**Abstract.** Ship emissions and coastal air pollution around China are expected to be alleviated with the gradually implemented gradual implementation of domestic ship emission control (DECA) policies. However, ~~there is so far a lack of~~ a comprehensive post-assessment on the ~~ship emission response after the policy implementation~~ policy's effectiveness is still lacking. This study developed a series of high spatiotemporal ship emission inventories around of China's inland rivers and the 200 Nm coastal zone from 2016 to 2019 based on an updated Ship Emission Inventory Model (SEIM v2.0), and analysed the interannual changes in of emissions under the influence of both ship activity increases and gradually promoted policies. In this model, NO<sub>x</sub>, SO<sub>2</sub>, PM and HC emissions from ships in China's inland rivers and the 200 Nm coastal zone were estimated ~~in every single day~~ with a spatial resolution of 0.05 × 0.05 degrees, based on a combination of Automatic Identification System (AIS) data and the Ship Technical Specifications Database (STSD). The route restoration technology and classification of ocean-going vessels (OGVs), coastal vessels (CVs) and river vessels (RVs) has greatly improved our model in SEIM v2.0 in the spatial distribution of ship emissions. ~~has greatly improved the spatial distribution of ship emissions and the river vessels (RVs) are better distinguished by using the spatial frequency distribution method.~~ From 2016 to 2019, SO<sub>2</sub> and PM emissions from ships decreased by 29.6% and 26.4%, respectively, while ship NO<sub>x</sub> emissions increased by 13.0%. Although the DECA 1.0 policy has been implemented since 2017, it was not until 2019 ~~with the~~ when DECA 2.0 came into effect that a significant emission reduction was achieved, e.g., a year-on-year decrease of by 33.3% ~~from 2018 to 2019~~, regarding SO<sub>2</sub>. Considering the potential emissions brought by the continuous growth of maritime trade, however, an even larger SO<sub>2</sub> emission reduction effect of 39.8% was achieved in these four years compared with the scenario without switching to cleaner fuel. Containers and ~~bulk carriers~~ bulk carriers are still the dominant ~~dominate~~ contributors to ship emissions, and newly-built, large ships and ships using clean fuel oil account for ~~are taking~~ an increasingly large proportion in of emission structures. ~~The~~ Four -year consecutive daily ship emissions were presented for major ports, which ~~timely~~ reflects the influence ~~response~~ of the step-by-step DECA policy on emissions in a timely manner and may provide useful references for port observation experiments and local policy making. In addition, the spatial distribution shows that a number of ships detoured outside the scope of DECA 2.0 in 2019, perhaps to save ~~the costs~~ on more expensive low sulfur oil, which would ~~increase~~ ing emissions in farther maritime areas. The multi-year

ship emission inventory provides high-quality datasets for air quality and dispersion modellings, as well as verifications for in-situ observation experiments, which may also guide further ship emission control directions in China.

## 1 Introduction

Shipping is an important ~~important~~ significant anthropogenic source of air pollutants and greenhouse gases, ~~which~~ and has come into the view of scientists and the public since the end of the last century (Corbett and Fischbeck, 1997; Capaldo et al., 1999; Lawrence and Crutzen, 1999). Air pollutants emitted from ships can be further transported to inland areas by the onshore flow, along with ~~the~~ atmospheric chemical transformations, aggravating air pollution and endangering human health (Endresen et al., 2003; Eyring et al., 2007; Eyring et al., 2010; Corbett et al., 2007). In ~~the past~~ recent decades, despite the improvement of global fuel quality and engine post-treatment technology, shipping emissions ~~are still increasing driven by~~ have continued to increase due to the ever-growing maritime trade (IMO, 2020; UNCTAD, 2019). Recent studies ~~showed~~ show that global shipping emissions constituted 3% of anthropogenic CO<sub>2</sub> emissions in 2017 (IMO, 2020), and much more proportions of ~~for~~ reactive gases, e.g., 20% ~~to~~ of NO<sub>x</sub> and 12% ~~to~~ of SO<sub>2</sub> emissions (McDuffie et al., 2020). China, as the world's largest maritime trading country, and sitting on seven of the world's top ten ports with even more densely distributed coastal ports, is meeting an ~~more~~ even tougher challenge due to ~~the~~ its lagging emission control measurements compared to European and American countries (Mao and Rutherford, 2018b).

In recent years, numerous researchers have attempted to quantify ship emissions in ~~of~~ China and evaluate their air quality impacts. These studies suggest that ship emissions of SO<sub>2</sub> in China are nearly 5 times those ~~of that~~ from road transportation (Chen et al., 2017a), and emissions within 12 nautical miles (Nm) accounts for ~ 40% of the total emissions from all ship emissions in coastal areas (Zhang et al., 2017; Li et al., 2018). The influence of coastal ships on the ~~to~~ annual average PM<sub>2.5</sub> concentration (> 0.1 µg/m<sup>3</sup>) can reach as far as 960 kilometers ~~resers~~ inland in China (Lv et al., 2018). Exhaust emissions from ships have contributed significantly to air pollution in major port clusters, e.g., the Bohai Rim Area (BRA), the Yangtze River Delta (YRD) and the Pearl River Delta (PRD) regions, and the maximum increase in ~~of~~ annual PM<sub>2.5</sub> concentrations has reached ~~up to~~ 2 ~ 5 µg/m<sup>3</sup>, with the greatest impact on YRD region (Chen et al., 2018; Liu et al., 2018; Lv et al., 2018; Feng et al., 2019). During ship plume-influenced periods, ships can even contribute to over 20% of the total PM<sub>2.5</sub> concentrations in port centres, e.g., Shanghai Port, and Qingdao Port (Fan et al., 2016; Chen et al., 2017b). The adverse impact ~~brought~~ by ~~of~~ ship emissions also places an enormous ~~lay huge~~ burden on human health, causing 14,500 ~ 37,500 premature deaths in ~~a large scale of~~ East Asia and ~~also~~ hundreds of that in ~~regional areas of~~ the PRD of China (Liu et al., 2016; Chen et al., 2019).

60 These previous evaluations have made great efforts to support the formulation of China's domestic emission control area (DECA) initially designed for BRA, YRD and PRD and later upgraded expanded to the entire ~~whole~~ water areas of 12 Nm from the baseline of Mainland China, ~~where~~ Ships entering the DECA ~~were~~ are required to switch clean fuel oil with a lower

sulfur content. However, these assessments are mostly so-called “prior assessments”, namely, evaluations of the cost and benefits of environmental and health improvement by assuming control scenarios based on the earlier ship activities before the implementation of the policy. Under the circumstance of increasing shipping demand and, synchronized by the step-by-step implementation of control measures, the “post evaluation” is of equal importance to seek the response of actual ship activities and emissions to the access whether the policies are effective and as well as to provide powerful foundations for in-situ observation experiments (Wu et al., 2021). Although a number of studies have demonstrated the air quality benefits due to ships switching to low sulfur oil in local port areas (Zhang et al., 2018a; Zhang et al., 2019b; Zou et al., 2020; Zhang et al., 2018b), there is so far a lack of a comprehensive national-scale evaluation that reflects the benefits of gradually promoted DECA policy, which is vital to guide further ship emission control direction in China.

With the advent of the big data era, the characterization of ship emissions has evolved from the earlier “top-down” estimation based on global fuel consumption (Corbett et al., 1999; Endresen et al., 2003) to the “bottom-up” model based on the big data from ship’s automatic identification system (AIS) (Jalkanen et al., 2009; Winther et al., 2014; Liu et al., 2016; Johansson et al., 2017; Nunes et al., 2017). The AIS-based ship emission inventories have great advantages in improving the spatial-temporal resolution for numerical simulations, as well as providing possibilities for near-real-time emission estimations to meet regulatory needs (Miola and Ciuffo, 2011; Nunes et al., 2017; Huang et al., 2020). However, emission calculation methods based on big data greatly depend on the data quality, thus demanding tedious complicated steps for data cleaning. As the loss of AIS signal occurs in many cases, dealing with long-time missing AIS signals has been one of the key technical problems both for both scientific research and supervision (Zhang et al., 2019c; Peng et al., 2020; Zhang et al., 2020). Without targeted measures, the estimated ship emissions would be spatially and temporally misallocated, thus further raising uncertainties in environmental impact assessments.

In this study, we developed a series of ship emission inventories (0.05° × 0.05°, daily) for the inland rivers and the 200 Nm coastal zone of China from 2016 to 2019 based on the global AIS data and the updated version of the Shipping Emission Inventory Model (SEIM v2.0). The global AIS database with annually ~30 billion signals annually, together was combined with the Ship Technical Specifications Database (STSD) covering over 350 thousand individual vessels, creating the combined as fundamental data for emission calculation. The technical details of upgrading the previous SEIM v1.0 to SEIM v2.0 were introduced in the Methods section. Based on the multi-year ship inventory data, the four-year consecutive daily ship emissions and emission structure were analyzed from the national to port level to track the variations at a fine time scale. The interannual spatial changes in emissions from ocean-going vessels (OGVs), coastal vessels (CVs) and river vessels (RVs) were presented and compared. In addition, a scenario without the DECA policy was performed in order to evaluate the effect of China's gradually implemented DECA policy, considering the actual change of interannual ship activities. The results of this study provide high-quality emission inventory data for the further numerical simulation of air quality and health benefits of ship emission reduction.

## 2 Methods

### 2.1 Ship emission inventory model (SEIM v2.0)

The SEIM v1.0 model ~~was~~ ~~has been~~ established in our previous work ~~to~~ ~~for~~ ~~developing~~ a multi-scale ship emission inventory with a high spatial and temporal resolution, which is driven by high-frequency ship AIS data (Liu et al., 2016; Fu et al., 2017; Liu et al., 2018). In this model, emissions were calculated based on the instantaneous operating status and power changes for each individual ship between two successive AIS signals, usually ranging from a few seconds to a few minutes. Each active ship in the AIS data was dynamically matched with its technical profiles for ~~identification~~ ~~classification~~ and emission calculation. With a high-frequency AIS signal transmission time and geographic locations, the ~~total~~ emissions could be ultimately ~~be~~ aggregated by ~~taking those that~~ from all ships of all time intervals in the ~~entire~~ ~~whole~~ year, resulting in an inventory with a high temporal and spatial resolution. Technical details including the data collection and cleaning, calculation formula, emission factor (EF) adoption ~~and~~ ~~as well as~~ default parameter setting of the SEIM model ~~were~~ ~~has been~~ introduced in our previous studies (Liu et al., 2016; Fu et al., 2017). The general calculation formula of the SEIM model is summarized in the Supplementary Methods. Currently, the SEIM considers ship emissions for both air pollutants (e.g., SO<sub>2</sub>, PM, NO<sub>x</sub>, CO and HC) and greenhouse gases (e.g., CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O) from the main engines, auxiliary engines and boilers.

To reduce the uncertainties in emission calculations, we have previously introduced several techniques in SEIM v1.0 (Liu et al., 2016): 1) a double-nested research domain was applied to reduce the boundary effects (i.e., sharp increase/decrease on the boundary when calculating the emission inventory in a defined region); 2) the Gradient Boosting Regression Tree (GBRT) method was adopted to predict missing values of the ship properties; 3) the propeller law was used to calculate the instantaneous engine loads; 4) the 10-minute linear interval interpolation method was used to fill long-distance AIS signal gaps. These factors all contributed to improving the reliability of the ship emission inventories. Here, we introduce a refined upgraded version of the SEIM (SEIM v2.0). ~~M v2.0 to describe the improvement of the model that applied for estimating annual ship emission inventory around China.~~ The major improvements include: 1) developing a route restoration module to restore the most likely trajectory for missing AIS signals; 2) distinguishing river vessels from AIS data based on spatial frequency distribution of ship trajectories; ~~and~~ 3) incorporating a step-by-step Chinese emission control policy with a daily scale to ~~timely~~ reflect the actual emission level in a timely manner. These improvements contributed to the consistency of the model in the real world and, to some extent, alleviated the uncertainties in our model. ~~However,~~ ~~But inevitably~~ several uncertainties inevitably still exist in this model, including AIS data gaps and anomalies (influenced by methodological conditions, equipment ~~maintenance~~ ~~maintaining~~, etc.), accuracy and coverage of STSD information, accuracy of RVs, CVs and OGVs classification, route restoration algorithm, obedience of ships under DECA policy, etc.

Figure 1 shows the ~~current structure and~~ flow chart of the SEIM v2.0, which is composed of several key modules: data pre-processing, route restoration, emission calculation, policy-abutted modification, and post-processing. First, the originally

130 collected raw AIS data and ship profile data from multiple sources are combined to form a ship activity database and STSD, and the RVs ~~are~~ will be identified based on the ship trajectories. Second, a route restoration module is applied for cross-land trajectory with a long distance in the AIS data, in which the 10-minute linear interpolation will be applied on the shorted paths instead. Third, the instantaneous emission along with the movement of the ship's trajectory will be calculated d based on the ship's static technical parameters, dynamic load changes, as well as ~~a series of extra prepared~~ parameters and factors. Then, 135 the policy-abutted modification will be applied for vessels entering the DECAs to switch to low sulfur fuels. Finally, ~~the~~ ship emission inventory datasets will be established and used for visualization and analysis from multiple perspectives. As most of the technical methods have been described in our previous work, such as GBRT methods, emission calculation algorithms, and extra parameter preparations, we focus on the study area definition, the latest data evaluations, and the improvements ~~of~~ the in SEIM v2.0 to introduce the technical details for developing ~~the~~ ship emission inventories iesy around China.

