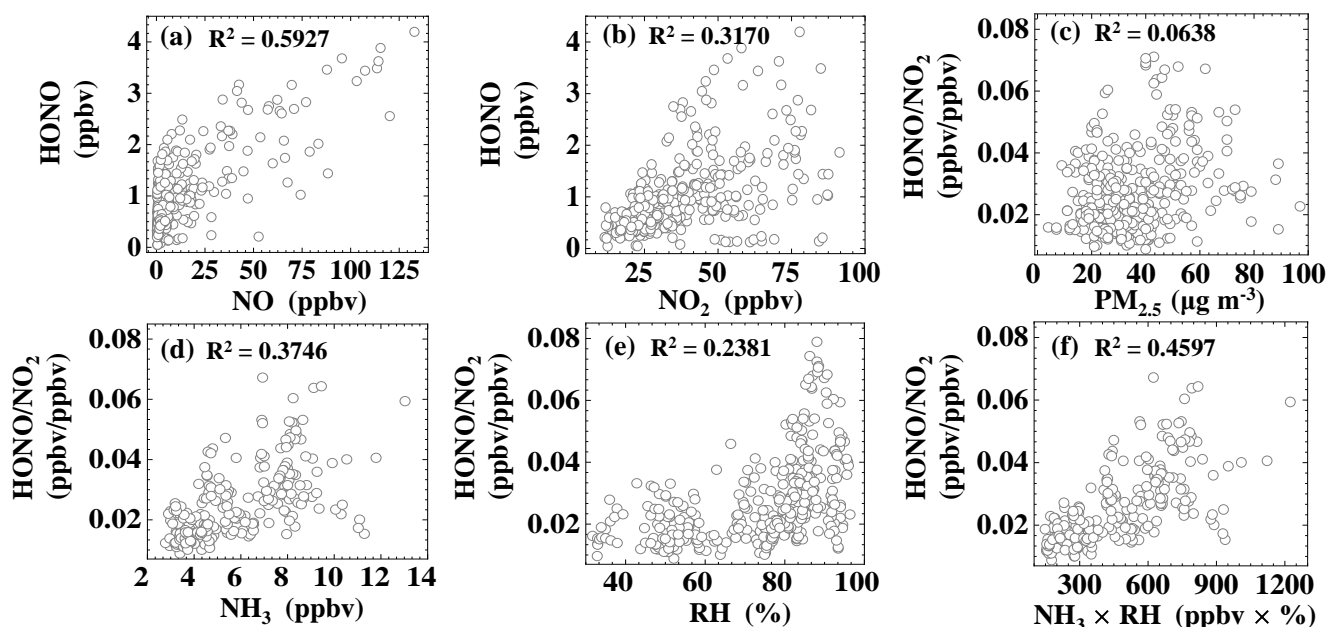

320 **Figure 3.** The mean nocturnal variation of  $P_{OH+NO}^{net}$ , HONO and NO. The blue line in the box and red circle refer to the median and mean, respectively. Boxes represent 25% to 75% of the data, and whiskers 95% of the data.

### 3.2.3 NO<sub>2</sub> to HONO heterogeneous conversion

Our analysis so far suggests that direct emissions and the homogeneous reaction between NO and OH are two major sources of HONO at night. This finding is in line with the relatively high correlation ( $R^2 = 0.5927$ ) between HONO and NO (Fig. 4 (a)). In the following, we present results from correlation analysis to explore possible pathways of heterogeneous NO<sub>2</sub> to HONO conversion at night (18:00–6:00).

325

The ratio of HONO/NO<sub>2</sub> has often been used to indicate the heterogeneous conversion efficiency of NO<sub>2</sub> to HONO (Lammel and Cape, 1996; Stutz et al., 2002), for being less influenced by transport processes or convection. Figure 4 (c) shows a weak correlation ( $R^2 = 0.0638$ ) between HONO/NO<sub>2</sub> and PM<sub>2.5</sub>, suggesting that the formation of HONO on aerosol surfaces might not be the main pathway (Kalberer et al., 1999; Kleffmann et al., 2003; Wong et al., 2011; Zhang et al., 2009; Sörgel et al., 2011a; VandenBoer et al., 2013). Because the surface area of ground (including vegetation surface, building surface and soil, etc.) is generally larger than the surface area of aerosols, some studies suggested that the heterogeneous reaction of NO<sub>2</sub> and water vapor on ground surfaces was the main source of HONO (Harrison and Kitto, 1994; Li et al., 2012; Wong et al., 2012). Furthermore, the correlations between HONO/NO<sub>2</sub> and NH<sub>3</sub> and RH are 0.3746 and 0.2381, respectively, and the correlation further improved between HONO/NO<sub>2</sub> and the product of NH<sub>3</sub> and RH ( $R^2 = 0.4597$ ). Some studies proposed that NH<sub>3</sub> can decrease the free-energy barrier in hydrolysis of NO<sub>2</sub> thus enhance the HONO formation (Xu et al., 2019; Li et al., 2018b; Zhang and Tao, 2010; Wang et al., 2021a).