## 140 2.2 Study area

Ships have a strong spatial mobility, unlike ~~the~~ on-road mobile sources, ~~that~~ which mostly have a fixed geographical range of activities. Due to the complexity brought by the inconsistency of the ships' flag state, operating country, and activity location, it is difficult ~~hard~~ to determine the attribution country of ship emissions. In this study, the target area for developing a ship emission inventory is ~~the~~ navigable inland rivers and the coastal waters approximately within 200 Nm away from the Chinese mainland's territorial sea baseline (hereinafter referred to as the 200 Nm zone), as shown in Fig. 2. We defined the target area 145 ~~due to~~ for the following reasons. First, the 200 Nm zone is the water region with the most intensive ship traffic and complex routes. Ship emissions occurred in this region ~~are~~ have been proven ~~d~~ to have significant ~~contribution~~ impact on the ~~to~~ air pollution and human health of China (Lv et al., 2018), ~~thus it is reasonable to regard China as a receptor and investigate the regional air quality impact from the surrounding ships.~~ Second, as the current DECA is limited to 12 Nm to the baseline of the 150 territorial sea, which is far less than the proposed area of the international ECA (200 Nm), ~~thus it is possible to provide a scientific reference~~ by investigating the emission variation in the 200 Nm zone for further China's future ~~scheme~~ policy design ~~by investigating the emission variation in the 200 Nm zone.~~ In addition, ~~the 200 Nm zone is the water region with the most intensive ship traffic and complex route, which is an appropriate demonstration area to test the effect of route restoration.~~ The study area is also generally consistent to the research scope of other AIS-based ship emission inventories iesy of China ~~for so as~~ 155 ~~to make comparison~~ with other studies' ~~of the corresponding results.~~

A double-nested domain is set to calculate the ship emissions and reduce the boundary effect, ~~in which~~ As illustrated in Fig. 2, the outer domain (D1) is 0°-90°N and 90°E-140°E and the inner domain (D2) is 14°-43°N and 104°E-130°E. The spatial distribution of emissions will be retained and presented with D2 as the boundary, and the statistical results for China will ~~be~~ 160 finally be made for the inland river and the 200 Nm zone. Figure 2 also shows the scope of ~~the~~ DECA 1.0, which includes three areas, namely, BRA, YRD and PRD (~~often called DECA 1.0~~), and the ~~coastal areas~~ scope of DECA 2.0, which is approximately equal to the area from the coastline to 12 Nm from the Chinese mainland's territorial sea baseline (hereinafter

referred to as baseline). Meanwhile, ship emissions within different coastal areas, i.e., from the coastline to 12 Nm, 12-50 Nm, 50-100 Nm, and 100-200 Nm from the baseline, illustrated in Fig. 2, are also decomposed and compared to investigate the spatial variation, which are also illustrated in Fig. 2.

### 2.3 Data pre-processing and evaluations

The global dynamic AIS data for the entire whole year of 2016–2019 (from January 1st to December 31st) with on average 30 billion signals per year, include integrating both satellite-based signals and terrestrial-based signals, were collected to build a ship activity database. This database provides high-frequency information including signal time, coordinate location, navigational speed, and operating status, etc. As the AIS data are composed of the satellite AIS signals and the terrestrial-based AIS signals, the same messages received from multiple base stations may lead to large quantities of duplicates, especially when ships are berthing. To deal with the redundant information and compress the data size, only one record was kept every 10 minutes the time spans of if the continuous AIS signals meet the condition that with their instantaneous speeds both equal to 0 with and displacements less than 0.01 degrees were enlarged to 10 minutes. In this way, on the premise of keeping the total operation time unchanged, the volume of the raw AIS data was reduced. After reductioning, the AIS coverage homogeneity in our study area was has been examined in terms of time and space (see Supplementary Methods and Fig. S1). Short period drops were probably the result of from missing or abnormal AIS signals due to for many reasons, such as disruption to satellites, equipment maintenance maintaining, data transmission faults, ships sailing beyond the terrestrial station receiving range, etc. AIS signals missing or anomaly which is a common phenomenon that has been noted pointed out by previous studies (Goldworthy et al., 2019; Johansson et al., 2017; IMO, 2020). To as ensure the reliability of total emissions, it's important to have whole year data from the entire year instead of using several weeks and then scaling them multiplied to the annual total.

The STSD describes ship properties such as the vessel type, dead weight tonnage (DWT), and engine power, designed speed, flag state, etc., which has also been updated to 2019. The extended STSD currently contains over 350,000 vessels, of which 101,638 are OGVs, which is consistent with the statistics of the United Nations (UNCTAD, 2019). Besides In addition to the ship data collected from Lloyd's Register and the Classification Societies of various countries, we have also incorporated fishing ships and smaller ships that do not have IMO numbers from Global Fishing Watch (GFW) (Kroodsmas et al., 2018). These ships were observed to be quite active along China's coast. A further introduction to the updated STSD was is provided in the Supplementary Methods.

During the emission calculation method, vessels in AIS data needs to match with their technical profiles in STSD. Detailed processing methods of data collection, cleaning and matching are described in our previous works (Liu et al., 2016). Table 1 shows the statistical results of the AIS messages and active ships for different years in this study. From 2016 to 2019, an annual average of approximately about 90,000 vessels were observed in the inland rivers and the 200 Nm zone of China, and where

the number of vessels showed a downward trend year by year. Figure 3 presents the statistics for dynamic activities and static technical specifications for different ships in the target region of China, after the matching of AIS and STSD. As shown in Fig. 3a, the average daily operating time of all vessels within the Chinese waters study area is approximately  $5.3 \times 10^5$  hours/day. Among all the vessel types, the bulk carriers operate for an especially long time, followed by fishing ships and containers. Most vessels show constant daily operating hours, except a slightly decrease in the Spring Festival. However, fishing ships drops significantly in summer due to the fishing-off season. Figure 3b shows the cargo fleet structure from the perspectives of the vessel number, total DWT and total installed power of the main engines. In terms of the vessel numbers, the fishing ship accounts for the largest proportion of 42.5%, while general cargo also accounts for 29.8%, respectively. As for the total DWT, the proportion of bulk carriers reaches 49.5%, and the oil tanker also occupies a considerable proportion (23.4%). For the total power of the main engines, the proportion of containers (35.4%) exceeds that of the bulk carrier (28.0%), indicating a higher engine power demand per unit volume for containers. Owing to the distinct technical specifications of different ship types, the total DWT, power, or navigation time as well as emissions would not be linear with the number of vessels of each type would not be linear with their DWT, power, navigation time, and thus emissions.

## 2.4 Model improvements

### 2.4.1 Route restoration

Even if the AIS data has a high frequency of reporting ship activities, there are sometimes long periods of signals loss due to equipment failure or a manual shutdown. This kind of signals only accounts for a minority of AIS data, but may lead to a large deviation of in terms of the amount and distribution of ship emissions, especially in the case of long operating hours. To solve this problem, a route restoration module was developed in SEIM v2.0 to predict the most likely navigation trajectories of the lost signals and spatially reallocate ship emissions. Similar methods but with featured details have been previously experimented with by Aulinger et al. (2016) on a regional scale and Johansson et al. (2017) on a global scale. Here, we referred to their method and applied it to China with a more refined resolution.

The ship route restoration method is based on the Dijkstra algorithm (Cherkassky et al., 1996), which interpolates the lost signals evenly on the shortest shipping route connecting two endpoints, namely, the experiential routes. Thus, a comprehensive ship route network needs to be established before applying the route restoration algorithm. As the global AIS data provide massive signals of ship locations, the historical navigation trajectories for all in-service vessels are clearly visible on the map. Based on the aggregated ship traffic distribution and the geographic domain of D1 in this study, the shipping route map was drawn and split into 870 arcs connected by 656 nodes, as depicted in Fig. S1. Regarding the shipping route map as an undirected graph, by applying the Dijkstra shortest-path algorithm, the shortest route path between each node-pair can be calculated, as well as the geodesic distance aggregated by all arcs. In this way, the ship route network connected with nodes and arcs was

established ahead of time, and the shortest geodesic paths for all the node\_pairs were pre-stored as a database to ~~look up, so as to~~ improve the operation efficiency.

230 Figure 4 illustrates the ship route restoration algorithm, taking a segment of the AIS positions as an example. The method can be summarized using the following steps: 1) For each two consecutive AIS points  $A$  and  $B$ , judge the geographical relationship between line  $AB$  and the continent; 2) If line  $AB$  intersects the continent and is not contained in the continent, apply the route restoration algorithm by ~~firstly~~ finding the nearest start node  $A'$  and end node  $B'$  by traversing the pre-stored node library; 3) Look up the shortest path connecting nodes  $A'$  and  $B'$  (e.g.,  $A'O_1O_2O_iO_j \cdots B'$ ) from the pre-stored ship route  
235 network database and calculate the average speed ~~resulting~~ from the geodesic distance of  $D_{A'O_1O_2O_iO_j \cdots B'}$  and time interval  $T_{AB}$ ; 4) For each segment  $O_iO_j$  in route  $A'B'$ , interpolate points  $p_1, p_2, p_m, p_n \cdots$  with a time span of 600 seconds along the  $O_iO_j$  if  $T_{O_iO_j} > 600s$ ; 5) For each arc  $p_m p_n$ , calculate the ship emissions based on the average speed, instantaneous power and emission factors; 6) Calculate emissions  $\sum E$  summed from each time span along the restored route. However, as it was rather time-consuming to judge the geographical relationship between the trajectory line and the continent polygon, an additional  
240 distance threshold of 50 km was finally added in the model, i.e., the restoration method would only be applied for “cross-land trajectory with a long distance”. This setting would skip some cases ~~when~~ where ships were sailing in the estuaries, their trajectories crossing the coastlines.

#### 2.4.2 Classification of OGV, CV and RV

In ~~the~~ SEIM v2.0, vessels are classified into OGVs, CVs, and RVs for emission estimation. In China, the number of inland  
245 vessels ~~are having an increasing number with~~ the AIS equipment installed is increasing in recent ~~these~~ years. As the fuel standard for RVs ~~are~~ is more stringent than that for ~~compared to~~ OGVs, it is necessary to distinguish them from the AIS data in order to calculate emissions accurately. In the methodology, since OGVs are mostly engaged in international trade following the management of the International Maritime Organization (IMO), they are identified by ~~meeting the condition that~~ both valid IMO numbers and the Maritime Mobile Service Identify (MMSI) numbers ~~are available~~. CVs and RVs are both domestic  
250 vessels designed to operate in rivers and coastal areas, respectively. However, in some cases, they do cross ~~each one another's~~ navigational waters when the inland waterway system borders the coastline (Mao and Rutherford, 2018a). Thus, we identified RVs with a ~~by~~ activity-frequency distribution method based on the navigation trajectories for each vessel. By defining the geographic domain of D2 in Fig. 2, vessels with more than 50% of the AIS signals throughout the entire ~~whole~~ year ~~occurring~~  
255 ~~traveling~~ into ~~the~~ estuaries. Finally, vessels that are not identified by OGVs and RVs are regarded as CVs.

Figure 5b shows the identification results of OGVs, CVs and RVs, taking ~~the year~~ 2016 as an example. It is clear that the OGVs navigate between the major coastal ports of China and other countries, with a few ~~proportions~~ entering the Yangtze

River. CVs operating around the coastal seas of China, seldom contacting ~~with~~ other countries. RVs mostly ~~mainly~~ sail on the Yangtze River and Pearl River systems, with a small proportion wandering in coastal seas. The spatial distribution of ~~the~~ AIS signals of OGVs, CVs, and RVs were ~~essentially~~ basically consistent with experience, with OGVs mainly at seas, CVs near the coast and RVs in inland waters.