**Figure 4. Correlations between HONO, HONO/NO<sub>2</sub> and various parameters during the time interval of 18:00–6:00.**

In Fig. S5, we further explored the RH effect by focusing on high HONO/NO<sub>2</sub> values, i.e., the 5 highest HONO/NO<sub>2</sub> values for 5% RH intervals (Stutz et al., 2004). When RH was lower than 87.5%, HONO/NO<sub>2</sub> increased with RH, which is in accordance with the reaction kinetics of disproportionation reaction of NO<sub>2</sub> and H<sub>2</sub>O. Furthermore, the slope of linear fitting between HONO/NO<sub>2</sub> and RH was much smaller for RH range of 30% ~ 70% (slope = 0.04%;  $R^2 = 0.5202$ ) than for the RH range of 70% ~ 87.5% (slope = 0.25%,  $R^2 = 0.8767$ ). Similar piecewise correlations between HONO/NO<sub>2</sub> and RH have been found in previous studies (Qin et al., 2009; Zhang et al., 2019), which have been interpreted as evidence for the non-linear dependence of NO<sub>2</sub>-to-HONO conversion efficiency on RH. Once the relative humidity exceeded 87.5%, NO<sub>2</sub>-to-HONO

conversion appeared to be inhibited by RH (slope = -0.32%;  $R^2 = 0.9750$ ). A possible explanation is that the number of water layers formed on various surfaces increased rapidly with RH, resulting in effective uptake of HONO and making the surface inaccessible or less reactive to  $\text{NO}_2$ . Previous studies also found fast growth of aqueous layers when RH over 70% for glass (Saliba et al., 2001) and over 80% for stone (Stutz et al., 2004). The tipping point inferred from ambient observations appear to vary across locales, likely reflecting the different composition of the ground surfaces, e.g., 60% for Chengdu (Yang et al., 2021b), 65–70% for Beijing (Wang et al., 2017a), 70% for Back Garden (Li et al., 2012), 75% for Shanghai (Wang et al., 2013), and 85% for Xi'an (Huang et al., 2017).

We calculated the strength of the HONO formation from  $\text{NO}_2$  heterogenous reaction on on ground surface ( $P_{\text{ground}}$ ) and aerosol surface ( $P_{\text{aerosol}}$ ) based on the empirical data derived from either experiments or observations.

$$P_{\text{ground}} = \frac{1}{8} \gamma_{\text{NO}_2 \rightarrow \text{ground}} \times [\text{NO}_2] \times C_{\text{NO}_2} \times \frac{S_g}{V} \quad (7)$$

$$P_{\text{aerosol}} = \frac{1}{4} \gamma_{\text{NO}_2 \rightarrow \text{aerosol}} \times [\text{NO}_2] \times C_{\text{NO}_2} \times \frac{S_a}{V} \quad (8)$$

$$\frac{S_g}{V} = \frac{2.2}{H} \quad (9)$$

Where  $C_{\text{NO}_2}$  is the mean molecular velocity of  $\text{NO}_2$  ( $\text{m s}^{-1}$ ),  $\gamma_{\text{NO}_2 \rightarrow \text{ground}}$  and  $\gamma_{\text{NO}_2 \rightarrow \text{aerosol}}$  represent the uptake coefficient of  $\text{NO}_2$  on ground surface and aerosol surface, respectively,  $S_g/V$  and  $S_a/V$  are the surface area to volume ratio ( $\text{m}^{-1}$ ) for both ground and aerosol, respectively. Considering the land use type of the study site, we treated the ground as an uneven surface, and a factor of 2.2 per unit ground surface measured by Voogt and Oke (1997) was adopted to calculate the total active surface. Hence,  $S_g/V$  can be calculated by Eq. (9), where  $H$  is the mixing layer height. The surface area-to-volume ratio  $S_a/V$  of  $\text{PM}_{10}$  was not available in this study and was estimated according to  $\text{PM}_{2.5}$  and  $S_a/V$  value in Guangzhou Xinken by Su et al. (2008a). The uptake coefficients of  $\text{NO}_2$  on ground surface and aerosol surface were assumed to be  $4 \times 10^{-6}$  following previous studies (Li et al., 2018a; Liu et al., 2019a; Zhang et al., 2021) (the summary of the parameterisations used for nighttime HONO budget calculation can be found in Table S5). With these assumptions, an average value of  $P_{\text{ground}}$  of  $0.27 \pm 0.13$  ppbv  $\text{h}^{-1}$  can be derived, which is far larger than  $P_{\text{aerosol}}$  ( $0.03 \pm 0.02$  ppbv  $\text{h}^{-1}$ ) (Fig. 5 (c) and (d)).

370

In sum, our correlation analysis for HONO/ $\text{NO}_2$  and parameterized calculations suggested that nighttime heterogenous conversion of  $\text{NO}_2$  into HONO at our site mainly occurred on the ground rather than on aerosol sources, while the correlation analysis provides evidence for the role of  $\text{NH}_3$  and water vapor in HONO formation. It should be noted that, unlike the  $\text{NO} + \text{OH}$  reaction or the primary emission, which turned out as major HONO sources even at their lower limit considering uncertainties, the magnitude of the heterogenous source as well as its contribution to overall HONO budget varied greatly with the assumed uptake coefficients of  $\text{NO}_2$ , which can span two orders of magnitude.