### 2.4.3 Ship emission control policy

In recent years, a series of policy documents have been issued to control ~~the~~ air pollution from ships, among which the most effective measure is the establishment and implementation of DECA (MOT, 2015, 2018). China's DECA policy ~~was~~ were put into effect step by step from 2016 to 2019. Figure 6 summarizes the ~~evolution~~ evolutionary of DECA, including the control area and fuel standards, as well as their comparison with international ECA. Before the global sulfur cap taking effect in 2020, ~~the~~ heavy fuel oil (HFO) with a sulfur content as high as 3.5% had ~~s~~ long been used in ships worldwide ~~all over the world~~. In 2017~~s~~, China initially established three DECAs along the coastline (DECA 1.0), covering the most ~~densely distributed area~~ of busy port clusters in the worlds, with gradual mandates for ships to use low sulfur fuel (LSF) with sulfur content <0.5% m/m. Later, DECA 1.0 evolved from regulating ships in core ports to the whole ports clusters ~~regions~~ and ships ~~from~~ berthing to all operating modes, ~~in order to reduce SO<sub>2</sub> and PM emissions~~. In 2019~~s~~, an upgraded DECA 2.0 was proposed to expand the region to cover the entire coastline (within 12 Nm from the Chinese mainland's territorial sea baseline, Fig. 2) in which ships are required to use LSF regardless of the operating status. In addition to fuel requirements, the DECA 2.0 policy also defined the control requirement of NO<sub>x</sub> emissions from ships, in which ~~that~~ diesel engines above 130 kW built or modified on or after March 1, 2015, must ~~shall~~ meet the Tier II NO<sub>x</sub> emission limits of revised MARPOL Annex VI rules, which is in line with the international ships under the control requirement of IMO.

Despite the mandatory implementation time of DECA, some developed regions ~~where economic conditions permit~~ were encouraged to experiment in advance. ~~In order to~~ provide a timely feedback on the effect of policies, a broad investigation of the actual performance of DECA was conducted, including both ~~the~~ coastal seas and inland rivers in 2016-2019 (Table S1). Before the mandatory date of January 1<sup>st</sup> 2017, core ports in the YRD and Shenzhen port pioneered the DECA 1.0 policy nine months and three months earlier, respectively. Core ports in YRD are supposed to implement the DECA 2.0 policy three months before fully coming into effect ~~in~~ on January 1<sup>st</sup> 2019. Meanwhile, RVs are required to use the general diesel fuel (GDO) with a much lower sulfur content, gradually iterating from 350 ppm to 10 ppm; and finally keeping pace with the China V standard of on-road diesel fuel in 2018.

To be consistent with ~~Based on~~ the DECA policy, a policy-abutted modification module was developed in SEIM 2.0 ~~to~~ incorporate the actual implementation of ship emission control policies with daily scale in China. At Firstly, each AIS signal point will be dynamically judged whether the vessel is located inside the scope of DECAs, ~~according to the geographic location~~; Combined with the signal transmission time and the vessel's operating mode, the module will then determine whether the

~~vessel need switch fuels or not.~~ the vessel will be dynamically judged whether it enters the scope of DECAs at that time and select the required fuel type and sulfur content. Then ~~Finally, for vessels demanding fuel switching,~~ a fuel correction factor, ~~which is~~ resulted from the quotient of the emission factors of the switched fuel and original fuel, will be further ~~applied to~~ ~~correct the emissions.~~ multiplied in the emission calculation formula. ~~The d~~ Details about the emission factors regarding different fuel types ~~were~~ ~~are~~ introduced in the Supplementary Methods. It is worth noting that, as far as we know, there has not been sufficient evidence showing ~~that~~ all vessels ~~are sticking to~~ DECAs or the violation rate each year. ~~However,~~ ~~But~~ there ~~have been~~ ~~are~~ studies indicating the effectiveness of DECAs in recent years (Liu et al., 2018; Zhang et al., 2019; Zhao et al., 2020; Zou et al., 2020). Not only have fuels been found to be cleaner (Zhang et al., 2019), but ~~also~~ air pollution caused by shipping activities has ~~also~~ been less ~~in~~ important ~~in busy~~ ports alongside ~~the~~ Chinese coast (Zou et al., 2020). Guaranteed by the authority of Chinese government, we assume that the DECA policy should mostly be effective, but ~~there is a~~ lack of evidence about ~~the violations~~ of DECAs, ~~which would~~ added to uncertainties in this model.

## 2.5 Simulation scenario setting

To comprehensively investigate the effects of gradually implemented DECA policies under the condition of ~~a~~ growing waterway transport demand, we designed a scenario (No-DECA scenario) in SEIM v2.0, ~~with its details~~ as listed in Table 2. Compared to the base ~~condition~~ scenario embedded with ~~the~~ actual DECA policy described in section 2.4.3, the No-DECA scenario was designed to ~~simulate the ship emissions around China by~~ assuming ~~vessels do~~ observed in AIS data of target year ~~not to implement the DECA policy, namely, to simulate the ship emission of China's inland waters and the 200 Nm zone supposing all active vessels continued to~~ ~~keep using~~ fuels with sulfur contents ~~at~~ pre-DECA level. By comparing the emission results from ~~the B~~ base condition and ~~the~~ No-DECA scenario, the ~~objective~~ ~~absolute~~ emission reduction effect of gradually implemented DECA policies could be vividly illustrated.

## 3 Results and discussion

### 3.1 Overall

With the development of China's waterway transport, seaborne trade ~~has been~~ increasing through 2016-2019. As illustrated in Fig. 7a, Chinese ports' total passenger turnover, cargo turnover and cargo throughput ~~remained stable rise and~~ ~~increased~~ ~~added~~ by 10.9%, 6.8% and 17.4% in 2019 compared to 2016, respectively. ~~A~~ ~~G~~rowing ~~demand for~~ water transport ~~demand~~ ~~has~~ stimulated ship activities and fleet loading capacity ~~ies~~ improvements, coinciding ~~ing~~ with gradually implemented DECA policies ~~iesy~~ and upgraded vessel engine standards, resulting in different interannual trends in ship emissions for different pollutants.

Figure 7b&c shows the annual ship emissions of SO<sub>2</sub> and NO<sub>x</sub> in China's inland waters and the 200 Nm zone from 2013 to 2019. Before the enforcement of DECA policy, ship emissions of SO<sub>2</sub>, NO<sub>x</sub>, PM<sub>2.5</sub> and HC in 2016 were estimated to be 1.8×10<sup>6</sup>,

2.5×10<sup>6</sup>, 2.3×10<sup>5</sup> and 1.1×10<sup>5</sup> Mg/year, respectively. The emission results are generally higher than other AIS-based ship emission inventories of China in recent years (Table S2) (Chen et al., 2017a; Li et al., 2018; Fu et al., 2017; Huang et al., 2019).

325 The primary reason might be that our study established a larger ship activity database based on global AIS data (~30 billion signals per year), and [that](#) the incorporation of [the](#) GFW database also improved the recognition of ships, especially CVs and RVs in China. In addition, the annual increase [in](#) of ship activity driven by maritime trade could also contributed to ship emission growth.

330 Among all vessels, OGVs composed the largest part [of](#) in ship emissions, with a proportion of 70.4% regarding SO<sub>2</sub> and 59.7% regarding NO<sub>x</sub> in 2016. Compared to a recent estimation of global ship emissions (IMO, 2020), it is striking that OGVs in the 200 Nm zone of China contributed to 9.7 ~ 14.3% of global OGV emissions (Table S3), despite only [being](#) <1% of the world's sea area. Such [a](#) result suggests [a](#) the substantially [high](#) concentration of shipping emissions [intensity](#) around China generated from [the activities of the](#) global fleet around China. CVs [are](#) ranked after OGVs, with [a](#) 29.4% contribution to SO<sub>2</sub> emissions and 27.1% to NO<sub>x</sub> emissions; while [the](#) RVs' composition was relatively small, accounting for 13.2% for NO<sub>x</sub> and <1% for SO<sub>2</sub>. The emission shares of RVs may differ from [those](#) that by Li et al. (2018), considering ~~the~~ two major reasons. One ~~the~~ one hand, ~~as~~ we identified RVs based on [the](#) spatial frequency distribution of ship trajectories in AIS, which allows vessels [to](#) sometimes operating in coastal waters. Given ~~the~~ fact that CVs and even OGVs [sometimes](#) sail [in](#) at inland waters sometimes, ~~there exists~~ [it is](#) possibilities that some CVs and OGVs are mistakenly identified as RVs. Thus, the identified vessels of RVs  
335 might be higher than that in Li et al. (2018). One the other hand, since we applied GDOs with sulfur content up to the national standard to RVs, for which and the emission factors of SO<sub>2</sub> would be much lower, the emission shares of SO<sub>2</sub> appeared to be lower than that in Li et al., (2018); but it was opposite for NO<sub>x</sub> and other pollutants.

[From 2016 to 2019](#) Through the four years, ship emissions of SO<sub>2</sub> and PM has decreased by 29.6% and 26.4%, respectively  
345 [\(Table S2\)](#). During the DECA 1.0 [period](#) implementation, [the](#) annual ship emissions of SO<sub>2</sub> around China increased by 1.6% in 2017 compared to 2016 and 3.8% [year-on-year](#) in [2017 and](#) 2018 compared to 2017, [respectively](#); while [After the implementation of DECA 2.0, however, ship SO<sub>2</sub> emissions in 2019](#) it dropped [significantly](#) by 33.3% in 2019 compared to 2018, owing to extended control area and more stringent requirement. Moreover, ship SO<sub>2</sub> emissions in 2019 was even 2.8% lower than [those](#) at in 2013 (Fu et al., 2017), [showing great](#) indicating the benefits of more stringent DECA 2.0 policy [with](#)  
350 [extended control area and more stringent requirements](#). ~~Through the four years, ship emissions of SO<sub>2</sub> and PM has decreased by 29.6% and 26.4%, respectively (Table S2)~~. In terms of NO<sub>x</sub>, however, emissions continuously increased year by year, with a total increase of 13.0% from 2016 to 2019; while emissions of other pollutants also showed a gradually increasing trend (Table S2). Therefore, the ship DECA policy has a significant impact on reducing SO<sub>2</sub> and PM emissions ~~but~~ [but the](#) current vessel engine emission standard only has [ve](#) [a](#) limited influence on controlling NO<sub>x</sub> emissions. In addition, although the DECA  
355 1.0 policy has been implemented since 2017, it was not until 2019 that significant emission reduction was achieved.

## 3.2 Four-year consecutive daily emission

### 3.2.1 Emission composition variation

On a more refined time scale, we investigated the 5-day moving average ship SO<sub>2</sub> and NO<sub>x</sub> emissions on a daily basis for the inland rivers and the 200 Nm zone of China from 2016 to 2019, as shown in Fig. 8. It is evident that ship emissions of SO<sub>2</sub> was seasonally growing in 2016-2018, until a sharp drop on 1<sup>st</sup> January, 2019, due to the implementation of the stringent control DECA 2.0 policy. The maximum daily ship emission of SO<sub>2</sub> reached 6.4×10<sup>3</sup> Mg/day on September 22<sup>nd</sup>, 2018, which was 2.9 times that of the lowest point, 2.2×10<sup>3</sup> Mg/day on January 1<sup>st</sup>, 2019, while the daily discrepancy of ship NO<sub>x</sub> emission intensity also reached 3.0 times throughout the four years. The monthly variation of ship emissions for most vessel types was generally constant, except for a temporary decrease during the Spring Festival in February (Fig. 8a). However, fishing ships showed significant seasonal variations, which declined annually in the summer and returned in autumn due to the fishing ban in China. This has also been demonstrated by other studies (Chen et al., 2017a;Fu et al., 2017).

Figure 9 also exhibits the emission structure of SO<sub>2</sub> composed by vessel type and fuel type, and NO<sub>x</sub> composed by building year and DWT. The full composition of the emission contribution for all pollutants from different aspects are summarized in Table S4. Containers had been accounted for the largest part and the contribution had been increasing through over the four years, e.g., from 31.7% in 2016 to 42.9% in 2019 for SO<sub>2</sub> (Fig. 8a). Although containers accounted for only about 3.5% of the vessel number and 4.6% of the operating hours in Chinese waters (Fig. 3), their relatively higher engine power contributed to significant emission intensities compared to other ships of the same size, such as bulk carriers (Fig. 3). The HFO contributed to the majority of ship SO<sub>2</sub> emissions due to its high content of sulfur, part of which, however, was gradually being substituted by marine gas oil (MGO) with the implementation of the DECA policy (Fig. 8b). In 2019, the MGO had accounted for 15.4% of the ship SO<sub>2</sub> emissions and 38.9% of the NO<sub>x</sub> emissions (Table S4). In terms of vessel build year, ships built after 2016 made an increasing contribution to annual NO<sub>x</sub> emissions, reaching 10.6% in 2019 (Fig. 8c). Even though the Tier II engine standard had been applied to domestic ships built after 2016, ship NO<sub>x</sub> emissions were not found to decrease as the emission standard of Tier II only has minor improvement compared to Tier I. In addition, we also found that ships with larger DWT have a growing proportion in vessel fleets as well as emission contributions (Fig. 8d), indicating the developing trend of ship upsizing in the past few years. However, even though the newly-built, large-scale ships and as well as ships using clean fuel oil are all taking an increasingly large part in emission structure, the rising trend of NO<sub>x</sub> emissions has not yet reversed.