375

### 3.2.4 Removal of HONO

As discussed above, strong sinks are required to balance the nighttime HONO production. Since the reactions of HONO + OH and HONO + HONO are negligible (Kaiser and Wu, 1977; Mebel et al., 1998), it is conceivable that nighttime HONO is mainly removed through deposition  $L_{\text{Dep}}$  (El Zein and Bedjanian, 2012; Li et al., 2012; Hao et al., 2020; Meng et al., 2020), transport processes, e.g. entrainment of background air  $L_{\text{dilution}}$  (Gall et al., 2016; Meng et al., 2020), and uptake on aerosols  $L_{\text{aerosol}}$ . These terms can be expressed as follows:

$$L_{\text{Dep}} = \frac{V_d \times [\text{HONO}]}{H} \quad (10)$$

$$L_{\text{aerosol}} = \frac{1}{4} \gamma_{\text{HONO} \rightarrow \text{aerosol}} \times [\text{HONO}] \times C_{\text{HONO}} \times \frac{S_a}{V} \quad (11)$$

$$L_{\text{dilution}} = k_{(\text{dilution})} \times ([\text{HONO}] - [\text{HONO}]_{\text{background}}) \quad (12)$$

where  $V_d$  is the average deposition velocity,  $\gamma_{\text{HONO} \rightarrow \text{aerosol}}$  is the uptake coefficient of HONO on aerosol surface,  $k_{(\text{dilution})}$  is the dilution rate (including both vertical and horizontal transport) (Dillon et al., 2002).  $C_{\text{HONO}}$  is the mean molecular velocity of HONO ( $\text{m s}^{-1}$ ), and  $[\text{HONO}]$  and  $[\text{HONO}]_{\text{background}}$  represents the HONO concentration at the observation site and the background site, respectively. In this work, the lowest nighttime HONO concentration was taken as the  $[\text{HONO}]_{\text{background}}$ .

The average loss rate of HONO by dilution was calculated to be  $0.18 \pm 0.16 \text{ ppbv h}^{-1}$ , which is in the range of prior results (Gall et al., 2016; Liu et al., 2020a; Liu et al., 2020b). The average value of  $L_{\text{aerosol}}$  and  $L_{\text{OH+HONO}}$  was  $0.008 \pm 0.006 \text{ ppbv h}^{-1}$  and  $0.008 \pm 0.012 \text{ ppbv h}^{-1}$ , respectively. In order to balance the nighttime HONO budget and assuming dry deposition to be responsible for the remaining amount of HONO loss, a dry deposition rate of  $\sim 2.5 \text{ cm s}^{-1}$  was adopted accounting for an average loss rate of  $0.41 \pm 0.31 \text{ ppbv h}^{-1}$  by deposition between 18:00–6:00, when using the median parameter values in Table S5 to calculate the HONO sources and sinks. This result is consistent with previous studies suggesting dry deposition as the dominant loss way for HONO during night (Li et al., 2012; Hao et al., 2020; Meng et al., 2020). The upper limit of  $L_{\text{aerosol}}$  is only  $0.10 \pm 0.08 \text{ ppbv h}^{-1}$ , suggesting that HONO loss on aerosols was not a major sink, as also suggested by prior studies (El Zein and Bedjanian, 2012; El Zein et al., 2013; Romanias et al., 2012).

### 3.2.5 Nighttime HONO budget: relative importance of sources and their uncertainties

It is useful to evaluate the balance of HONO budget by evaluating calculated/parameterized sources and sinks against the observed HONO level and variability. The observed production rate of HONO  $P_{\text{obs}}$  can be defined as the sum of the total loss rates and change rates of HONO (Gu et al., 2021). When using the median values of parameters (Table S5) and taking an average throughout the night (18:00–6:00), all five sources are greater than or close to the average accumulating rate of

HONO at night derived from observed HONO variation ( $0.02 \pm 0.06$  ppbv  $\text{h}^{-1}$ ), indicating a balanced HONO budget  
410 considering all uncertainties. Ranking the source strengths with their median estimates suggested that heterogeneous  
conversion of  $\text{NO}_2$  on ground surface ( $0.27 \pm 0.13$  ppbv  $\text{h}^{-1}$ ), primary emission from vehicle exhaust (between  $0.04 \pm 0.02$   
ppbv  $\text{h}^{-1}$  and  $0.30 \pm 0.15$  ppbv  $\text{h}^{-1}$  with a middle value of  $0.16 \pm 0.07$  ppbv  $\text{h}^{-1}$ ) and the homogeneous reaction of  $\text{NO} + \text{OH}$   
( $0.14 \pm 0.30$  ppbv  $\text{h}^{-1}$ ) were major sources of HONO at night. Nighttime soil emission rate ( $0.019 \pm 0.009$  ppbv  $\text{h}^{-1}$ ) and  
heterogeneous  $\text{NO}_2$  conversion on the aerosol surfaces ( $0.03 \pm 0.02$  ppbv  $\text{h}^{-1}$ ) were two other minor sources. Dry deposition  
415 ( $0.41 \pm 0.31$  ppbv  $\text{h}^{-1}$ ) was the principal loss process of nighttime HONO, followed by dilution ( $0.18 \pm 0.16$  ppbv  $\text{h}^{-1}$ ), while  
the homogeneous reaction of  $\text{HONO} + \text{OH}$  ( $0.008 \pm 0.012$  ppbv  $\text{h}^{-1}$ ) and HONO uptake on the aerosol surfaces ( $0.008 \pm$   
 $0.006$  ppbv  $\text{h}^{-1}$ ) were insignificant.