### 3.2.2 Emission variation of major ports

As it was step by step that the DECA policy was implemented in different ports in China, we extracted the 5-day moving average ship SO<sub>2</sub> emissions of the major ports in the BRA, YRD and PRD to track the consecutive emission changes throughout the four years, as shown in Fig. 9. In the initial stage, restriction on fuels with no more than a 0.5% sulfur content was only imposed on ships at berth for core ports in these three crucial port clusters (Fig. 2 and Table S1). Before the mandatory date

of DECA 1.0 January 1<sup>st</sup> 2017, core ports in the YRD and Shenzhen port pioneered the implementation nine months and three months earlier, respectively, which significantly showed a significant decrease in ship SO<sub>2</sub> emissions beginning from on April 1<sup>st</sup> and October 1<sup>st</sup> in of 2016, respectively. For other core ports in BRA and PRD, a noticeable decline could be observed on schedule on January 1<sup>st</sup> 2017. However, the emission of ships at berth accounted for took a relatively smaller percentage (7.5% ~ 13.7%) in the 200 Nm zone according to our results (Table S4); thus, the emission reduction was rather conservative inside the DECA 1.0 region in 2018, even though the requirement was popularized to all ports. In contrast, On the contrary, owing due to intensified ship activities, ship SO<sub>2</sub> emissions for some ports even largely increased, such as Ningbo-Zhoushan Port and Shenzhen Port, which increased by 19.4% and 11.4% in 2018 compared to 2017. Fortunately, in 2019, when the more rigorous DECA 2.0 policy was implemented, it is clearly illustrated in Fig. 9 that all ports' SO<sub>2</sub> emissions were sharply reduced. Core ports in the YRD were supposed to implement the DECA 2.0 policy three months before fully coming into effect. Notably, those pilots witnessed an earlier decline in SO<sub>2</sub> emissions, which also proved the timely and flexible response of the SEIM 2.0 model to the changeable DECA policy.

In addition to policy-driven emission changes, different ports showed distinct monthly emission variations that were highly related to their geographical location and ocean resources. For example, ship emissions in the YRD region had a low point in July as their activities were influenced by typhoons, particularly in the YRD (Weng et al., 2020), while ship emissions in Ningbo-Zhoushan Port, Tianjin Port and Shenzhen appeared to be larger in spring and autumn, probably owing to the large-scale fishing ship operations (Chen et al., 2016; Yin et al., 2017). In addition, steep short-term increases in SO<sub>2</sub> emissions were observed for Tianjin, Ningbo Zhoushan, and Shenzhen ports in September, 2019. These peaks were speculated to be due to the inaccurate vessel dynamic information in AIS signals caused by the interference of adverse weather, i.e., "Super Typhoon Mangkhut". However, more evidence is needed to verify the influence of extreme meteorological conditions on AIS signals. The above port-based emissions fully presented the daily ship emission variations for a long period from 2016 to 2019, which may also provide useful data references for port observation experiments.

### 3.3 Spatial distribution change

#### 3.3.1 Evaluation of the route restoration

Since the shipping route restoration module was developed in SEIM v2.0 to solve the problem of AIS discontinuity, the spatial distribution of ship emissions after route restoration was evaluated, as shown in Fig. 10. Direct interpolations for AIS signals along the loxodrome would lead to part of the emissions being distributeding on unrealistic routes, e.g., crossing the land areas, which could be even be as long as connecting the South China Sea and the Bohai Sea (Fig. 10a). By using the route restoration method, the ship's navigation trajectory and emissions can be restored to more realistic shipping routes, thus reducing the deviation of the spatial distribution of emissions (Fig. 10b). Statistically, 15.3% of NO<sub>x</sub> emissions and 7.5% of SO<sub>2</sub> emissions were spatially corrected in the study area. More improvements were obtained around Taiwan Island, the Korean Peninsula

420 and the Philippine Islands, probably due to [the](#) worse accessibility of high-quality shore-based AIS signals. The misallocation of emissions in China's land areas resulted in NO<sub>x</sub> underestimates of up to 2 ~ 4 Mg/grid in the downstream of [the](#) Yangtze River and Pearl River, and the misallocation of emissions in water regions is more notable on shipping routes farther from the coast. This spatial improvement of ship emissions with the route restoration method is expected to improve the results of any air quality model applications.

### 425 3.3.2 Spatial change of ship emissions

Figure 11 presents the spatial changes [in](#) of SO<sub>2</sub> and NO<sub>x</sub> emissions [from](#) ~~from~~ ships in different coastal regions defined in Fig. 2 from 2016 to 2019. Remarkably, within 12 Nm, which approximately equates to the scope of DECA 2.0 in 2019, SO<sub>2</sub> emissions decreased by 78.8% ( $7.2 \times 10^5$  Mg/year) compared to 2016. Despite the year-by-year growth of seaborne trade, [the](#) DECA policy effectively reduced ship-emitted SO<sub>2</sub> overall and especially beneficial to coastal cities. However, we discovered that SO<sub>2</sub> emissions increased by 41.5% ( $1.3 \times 10^5$  Mg/year) [from 2016 to 2019](#) in areas between 12-50 Nm from the baseline, especially along the 12 Nm boundary ~~from 2016 to 2019~~. The proportion of ship SO<sub>2</sub> emissions from 12-50 Nm rose from 17.5% in 2016 to 35.3% in 2019, becoming the major spatial contributor in 2019. ~~E~~[The](#) emission of PM exhibited [a](#) similar pattern (Fig. S2a). This peculiar phenomenon implies the fact that some ships possibly made a detour to evade switching [to](#) clean fuel oil, which could also be demonstrated by the larger growth rate in [the](#) cargo turnover than throughput (Fig. 6a).

435

Figure 12b shows that NO<sub>x</sub> emissions from ships [that](#) occurred within 12 Nm of the baseline ~~were~~ continuously [increasing](#) from 2016 to 2018, until it declined by 5.0% ( $6.4 \times 10^4$  Mg/year) in 2019 compared to the last year. Meanwhile, NO<sub>x</sub> emissions [occurring](#) in areas between 12-50 Nm also ~~turned to~~ [showed](#) a higher annual increase rate in 2019 (21.4%) than [in the](#) previous two years (7.4% ~ 8.2%). Such phenomenon once again proves the possibility of ship detours. Other species generally showed ~~the similar~~ emission pattern [similar to those of](#) ~~as~~ NO<sub>x</sub> (e.g., HC in Fig. S2b). In [summary](#), [the](#) DECA 2.0 policy has a positive effect on ships' SO<sub>2</sub> and PM emissions control as a whole, ~~and~~ especially for coastal areas. However, several ships detoured outside the scope of DECA 2.0, [perhaps](#) to save the cost on more expensive clean fuel oil, which further elongated the sailing distance and thus increased emissions in farther maritime areas.

440

### 3.3.3 Spatial changes of OGVs, CVs and RVs emissions

445 Interannual spatial changes [in](#) of OGVs, CVs and RVs were further compared for [the](#) ship emissions of NO<sub>x</sub> and SO<sub>2</sub>, as shown in Fig. 12. ~~E~~[the](#) emission intensity of identified OGVs was apparently higher than [that of](#) CVs and RVs, demonstrating certain routes. The most intensive near-sea routes included China-Korea, China Mainland-Taiwan, the North Pacific Route, routes from Chinese ports to [the](#) Malacca Strait and routes between busy ports of China, such as main ports in [the](#) BRA, YRD and PRD (Fig. 12a). Since the main shipping routes are rather close to the land, OGVs within 12 Nm of the baseline make up for approximately 38% and 32% of [the](#) total OGV emissions for NO<sub>x</sub> and SO<sub>2</sub>, [respectively](#). From 2016 to 2019, OGV emissions

450

were generally increased in all regions, except SO<sub>2</sub> emissions at 0-12 Nm, which showed a significant drop due to the DECA 2.0 policy.

455 As for CVs, approximately 80% of NO<sub>x</sub> emissions and 70% of SO<sub>2</sub> emissions were annually distributed mainly within 12 Nm of the baseline, and the proportions that occurred outside 12 Nm were greatly reduced compared to the OGVs. Despite intensive emission routes between coastal ports, notable emissions from CVs were occurred more evenly distributed off the major routes (Fig. 12b), which was were attributed to large quantities of fishing ships operating (Kroodasma et al., 2018). In the region of 0-12 Nm to the baseline, the annual SO<sub>2</sub> emission reduction ratio of CVs (81.0%) in 2019 was even higher than that of OGVs (76.9%), indicating that CVs were more affected by the DECA 2.0 policy.

460 Compared to OGVs and CVs, RVs have specific routes that were constrained by inland waterways, with the most intensive emissions located on the Yangtze River and the Pearl River (Fig. 12c). Meanwhile, RVs also operate along the Chinese coast and produce a considerable proportion of emissions within 12 Nm of the baseline. With the increasingly stringent national fuel oil standards for RVs (MEE, 2018), i.e., a sulfur content from 350 ppm before June 30<sup>th</sup>, 2017, to the current 10 ppm beginning 465 from January 1<sup>st</sup>, 2018, SO<sub>2</sub> emissions from RVs had been reduced to a rather low level, both for inland rivers and coastal areas. However, other pollutants, such as NO<sub>x</sub> emissions from RVs, were still increasing going uphill. In addition, although China has required certain categories of ships to install AIS equipment since 2010 step by step, a large part of small RVs in China have not been equipped with AIS (Zhang et al., 2017). The lack of ship activity data level and highly reliable local emission factors all brings uncertainties to the emission estimation of RVs. However, the air quality and human health of 470 inland cities near waterways could be severely impacted severely by RVs emissions (Wang et al., 2018). Therefore, RV emissions need to be stressed and worth further investigation.

### 3.4 Emission reduction effect of the DECA policy

#### 3.4.1 Monthly effect evaluation

475 Since the shipping activity increase and emission control policy collectively resulted in the past emission trend influenced ship emissions, we designed a No-DECA scenario without DECA policy to evaluate the real emission reduction effect of DECA policy, considering the annual change of ship activities. Figure 13 illustrates the monthly ship emissions of SO<sub>2</sub> for the base (real) condition and the No-DECA scenario, which are aggregated from inland rivers and the 200 Nm zone of China. Without the DECA policy, ship emissions of SO<sub>2</sub> were estimated to increase from 1.8×10<sup>6</sup> Mg/year in 2016 to 2.1×10<sup>6</sup> Mg/year in 2019, with an annual increase rate of at 4.5%. Beginning in from April 2016, the prior implementation of DECA 1.0 led by 480 core ports of the YRD began started to see the emission reduction benefit. Since DECA 1.0, ship SO<sub>2</sub> emissions were reduced by 4.6×10<sup>4</sup>, 1.1×10<sup>5</sup>, and 1.4×10<sup>5</sup> Mg/year for in 2016, 2017 and 2018, respectively, compared with the No-DECA scenario. Emissions were reduced out down even more remarkably in the year of 2019 owing to the expansion of DECA 2.0, with

8.4×10<sup>5</sup> Mg SO<sub>2</sub> reduced compared to ~~the~~ No-DECA scenario. In retrospect, although ship SO<sub>2</sub> emissions ~~were had been~~ reduced by 29.6% in 2019 compared to 2016 ~~under in-~~base condition, ~~the DECA policy~~ actually achieved a larger benefit with a reduction of 39.8% compared to the same year considering the actual seaborne trade growth and ship activity increase.

### 3.4.2 Annual regional contribution

~~To date~~~~So far~~, the implementation of ~~the~~ DECA policy and the effect of ship emission reduction have been focused within 12 Nm of the baseline of China's territorial sea. To further investigate the regional contribution of emission changes in different regions, we finally summarized ~~the~~ ship<sup>s</sup> activity and emissions in ~~the~~ BRA, YRD and PRD, ~~respectively~~, from 2016 to 2019, ~~as~~ ~~As~~ shown in Fig. 14. ~~Although~~ the annual change ~~in~~ of SO<sub>2</sub> emissions in 2017 and 2018 was not significant, i.e., ~~it~~ decreased by 3.9% and increased by 1.3%, respectively, during the implementation of DECA 1.0; ~~it is undeniable that the policy had~~ indeed effectively reduced emissions, as the growth of ship activities would lead to 7.9% and 17.1% increases in emissions ~~if~~ without the DECA 1.0 policy. Moreover, YRD and BRA played a leading role in reducing ship SO<sub>2</sub> emissions in 2017 and 2018, respectively. However, ~~the~~ further tightened DECA 2.0 policy~~ies~~ implemented in 2019 more effectively reduced SO<sub>2</sub> emissions by 78.2%, in which YRD, BRA and PRD contributed 30.1%, 20.2% and 16.2%, respectively, while other waters contributed the ~~remaining~~ ~~rest~~ 26.7%. Therefore, even ~~though~~ the controlling area of DECA 2.0 was enlarged to 2.5 times ~~that~~ of DECA 1.0, the dominant regions of emission reduction were still the three major port clusters. The primary factor driving DECA 2.0 ~~to~~ ~~achieving~~ a larger ~~amount of~~ emission reduction is the fuel switching regulation for all operating statuses of ships sailing in the region rather than ~~only~~ limiting ~~the~~ ~~only~~ berthing status in DECA 1.0.

## 4 Conclusions and policy implications

### 4.1 Conclusions

The DECA policy ~~had~~ effectively reduced SO<sub>2</sub> and PM emissions from ships in sea areas around China from 2016 to 2019. Although the preliminary DECA 1.0 policy targeting ~~mainly on~~ berthing ships only had limited effects on ship-emitted SO<sub>2</sub> and PM, the DECA 2.0 policy, tightening its limitation by putting ships in all operating statuses under control and ~~expanding~~ the control areas from major ports to 12 Nm from the Chinese mainland's territorial sea baseline, resulted in ~~a~~ significant emission reduction. As a result, SO<sub>2</sub> and PM emissions from ships decreased by 29.6% and 26.4%, respectively, in ~~the~~ 200 Nm zone of China in 2019 compared to 2016. Considering the potential emissions brought ~~about~~ by continuous growth of maritime trade, a more substantial benefit was even achieved, e.g., ~~an~~ SO<sub>2</sub> emission reduction of 39.8% ~~regarding~~ SO<sub>2</sub> in 2019 compared with the scenario without any emission control policy. However, NO<sub>x</sub> emissions from ships increased by 13.0% throughout the four years, indicating the limited effect of ~~the~~ current control standard.

Based on a four-year consecutive daily emission analysis, it is noticeable that the ship emission structure had been gradually changing, i.e., newly built, large ships and ships using clean fuel oil were taking an increasingly large proportion in ~~the~~ emission

structure. Containers and bulk carriers were still the dominant vessel type in ship emission composition. On a local scale, ship emissions in various ports exhibited different patterns in terms of daily variation. For example, ports in [the](#) YRD were likely to encounter typhoons in July and fishing ships were particularly abundant in [the](#) BRA. Relevant findings may help provide useful data references for port observation experiments and local policy making.

The interannual spatial change ~~in~~ of ship emissions also showed ~~new~~ [particular](#) characteristics. ~~By~~ ~~Through~~ contrasting ship emissions within different distances from [the](#) Chinese coastal baseline, we discovered that in 2019, a number of ships detoured outside the scope of DECA 2.0. However, this elongated the sailing distance and resulted in more air pollutant emissions. This reminds us to pay attention to additional environmental effects brought by detouring ships during the continuous implementation of [the](#) DECA 2.0 policy. In addition, the route restoration method developed in SEIM v2.0 effectively restored [the](#) ship's navigation trajectory and emissions to more realistic shipping routes, thus reducing the deviation of the spatial distribution of emissions and could be expected to reduce uncertainties in the air quality model.

#### 4.2 Policy implications

Compared to the increasingly strict emission control policies of land-based sources and improving [the](#) air quality in China, policies and regulations for the prevention and control of ship emissions ~~w~~ could be more urgent to facilitate China's air quality to achieve the annual PM<sub>2.5</sub> concentration standard of World Health Organization (WHO) Air Quality Guidelines (Wang et al., 2020; Zhang et al., 2019a). Although the current emission policy has achieved significant control effect on SO<sub>2</sub> and PM emissions, under the global low sulfur oil demand, China still needs to further apply for international ECA to enlarge the control area and strengthen the requirements for fuel quality. ~~In order to~~ ~~To~~ make a comprehensive evaluation and in-depth improvement of the policy, attention is also needed during the design process of [the](#) ECA scheme, such as the corresponding impact of ship detours and further expansion of DECA 2.0 so as to enlarge the reduction effects within [the](#) 200 Nm zone. Meanwhile, the international cooperation is also urgently [needed](#) ~~called for~~ to jointly control ship emissions due to ships' strong spatial mobility and the intricate relations between the state of registration, [the](#) ship owner and [the](#) actual operator. With the gradual cleaning of marine fuel and the obsolescence of HFO, ship emissions of SO<sub>2</sub> and PM will be effectively mitigated in the near future. However, ship NO<sub>x</sub> emissions are still expected to increase until the gradual elimination of old ships and [the](#) iteration of [the](#) more stringent Tier III standard for newly built ships. Other related factors, such as [the](#) engine type, NO<sub>x</sub> post-treatment technology, etc., should be taken into consideration in the future. For local decision makers, it is also important to [clarify](#) ~~make clear~~ the local ship emission structure and meteorological conditions ~~in order to~~ conduct effective measures.

#### Data availability

The AIS data and STSD are restricted to the third party and used under license for the current study.

#### Code availability

Python codes used during the current study are available from the corresponding author on reasonable request.