We also made an attempt to obtain a time resolved HONO budget on an hourly basis, although the results are not satisfactory  
420 for all the hours at night, with obvious differences between observed and calculated rates of HONO variation, e.g., at 22:00  
and from 2:00 to 5:00 (Fig. S6). This is well expected considering much more amplified uncertainties associated with hourly  
variabilities of various quantities, which can be considerably reduced by averaging all hours. This is why subtle and careful  
data filtering is necessary when nighttime HONO chemistry is examined in detail (Wong et al., 2011). Such a granular  
analysis is more appropriate for the daytime when HONO lifetime is much shorter and uncertainties affecting the  
425 interpretation of HONO chemistry (e.g., emission and transport) are much muted. As a matter of fact, because the rate of  
HONO change shown in Fig. S6 is a first order derivative of the HONO concentration itself, one can expect that HONO  
concentrations from each source would show greater variations, making it more difficult to compare on an hourly basis.  
Another challenge is that since those parameters used for calculating HONO source strengths have a range in their estimates  
(Table S5), the HONO source strengths also have a wide range individually, and therefore there are numerous possible  
430 combinations of these sources with different strengths and rankings to close the budget.

The comparison and ranking of sources considering variability and uncertainty becomes less straightforward than ranking  
nighttime average source strengths (Fig. 5). Among the three largest sources, both primary (non-soil) emission and  $\text{NO}_2$   
heterogeneous source on ground showed an evening peak and decreased toward after midnight. The  $\text{NO} + \text{OH}$  source showed  
435 a different trend with its lowest level in the evening, making it the smallest source among the three at that time. Although the  
 $\text{NO}_2$  heterogeneous source on ground appeared the largest with its median parameter value, it also had the largest range of  
estimate, suggesting that its importance is more uncertain compared to the other sources. On the other hand, the other two  
minor sources, i.e., the  $\text{NO}_2$  heterogeneous source on aerosols and soil emission are unlikely more important than these three  
sources given their ranges of low estimates. The variability and uncertainty of dry deposition are largely dependant on other  
440 terms of sources and sinks since it is derived as a final term to balance the budget.

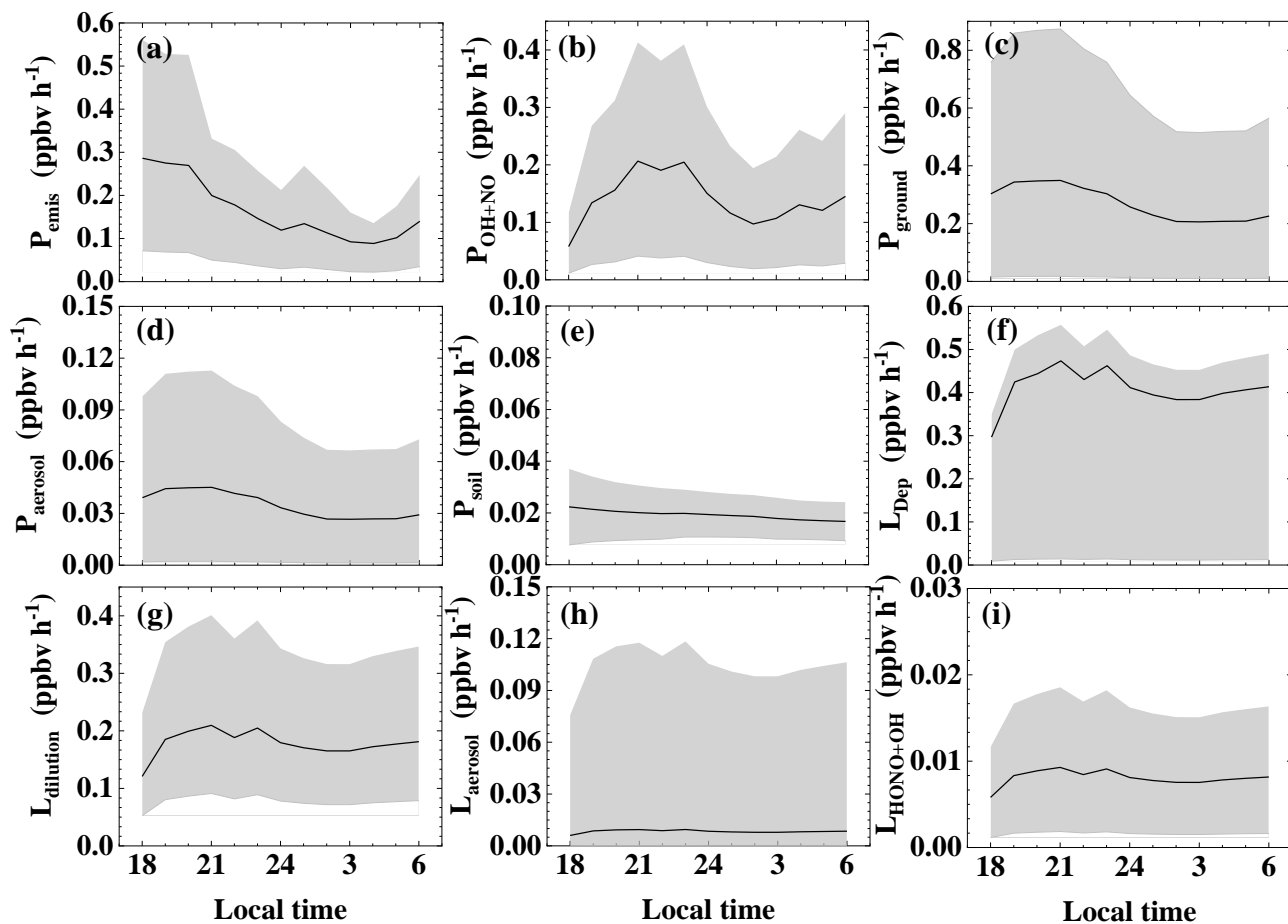

Figure 5. The nocturnal variation of the terms of HONO budget (a) primary emission from vehicle exhaust, (b) homogeneous reaction of  $\text{NO} + \text{OH}$ , (c) heterogeneous conversion of  $\text{NO}_2$  on ground surfaces, (d) heterogeneous conversion of  $\text{NO}_2$  on aerosol surfaces, (e) soil emission and HONO loss from (f) dry deposition, (g) dilution, (h) uptake on aerosols, (i)  $\text{HONO} + \text{OH}$  during Sep. 27–Nov. 9 2018 in Guangzhou. The black line is the HONO production rates with the median values of parameters, and the grey shadow represents their lower and upper limits.

### 3.3 Daytime HONO budget and unknown sources analysis

#### 3.3.1 Budget analysis

In this section, we move on to a detailed budget analysis for HONO during the daytime, when chemistry is distinctly different from at night. Similar to the nighttime analysis by invoking different terms for the daytime chemistry, the time variation of HONO concentration at our site can be related to its sources and sinks as follows:

$$455 \quad \frac{\partial[\text{HONO}]}{\partial t} = P_{\text{HONO}} - L_{\text{HONO}} = (P_{\text{OH}+\text{NO}} + P_{\text{Unknown}} + P_{\text{emis}} + P_{\text{soil}} + T_{\text{V}} + T_{\text{H}}) - (L_{\text{OH}+\text{HONO}} + L_{\text{Phot}} + L_{\text{Dep}}) \quad (13)$$

where  $\partial[\text{HONO}]/\partial t$  represents the time variation of HONO;  $P_{\text{HONO}}$  and  $L_{\text{HONO}}$  are the sources and sinks of HONO, respectively;  $P_{\text{OH}+\text{NO}}$  and  $L_{\text{OH}+\text{HONO}}$  are the homogeneous HONO formation and loss rates in Reactions R2 and R5, respectively;  $P_{\text{Unknown}}$  is the HONO production rate from unknown sources;  $T_{\text{V}}$  and  $T_{\text{H}}$  are two terms representing vertical and horizontal transport processes, respectively;  $L_{\text{Phot}}$  denotes the photolysis loss rate of HONO, which can be calculated with  $L_{\text{Phot}} = J(\text{HONO}) \times [\text{HONO}]$ ; deposition loss rate of HONO  $L_{\text{Dep}}$  can be calculated by Eq. (10). Assuming a daytime  $V_d$  of  $1.6 \text{ cm s}^{-1}$  (Hou et al., 2016; Li et al., 2011) and a daytime mixing height (H) of 1000 m (Liao et al., 2018; Song et al., 2019), the average  $L_{\text{Dep}}$  is  $0.003 \pm 0.001 \text{ ppbv h}^{-1}$ , three orders of magnitude smaller than  $L_{\text{Phot}}$  and therefore can be ignored in the following discussion.

465 OH was not measured and was calculated with a parameterized approach based on strong correlation between observed OH radicals and  $J(\text{O}^1\text{D})$ . The parameterization was first proposed by Rohrer and Berresheim (2006) and has been applied by several studies in China (Lu et al., 2013; Lu et al., 2012; Lu et al., 2014). In this study, OH was estimated with observed  $J(\text{O}^1\text{D})$  along with parameters from fitting the observed OH radicals and  $J(\text{O}^1\text{D})$  data in Guangzhou Back Garden by Lu et al. (2012). The daytime maximum OH concentration was estimated to be  $1.3 \times 10^7 \text{ cm}^{-3}$ , which is slightly smaller than the daily peak values of  $1.5\text{--}2.6 \times 10^7 \text{ cm}^{-3}$  observed in summer of Guangzhou by Lu et al. (2012). And the estimated daily average OH concentration is  $6.7 \times 10^6 \text{ cm}^{-3}$ , close to  $7.5 \times 10^6 \text{ cm}^{-3}$  measured in the PRD region in autumn of 2014 by Yang et al. (2017b). Daytime  $P_{\text{emis}}$  was calculated based on the method (3) (mentioned in Sect. 3.2.1). Because the HONO lifetime was in the order of 20 min under typical daytime conditions (Stutz et al., 2000) and the transport distance is only a few kilometers, 475 the NOx emission rate extracted from the  $3 \text{ km} \times 3 \text{ km}$  grid cell centred around sampling site is used to calculate the impact of primary emission on HONO.