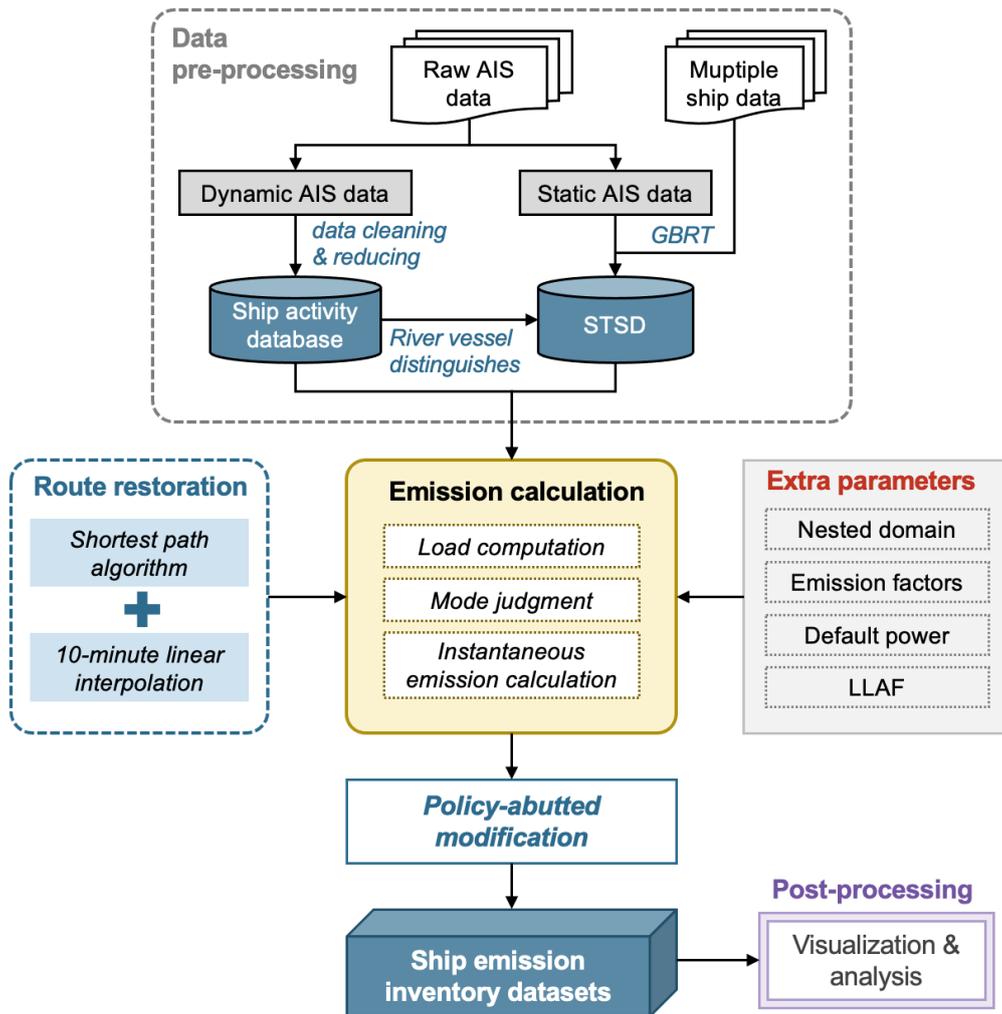

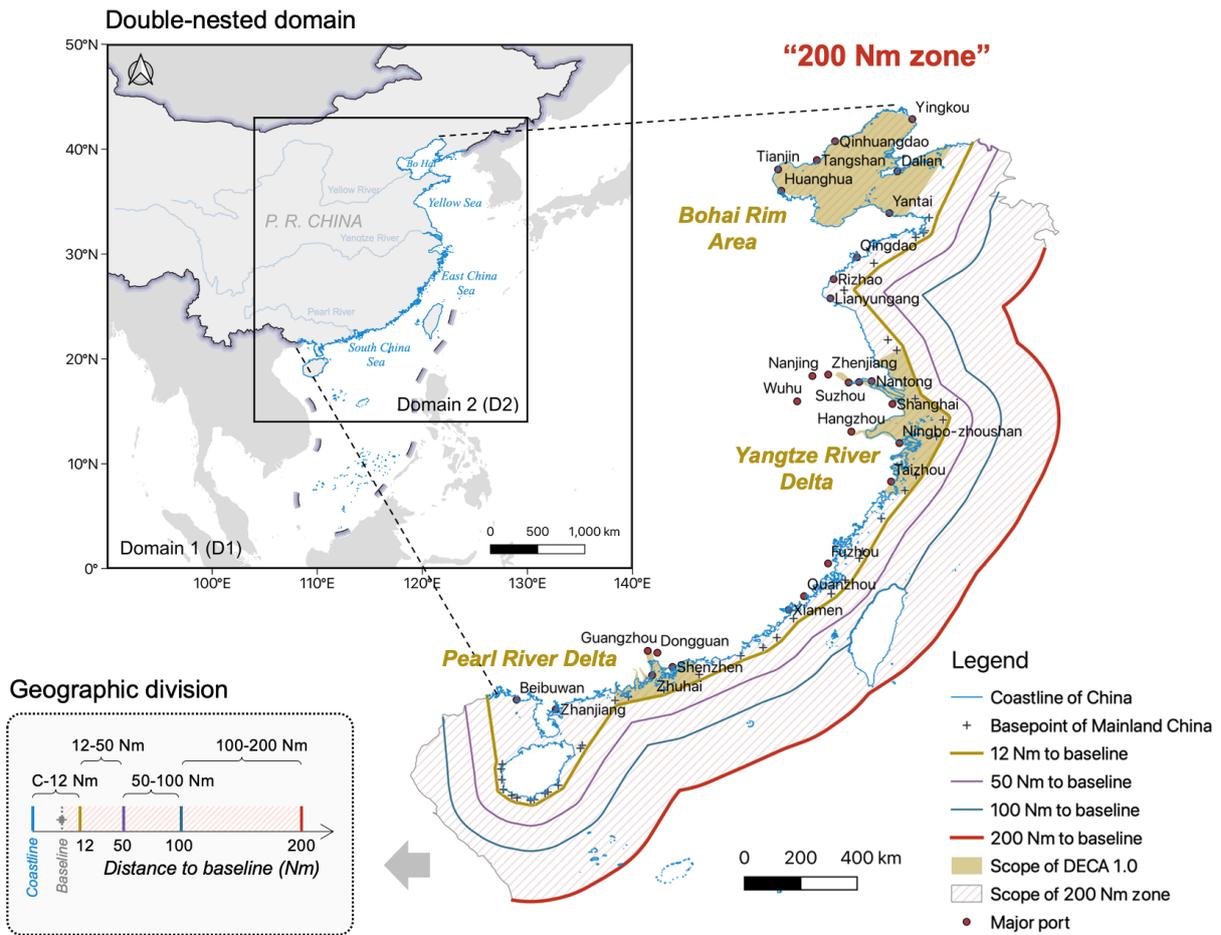

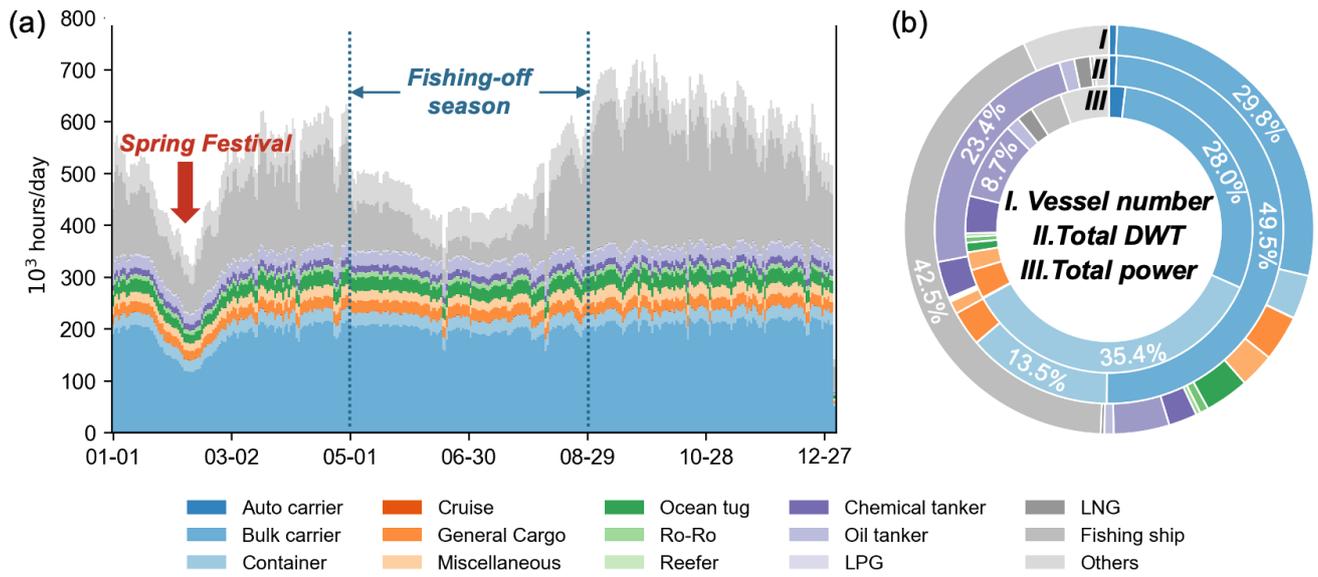

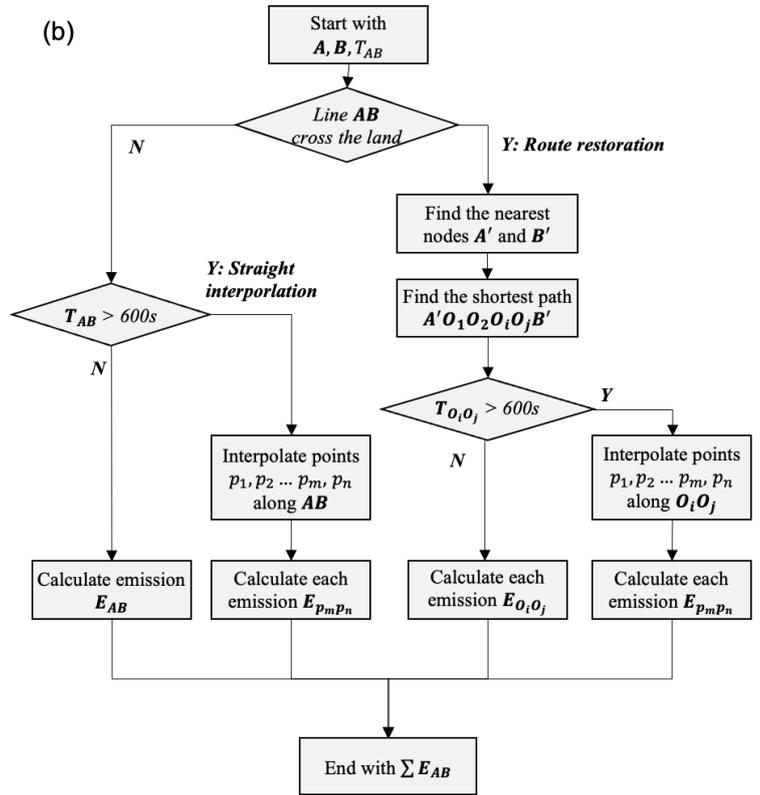

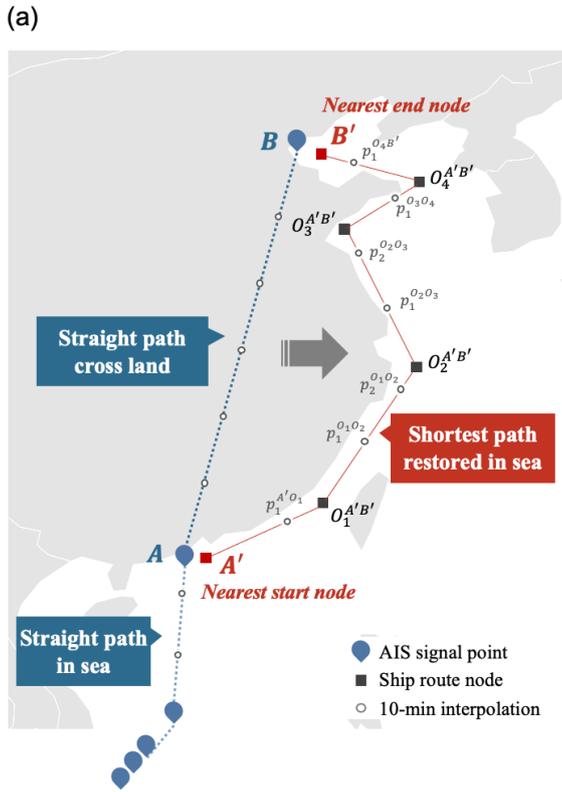

Figure 1: Structure and flow chart of [the](#) SEIM v2.0. The STSD stands for the ship technical specification database. The GBRT stands for the Gradient Boosting Regression Tree. The LLAF stands for the low load adjust factors.

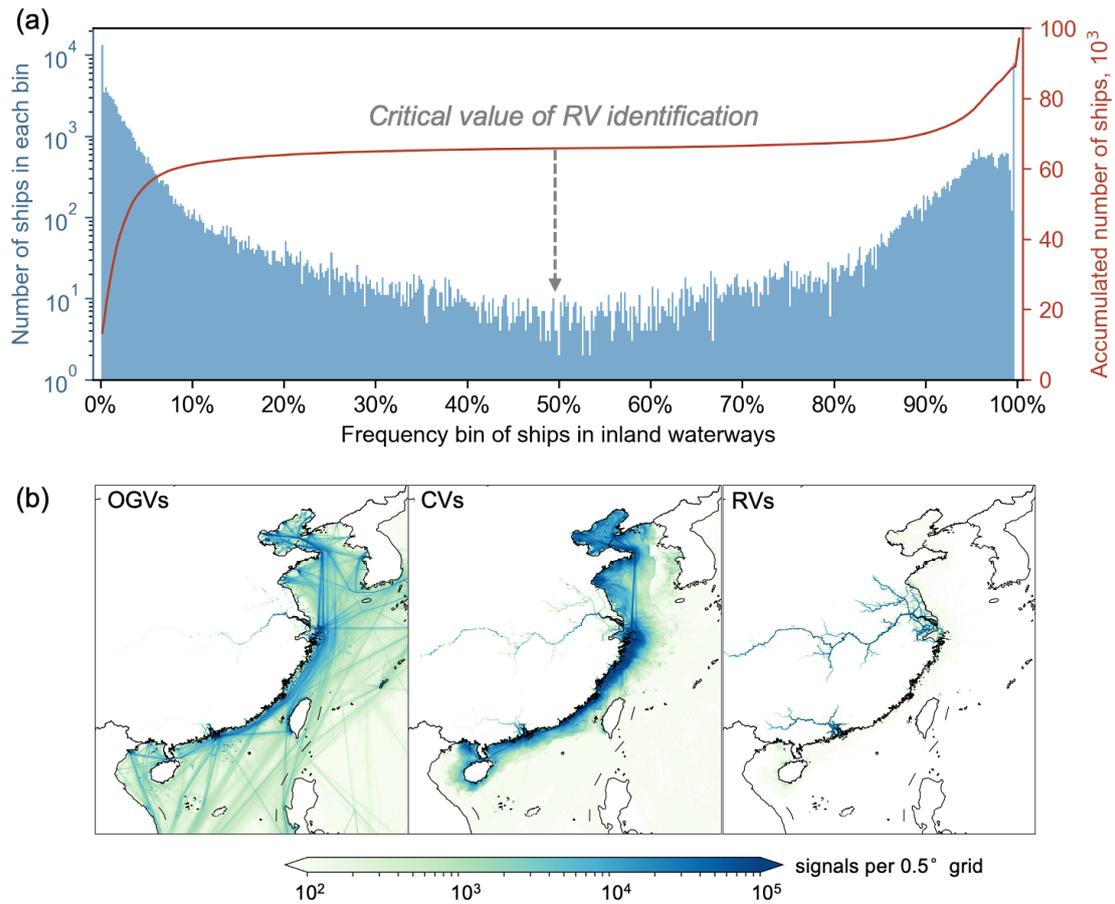

**Figure 2: Definition of the study area for ship emission estimation around China. The double-nested domain is used to filter global AIS data and reduce the boundary effect. The distances in the map all refers to the distance from the baseline of the Chinese mainland's territorial waters. The 200 Nm zone is the coastal area approximately within 200 Nm away from the baseline, which is further divided to different geographic regions according to the distance lines.**

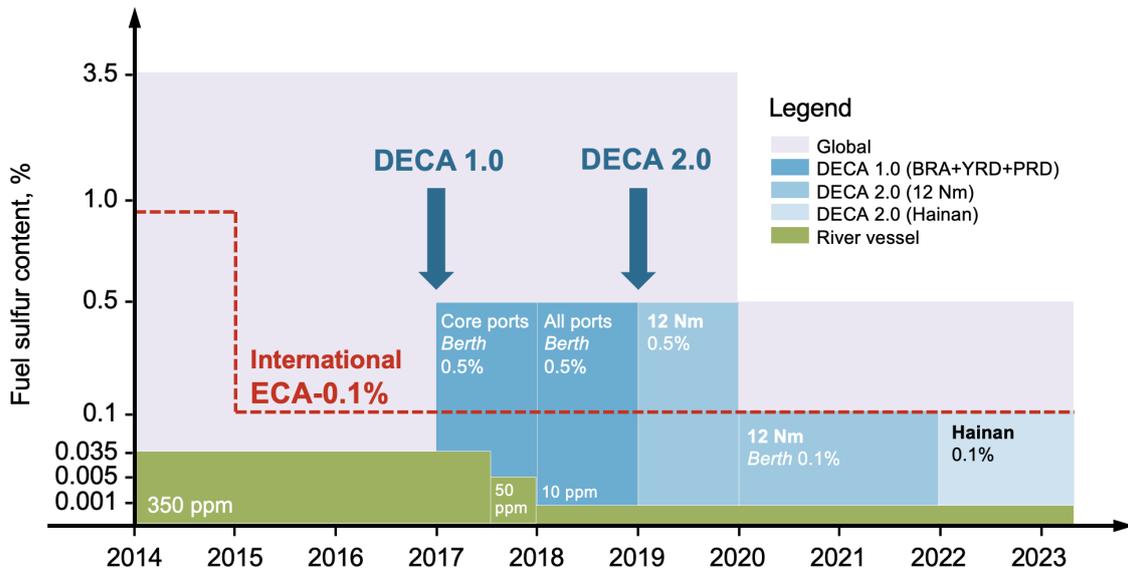

720 **Figure 3: Statistics of vessels' Vessel-dynamic and static information for 2016-2019 statistics. (a) Daily average operating hour averaged for 2016-2019. (b) Vessel fleet compositions from different aspects.**

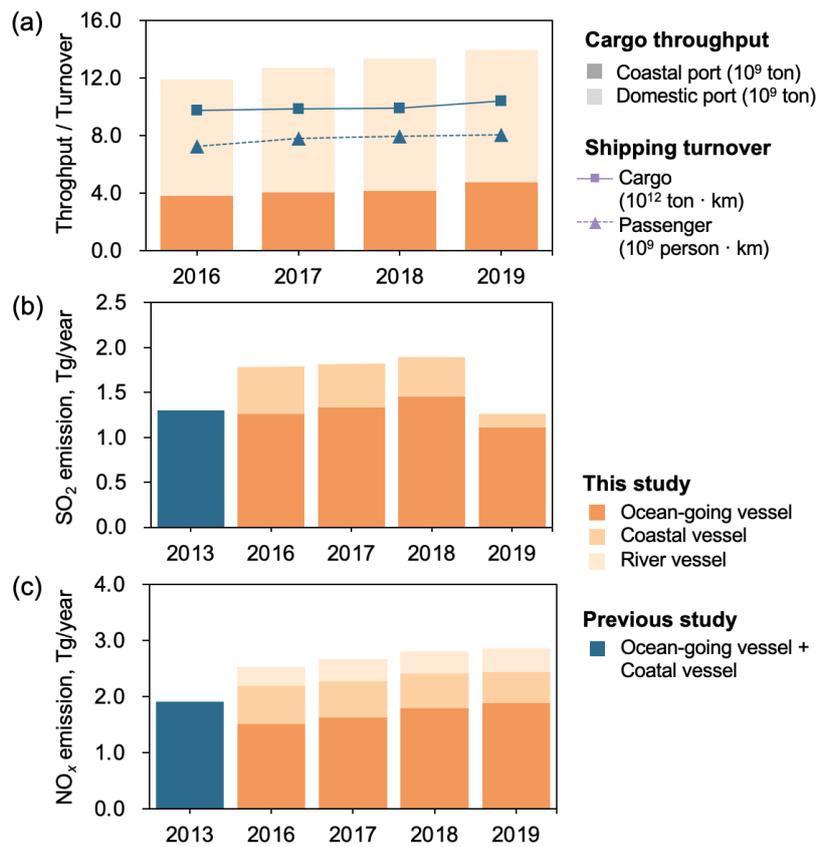

725 Figure 4: Diagrammatic sketch of the ship route restoration algorithm. (a) Sketch map of the route restoration algorithm with an example of route AB. (b) Algorithm flow chart of the example of route AB.

730 **Figure 5: Identification test and results of OGV, CV and RV. (a) Frequency test of ships in inland waterways. (b) Spatial distribution results of AIS signals of OGVs, CVs and RVs. The sample year is 2016.**

735 **Figure 6: Evolution of sulfur content requirements for fuels in DECA regions and inland rivers in China. The percentages refer to the sulfur content of the fuel. The italics refer to the operating mode constrained by DECA policy. The y-axis is unevenly distributed to show the standard of fuel sulfur content.**

740 | Figure 7: Annual changes of (a) seaborne trade and ship emissions of (b) SO<sub>2</sub> and (c) NO<sub>x</sub> from 2016 to 2019. Data in (a) are collected from Chinese Statistical Yearbook (NBS, 2020). Emissions [in](#) of 2013 are derived from our previous work for comparison (Fu et al., 2017).

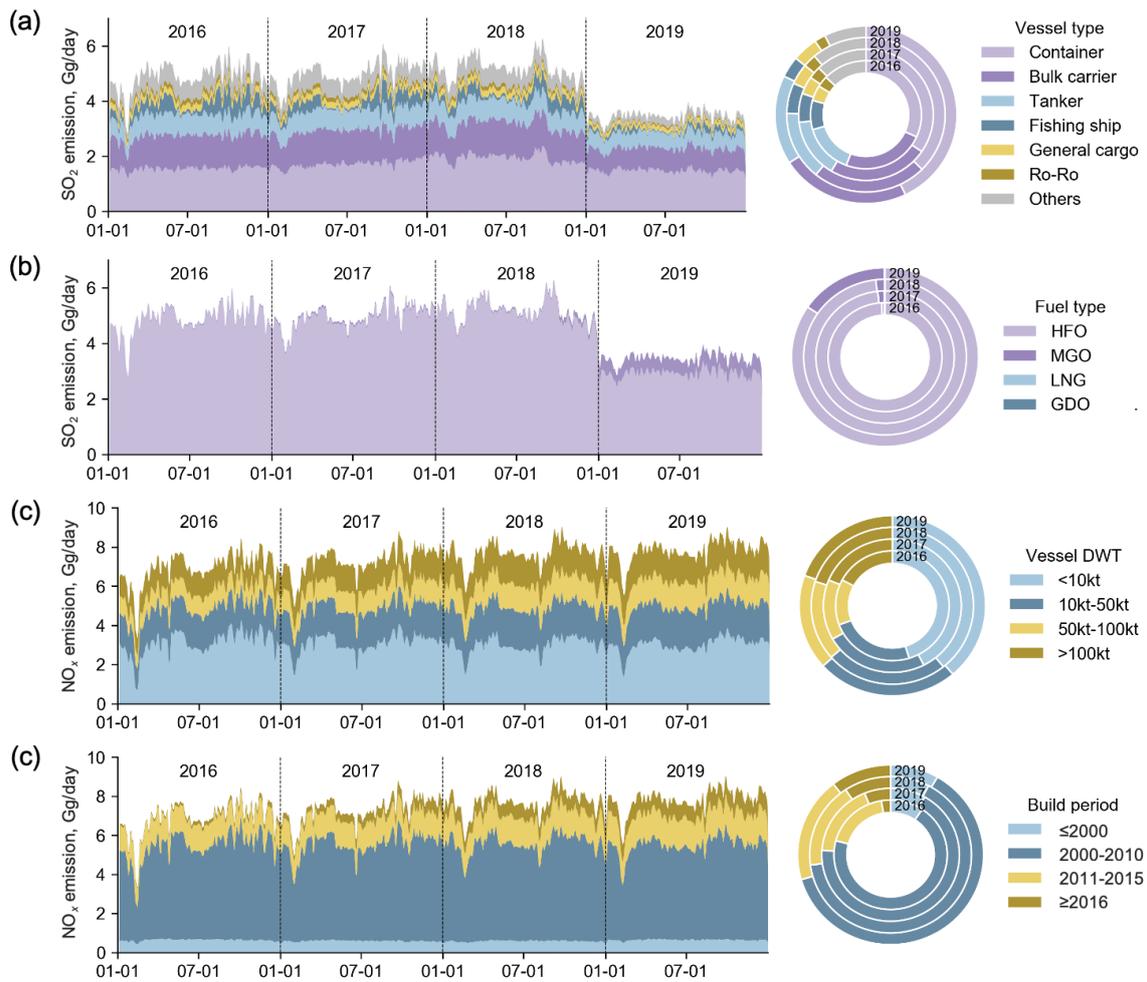

Figure 8: The 5-day moving average of SO<sub>2</sub> and NO<sub>x</sub> emissions from ships around China from 2016 to 2019. Ship SO<sub>2</sub> emission composition by (a) vessel type, (b) fuel type, and ship NO<sub>x</sub> emission composition by (c) vessel build period and (d) dead weight tonnage (DWT).

745

750

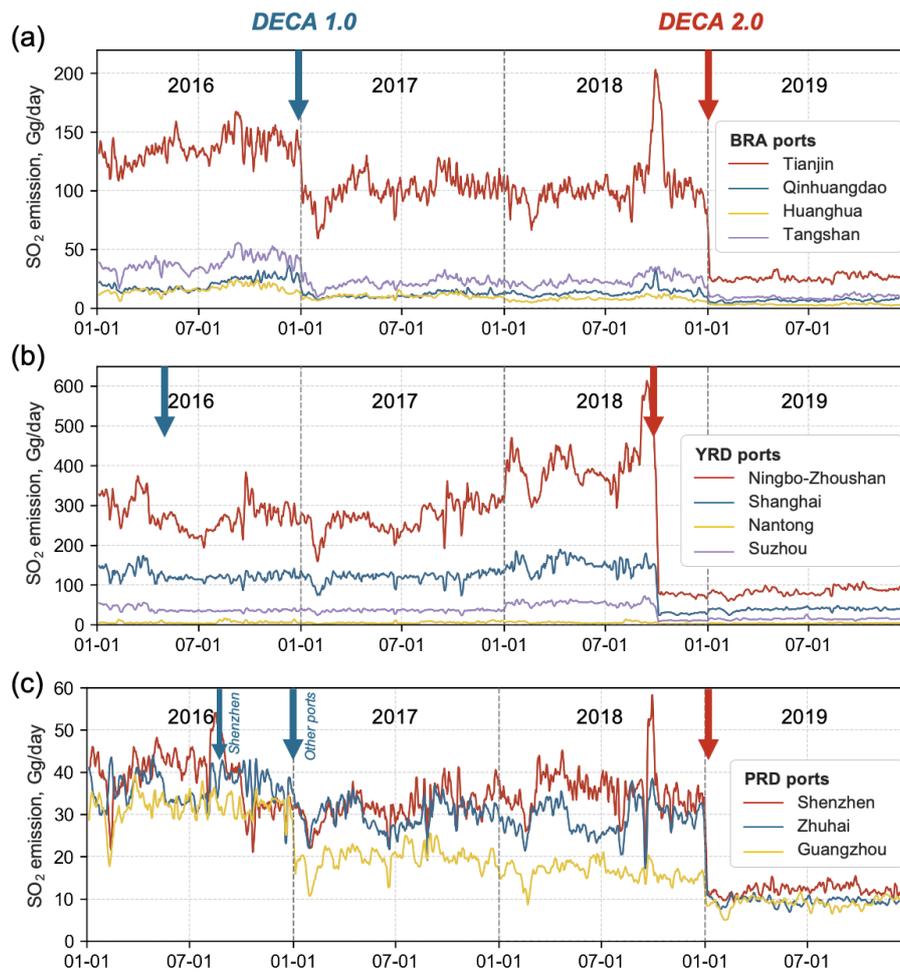

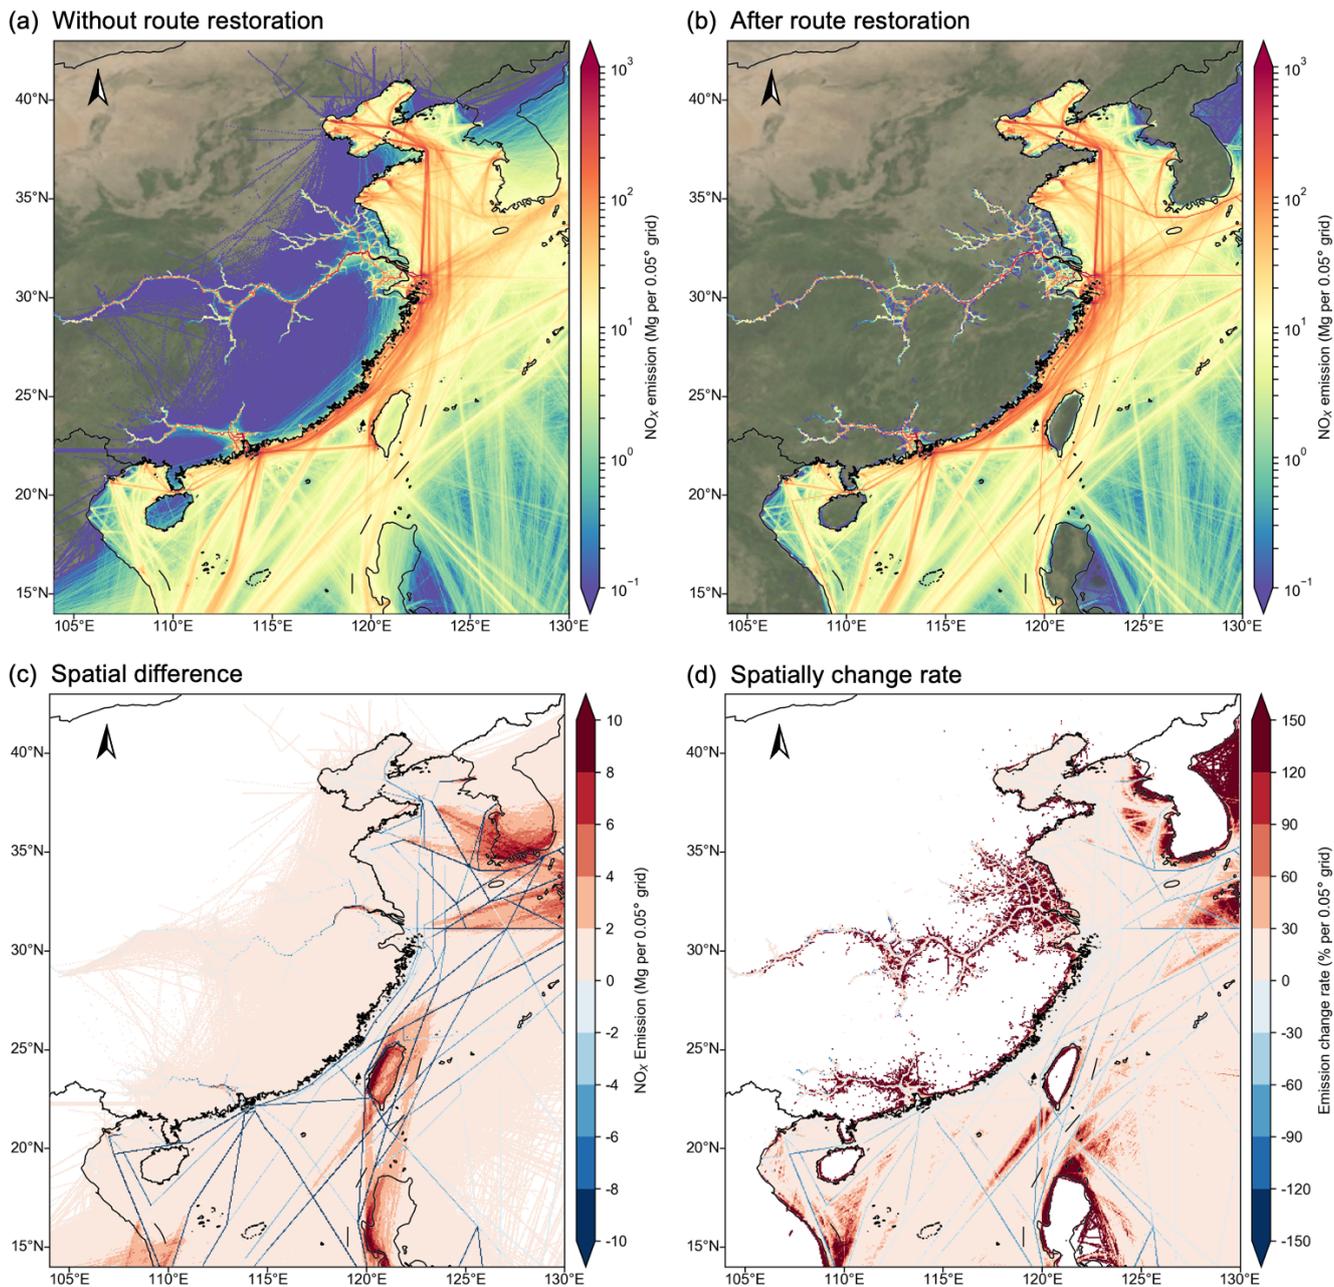

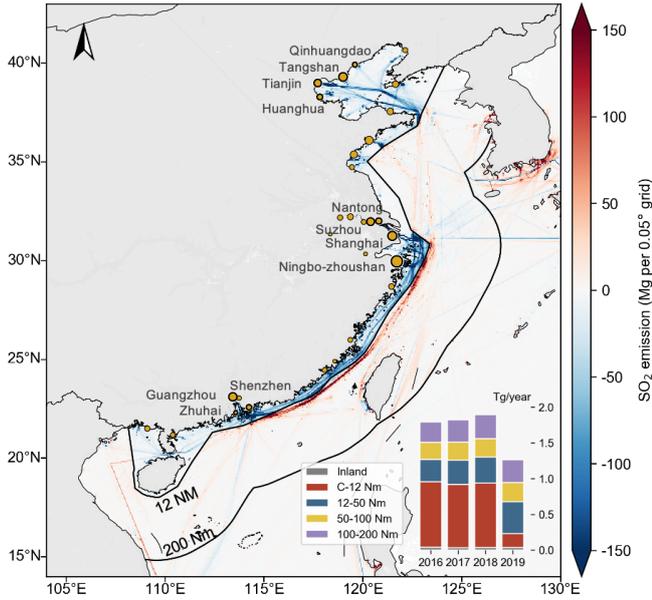

Figure 9: The 5-day moving average of SO<sub>2</sub> emissions from ships in major ports of China from 2016 to 2019. (a) Bohai Sea Area (BRA), (b) Yangtze River Delta (YRD), and (c) Pearl River Delta (PRD). The blue and red arrows mark the actual implementation dates of DECA 1.0 and DECA 2.0 policies, respectively.