To minimize interferences, we chose a period from 9:00 to 15:00 with intense solar radiation and a short HONO lifetime. Horizontal transport  $T_{\text{H}}$  was assumed negligible by selecting the cases with low wind speed (Su et al., 2008b; Yang et al., 480 2014). The magnitude of vertical transport  $T_{\text{V}}$  can be estimated by using a parameterization for dilution by background air according to Dillon et al. (2002), i.e.  $T_{\text{V}} = k_{(\text{dilution})} \times ([\text{HONO}] - [\text{HONO}]_{\text{background}})$ . Where  $k_{(\text{dilution})}$  is the dilution rate,  $[\text{HONO}]_{\text{background}}$  represents the background HONO concentration. Assuming a  $k_{(\text{dilution})}$  of  $0.23 \text{ h}^{-1}$  (Dillon et al., 2002; Sörgel et al., 2011a), a  $[\text{HONO}]_{\text{background}}$  value of 10 pptv (Zhang et al., 2009), and taking the mean noontime  $[\text{HONO}]$  value of 400 pptv in this study, a value of about  $0.09 \text{ ppbv h}^{-1}$  can be derived, which is much smaller than  $L_{\text{Phot}}$  and can be ignored in the 485 following discussion. The average daytime HONO emission rate from soil  $P_{\text{soil}}$  varied from 0.002 to 0.007 with a mean value

of  $0.004 \pm 0.002$  ppbv  $\text{h}^{-1}$ , which is three orders of magnitude smaller than  $L_{\text{Phot}}$ , and can also be ignored in the following discussion. As a result,  $P_{\text{Unknown}}$  can be expressed by Eq. (14), in which  $\partial[\text{HONO}]/\partial t$  is substituted by  $\Delta[\text{HONO}]/\Delta t$ .

$$\frac{\Delta[\text{HONO}]}{\Delta t} = (P_{\text{OH+NO}} + P_{\text{emis}} + P_{\text{Unknown}}) - (L_{\text{OH+HONO}} + L_{\text{Phot}}) \quad (14)$$

490

Figure 6 shows the budget of HONO from 9:00 to 15:00. As expected, photolysis HONO  $L_{\text{Phot}}$  ( $1.58 \pm 0.82$  ppbv  $\text{h}^{-1}$ ) was the main loss pathway in the day, followed by a small contribution by the homogeneous reaction of HONO + OH ( $L_{\text{OH+HONO}}$ ,  $0.07 \pm 0.03$  ppbv  $\text{h}^{-1}$ ). Among the sources,  $P_{\text{OH+NO}}$  and  $P_{\text{Unknown}}$  were comparable in magnitudes, with an average of  $0.79 \pm 0.61$  ppbv  $\text{h}^{-1}$  and  $0.65 \pm 0.46$  ppbv  $\text{h}^{-1}$ , respectively.  $P_{\text{Unknown}}$  showed a photo-enhanced feature, reaching its maximum at 12:00 at  $0.97$  ppbv  $\text{h}^{-1}$ , similar to the observations in Xinken (Su et al., 2008b), Beijing (Yang et al., 2014), Wangdu (Liu et al., 2019a), Changzhou (Zheng et al., 2020) and Cyprus (Meusel et al., 2016). The average of  $P_{\text{Unknown}}$  is comparable to the observation in Back Garden ( $0.77$  ppbv  $\text{h}^{-1}$ ) by Li et al. (2012), but smaller than those in Xinken ( $\approx 2.0$  ppbv  $\text{h}^{-1}$ ) by Su et al. (2008b) and Guangzhou city area ( $1.25$  ppbv  $\text{h}^{-1}$ ) by Yang et al. (2017a). Homogeneous reaction of NO + OH reached its maximum in the early morning, and contributed the most fraction in the whole day. Apparently, high NO concentrations at our site made  $P_{\text{OH+NO}}$  the biggest daytime source of HONO, exceeding  $P_{\text{Unknown}}$ , similar to other high-NO<sub>x</sub> sites such as Santiago de Chile (Elshorbany et al., 2009), London (Heard et al., 2004), Paris (Michoud et al., 2014), Beijing (Liu et al., 2021; Slater et al., 2020; Zhang et al., 2019; Liu et al., 2020b), Taiwan (Lin et al., 2006) and Hebei (Xue et al., 2020). Next, we investigate possible factors relating to  $P_{\text{Unknown}}$ .

495

500

505 **Figure 6. Items of the HONO budget (Eq. (14)) in Guangzhou during the observation period.**

Figure 7 shows the correlation between  $P_{\text{Unknown}}$  and  $\text{NO}_2$  and  $J(\text{NO}_2)$  was 0.0681 and 0.2713, respectively. The correlation between  $P_{\text{Unknown}}$  and  $\text{NO}_2 \times J(\text{NO}_2)$  further improved to 0.4116, indicating that  $P_{\text{Unknown}}$  may be related to the photo-enhanced reaction of  $\text{NO}_2$  (Jiang et al., 2020; Li et al., 2018a; Liu et al., 2019a; Liu et al., 2019b; Su et al., 2008b; Zheng et al., 2020; Huang et al., 2017).

### 510 3.3.2 Possible mechanisms for daytime HONO production

No correlation was found between  $P_{\text{Unknown}}$  and  $\text{PM}_{2.5}$  ( $R^2 = 0.00014$ ), indicating that particulate matters may not be a key factor in daytime HONO production (Wong et al., 2012; Li et al., 2018a; Sörgel et al., 2011a; Wang et al., 2017a; Zheng et al., 2020). Meanwhile, the correlations between  $P_{\text{Unknown}}$  and nitrate in  $\text{PM}_1$  and the sum of gaseous nitric acid and nitrate in  $\text{PM}_1$  were very low, with  $R^2$  of 0.0348 and 0.0062 respectively. And the correlation between  $P_{\text{Unknown}}$  and the product of nitrate and  $J(\text{NO}_2)$  was also poor  $R^2 = 0.0007$ , which does not relate  $P_{\text{Unknown}}$  to the photolysis of nitrate or gaseous nitric acid. Wang et al. (2016) and Ge et al. (2019) suggested that  $\text{NH}_3$  can efficiently promote the reaction of  $\text{NO}_2$  and  $\text{SO}_2$  to form

HONO and sulfate. However, we did not find good correlations for  $P_{\text{Unknown}}$  vs.  $\text{NH}_3$ ,  $P_{\text{Unknown}}$  vs.  $\text{SO}_2$ , or  $P_{\text{Unknown}}$  vs.  $\text{NH}_3 \times \text{SO}_2$ .

520 In summary, at our site with relatively strong traffic impact and high  $\text{NO}$ ,  $\text{NO} + \text{OH}$  appears to be the largest daytime HONO source followed by an unknown photolytic source, which does not seem to be related to aerosols, nor does it seem to be related to the photolysis of nitrate/nitric acid, nor the reaction between  $\text{NO}_2$ ,  $\text{SO}_2$  and  $\text{NH}_3$ .

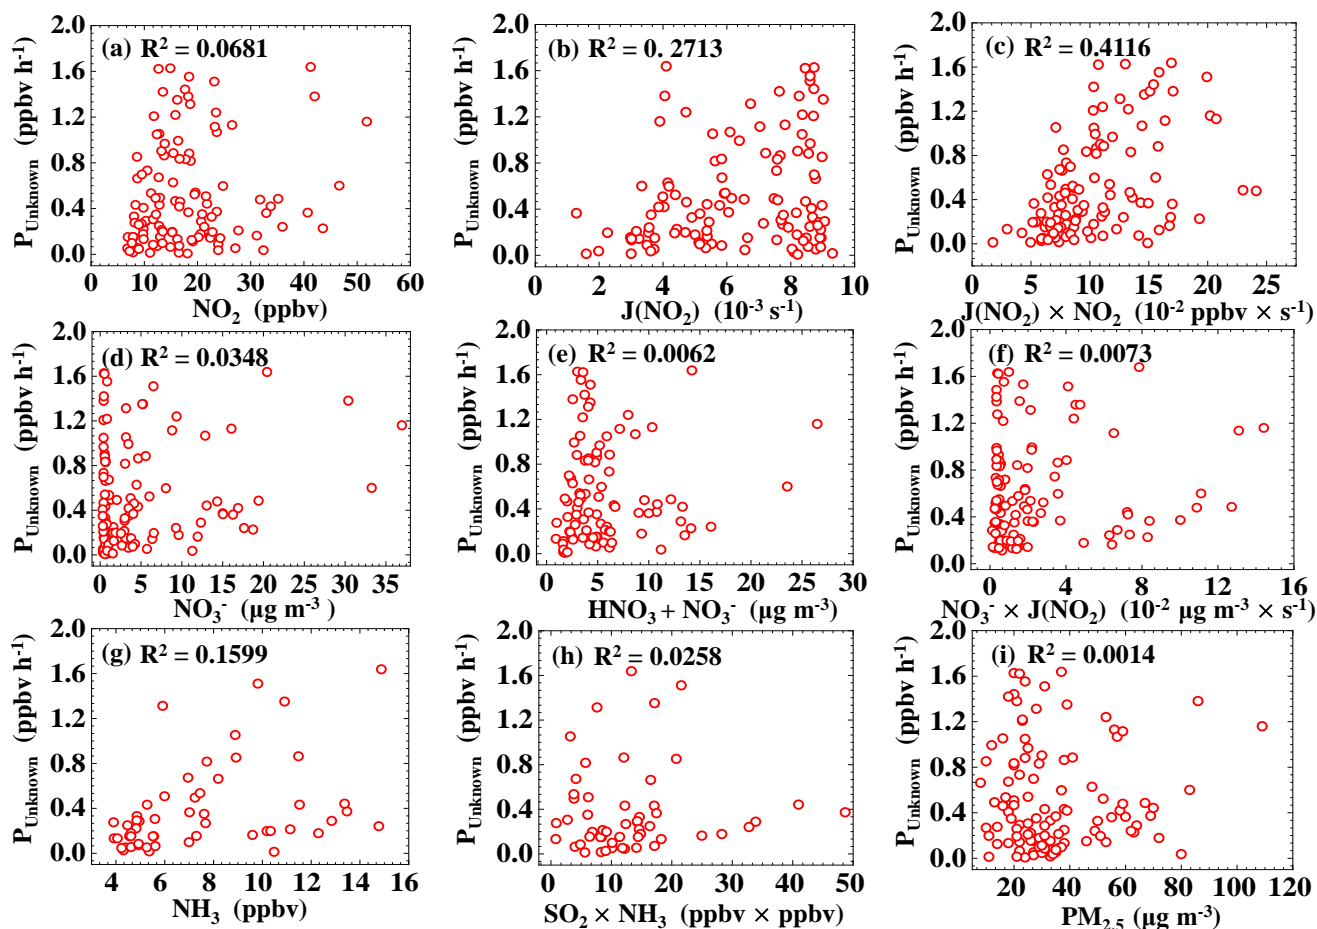

Figure 7. Correlations between daytime HONO unknown sources  $P_{\text{Unknown}}$  and related parameters.