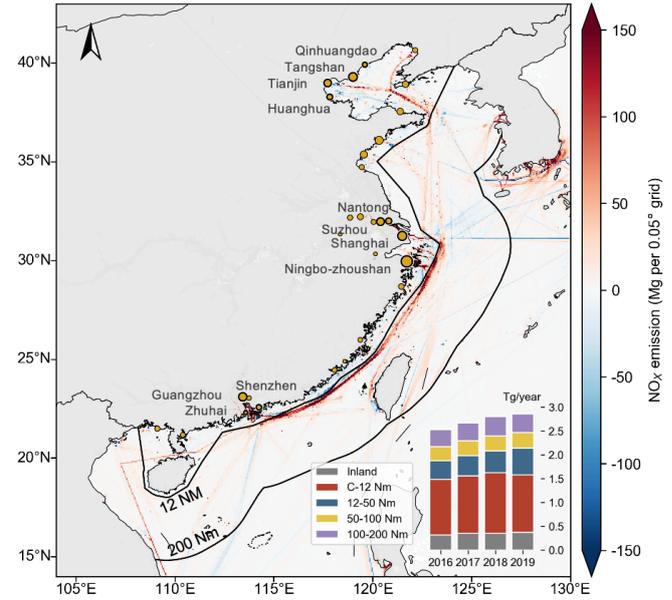

760 **Figure 10: Evaluation of estimating ship NO<sub>x</sub> emissions in China after route restoration. (a) Emissions without route restoration. (b) Emissions with route restoration. (c) Spatial difference of emission (a-b). (d) Spatially change rate of emissions, i.e., (a-b)/a. The selected year is 2016.**

(a) SO<sub>2</sub> emission change

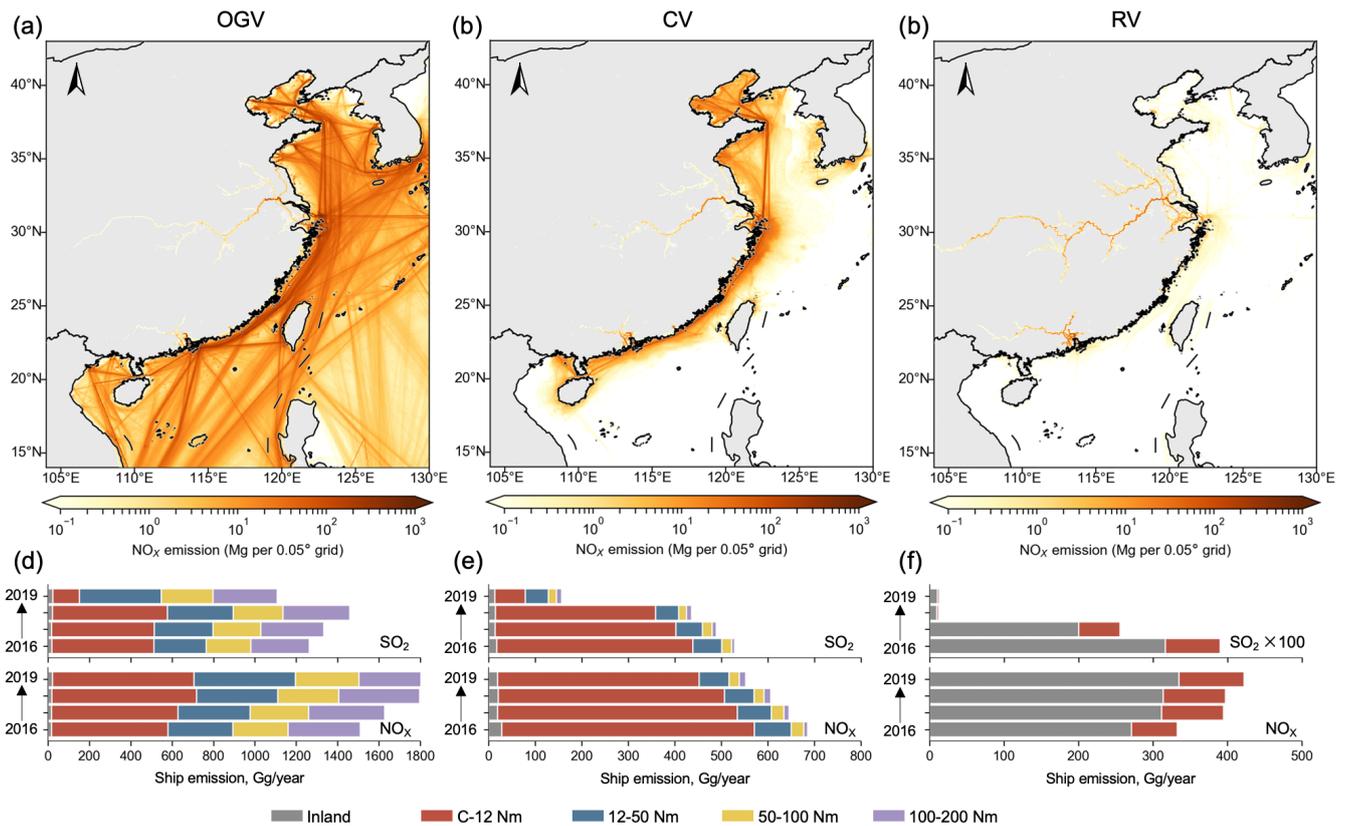

(b) NO<sub>x</sub> emission change

765

Figure 11: Spatial distribution changes of SO<sub>2</sub> and NO<sub>x</sub> emissions from ships over China in 2019 compared to 2016. The stacked bar plots indicate the annual emissions occurred at different distances off the coastline from 2016 to 2019. The “C-12 Nm” in the legend refers to the area from the coastline to 12 Nm from the baseline of the territorial sea (the same below), which is approximately equal to the scope of DECA 2.0.

**Figure 12: Interannual spatial changes of  $\text{NO}_x$  and  $\text{SO}_2$  emissions from ships over China from 2016 to 2019. Annual average spatial distribution comparison of  $\text{NO}_x$  emission for (a) OGVs, (b) CVs and (c) RVs. Interannual variations of  $\text{NO}_x$  and  $\text{SO}_2$  emission in different geographic regions for (d) OGVs, (e) CVs and (f) RVs.**

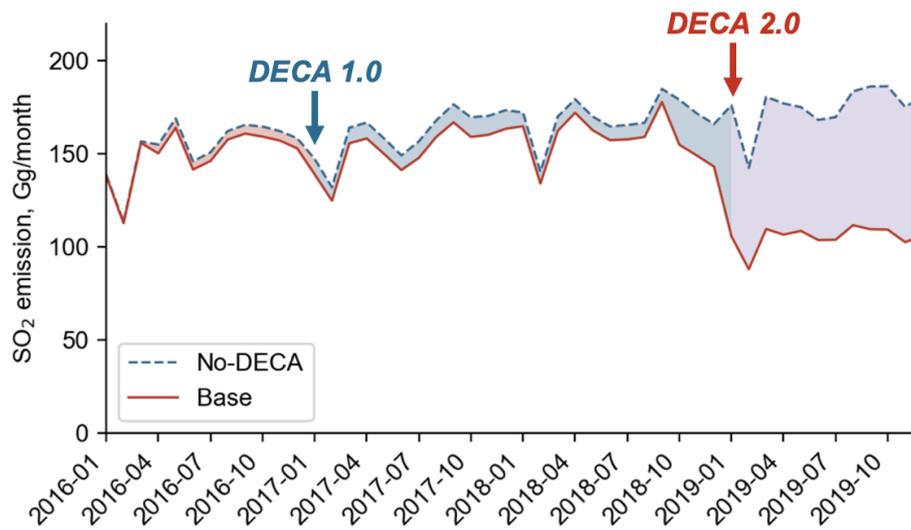

Figure 13: Monthly variation of ship SO<sub>2</sub> emissions in inland rivers and the 200 Nm zone of China under the Base condition and the No-DECA scenario in 2016-2019. The Base condition refer to the real condition. The No-DECA scenario condition reflects the emissions based on the real ship activities without the DECA policies.

780

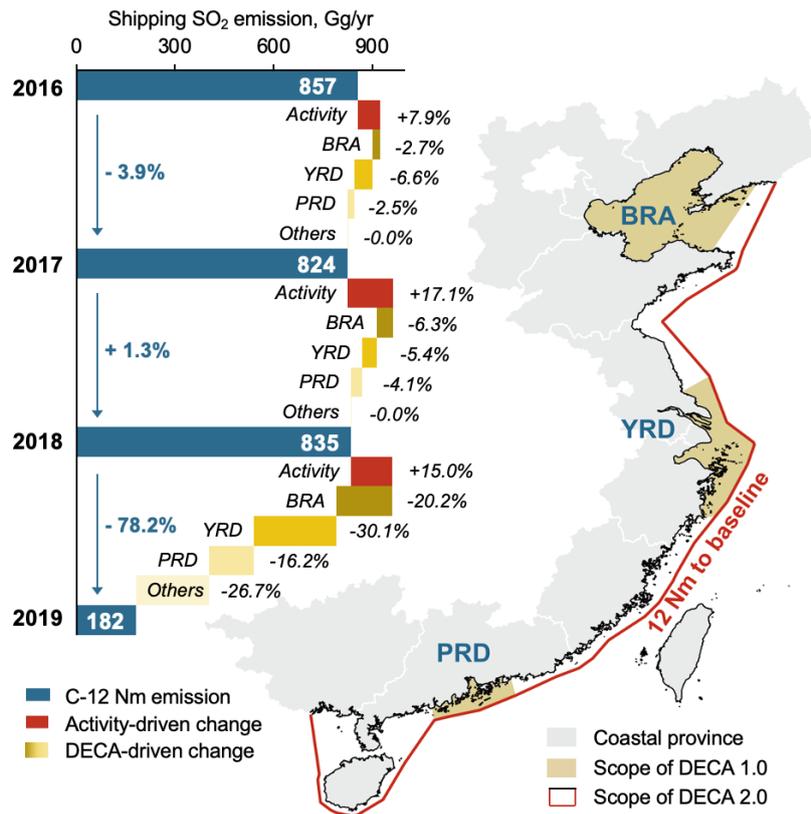

Figure 14: Regional contributions to annual reduction SO<sub>2</sub> emissions from ships within 12 Nm of the baseline of China's territorial sea. The figures inside the blue bars refer to the annual emissions, and the percentages refer to the relative change of emissions due to total ship activity change in C-12 Nm region or the DECA policies in each region.

785

**Table 1: Statistics of AIS messages and active ships in China in 2016–2019.**

<b>Statistical items</b>		<b>2016</b>	<b>2017</b>	<b>2018</b>	<b>2019</b>
<b>Global</b>	Archived AIS messages ( $10^9$ )	26	35	31	45
	Active ships with unique MMSI ( $10^3$ )	523	635	754	824
<b>China (River and 200 Nm zone)</b>	Number of identified ships ( $10^3$ )	96	92	88	85
	Total operating hours ( $10^6$ hours)	196	197	195	202

790 **Table 2: Simulation scenario setting in this study.**

	AIS data	Coastal sea		Inland river	
		Policy setting	Fuel setting	Policy setting	Fuel setting
Base condition	2016-2019	Actual implement of DECA 1.0 and DECA 2.0	Inside DECAs : LSF (S < 0.5% m/m) Outside DECAs: No requirement	As required	350 ppm, 50 ppm and 10 ppm chronologically
No-DECA scenario	2016-2019	No policy of DECA	Pre-DECA level (No requirement)	Assumed fuel	350 ppm