#### 525 4 Conclusions

Nitrous acid (HONO) was measured with a custom-built LOPAP instrument, along with meteorological parameters and other atmospheric constituents at an urban site in Guangzhou in Pearl River Delta from 27 September to 9 November 2018. The HONO concentrations varied from 0.02 to 4.43 ppbv with an average of  $0.74 \pm 0.70$  ppbv. Compared to prior

measurements in Guangzhou, a decreasing trend of HONO can be seen along with improved air quality in the city over the  
530 past decade.

We have investigated budget of HONO at this site using these data and our key findings are summarized as follows.

We found that the emission ratios (HONO/NO<sub>x</sub>) derived from an analysis of 11 fresh plumes varied from 0.1% to 1.5% with  
535 an average value of  $0.9\% \pm 0.4\%$ . Using this estimated emission ratio and an estimate of NO<sub>x</sub> emission rate extracted from a  
grid cell around our site in a high-resolution (3 km × 3 km) NO<sub>x</sub> emission inventory, we estimated a primary HONO  
emission rate of  $0.30 \pm 0.15$  ppbv h<sup>-1</sup>, which turned out far larger (almost by an order of magnitude) than what would be  
estimated with a city-level NO<sub>x</sub> emission estimate, which does not adequately represent NO<sub>x</sub> emission rate specifically for  
the observation site. Thus, for future analysis of HONO data to properly estimate direct emission of HONO, we suggest that  
540 high quality emission data be used to reduce uncertainty. This is especially crucial for a site that receives nearby traffic  
emissions like ours.

HONO produced by the homogeneous reaction of NO + OH at night was  $0.14 \pm 0.30$  ppbv h<sup>-1</sup>, which represents a secondary  
HONO source. Another major secondary HONO source at night is heterogeneous conversion of NO<sub>2</sub> on ground surface ( $0.27$   
545  $\pm 0.13$  ppbv h<sup>-1</sup>). Correlation analysis shows that the heterogeneous reaction of NO<sub>2</sub> related to NH<sub>3</sub> and RH may contribute  
to the nighttime HONO formation. These two secondary sources and the primary emission from vehicle exhaust (between  
 $0.04 \pm 0.02$  ppbv h<sup>-1</sup> and  $0.30 \pm 0.15$  ppbv h<sup>-1</sup> with a median value of  $0.16 \pm 0.07$  ppbv h<sup>-1</sup>) were found to be the three  
largest sources of HONO at night. Because of the large range of those parameter values assumed in their calculations (e.g.,  
the NO<sub>2</sub> uptake coefficient that spans two orders of magnitude), the relative importance of the three major sources depend on  
550 these assumptions. Soil emission ( $0.019 \pm 0.009$  ppbv h<sup>-1</sup>) and heterogeneous NO<sub>2</sub> conversion on the aerosol surfaces ( $0.03$   
 $\pm 0.02$  ppbv h<sup>-1</sup>) were two other minor sources. Our calculations suggested that dilution acted as a major sink ( $0.18 \pm 0.16$   
ppbv h<sup>-1</sup>), while loss of HONO on the aerosol surfaces played a much less important role. In order to balance the nighttime  
HONO budget and assuming dry deposition to be responsible for the remaining amount of HONO loss, a dry deposition rate  
of  $2.5$  cm s<sup>-1</sup> is required, equivalent to a loss rate of  $0.41 \pm 0.31$  ppbv h<sup>-1</sup>.

555 Daytime HONO budget analysis revealed that in order to sustain the observed HONO concentration around 450 pptv despite  
fast photolysis of HONO, an additional unknown source production rate ( $P_{\text{Unknown}}$ ) of  $0.65 \pm 0.46$  ppbv h<sup>-1</sup> was needed, in  
addition to primary emission  $P_{\text{emis}}$  at  $0.12 \pm 0.02$  ppbv h<sup>-1</sup>, and the homogenous reaction source  $P_{\text{OH+NO}}$  at  $0.79 \pm 0.61$  ppbv  
h<sup>-1</sup>. It is worth noting that the homogenous HONO source by NO + OH appeared to be a stronger source of HONO than the  
560 unknown source ( $P_{\text{Unknown}}$ ), because of high levels of NO at our site. Correlation analysis between  $P_{\text{Unknown}}$  and proxies of  
different mechanisms showed that  $P_{\text{Unknown}}$  appeared to be photo-enhanced, and yet the mechanism remains unclear. Aerosols

did not appear to be as important as ground as a heterogenous reaction media, as suggested by the weak correlation between  $P_{\text{Unknown}}$  and  $\text{PM}_{2.5}$ . No correlations were found between  $P_{\text{Unknown}}$  and nitrate/ $\text{HNO}_3$ ,  $\text{NH}_3$ ,  $\text{SO}_2$ .

565 Overall, these results from our study offer a unique perspective on HONO at an urban site receiving heavy traffic emissions  
in the PRD region. Our budget calculations and comprehensive uncertainty analysis suggest that at such locations as ours,  
HONO direct emissions and  $\text{NO} + \text{OH}$  can become comparable or even surpass other HONO sources that typically receive  
greater attention and interest, such as the  $\text{NO}_2$  heterogenous source and the unknown daytime photolytic source. Our findings  
emphasize the need to reduce the uncertainties of both conventional and novel HONO sources and sinks to advance our  
570 understanding of this important source of atmospheric OH.
