**Abstract.** Secondary organic aerosol (SOA) formation from mixtures of volatile precursors may be influenced by the molecular interactions of the products of the components of the mixture. Here, we report measurements of the volatility distribution of SOA formed from the photo-oxidation *o*-cresol,  $\alpha$ -pinene and their mixtures, representative anthropogenic and biogenic precursors, in an atmospheric simulation chamber. The combination of two independent thermal techniques (thermal denuder and the Filter Inlet for Gases and Aerosols coupled to a high resolution time of flight chemical ionisation mass spectrometer) to measure the particle volatility, along with detailed gas and particle phase composition measurements provides links between the chemical composition of the mixture and the resultant SOA volatility. The products that were only present in the SOA of the mixture had higher O:C and lower volatility compared to those deriving from the individual precursors. This suggests that new product formation can reduce the volatility in mixtures. At the same time, some of the larger molecules with lower volatility produced in the single  $\alpha$ -pinene and *o*-cresol system were not present in the mixture leading to an increase of the average volatility. These opposite effects resulted the volatility distribution of the SOA of the mixture to be between those of the individual precursors. For example, compounds with effective saturation concentration less or equal than  $0.01 \mu\text{g m}^{-3}$  represented 28, 39 and 37% of the SOA mass in the  $\alpha$ -pinene, *o*-cresol and mixed precursor experiments, respectively. We further explore the sensitivity limitations of our technique to the reported results and we show that the particle volatility can be qualitatively assessed, while caution should be held when linking the chemical composition to the particle volatility. These results provide the first detailed observations of SOA particle

15  
20  
25

30 volatility and composition in mixed anthropogenic and biogenic systems and provides an analytical context that  
can be used to explore particle volatility in chamber experiments.

## 1. Introduction

Aerosol particles are ubiquitous in the atmosphere with substantial impacts on climate (Ramanathan et al., 2001)  
35 and human health (Lelieveld et al., 2015; Brunekreef and Holgate, 2002). These particles may contain a wide variety  
of compounds, with the organic fraction contributing up to 90% of the mass in the submicron size range (Jimenez  
et al., 2009). The majority of this fraction is comprised by secondary organic aerosol (SOA) (Kanakidou et al.,  
2005; Hallquist et al., 2009; Shrivastava et al., 2017). SOA is formed by the oxidation of volatile organic compounds  
40 (VOC) in the atmosphere. These reactions result in a variety of products that can be more or less volatile than their  
precursors depending on the underlying chemical processes in the gas and/or condensed phase (Donahue et al.,  
2012). The less volatile products of these reactions tend to partition to pre-existing particles and/or nucleate to form  
new particles. SOA containing particles can substantially affect climate due to their optical properties (Moise et  
al., 2015) and their ability to act as cloud condensation nuclei (CCN) (McFiggans et al., 2006), while their potential  
adverse effects on human health have recently drawn the attention (Chowdhury et al., 2018; Kramer et al., 2016).  
45 Our current mechanistic understanding and the resulting SOA representation in predictive models remains  
inadequate (Shrivastava et al., 2017; McFiggans et al., 2019), leading to significant uncertainty of the assessment  
of their impacts.

The analytical limitations in the characterization and detection of all oxidation products as well as the complexity  
of the ever-evolving atmosphere (Isaacman-VanWertz et al., 2018), makes the understanding of the SOA behaviour  
50 challenging. Atmospheric simulation chambers have been employed as a tool to study the formation and aging of  
SOA under simplified conditions (Burkholder et al., 2017). The oxidation of biogenic VOC (bVOC) and  
particularly terpenes has been studied extensively in chamber experiments, mainly as a result of their large  
contribution to global emissions (Spracklen et al., 2011) and their strong SOA formation potential (Lee et al., 2006).  
Although anthropogenic VOC (aVOC) emissions contribute less to the global emissions (Goldstein and Galbally,  
55 2007) than the respective biogenic (Aiken et al., 2009), at a regional scale their relative emissions may be  
substantially higher, therefore they have been widely studied as SOA precursors in chamber experiments  
(Baltensperger et al., 2005; Wyche et al., 2009). These experiments have shown that both biogenic and

anthropogenic VOC oxidation can yield hundreds or thousands of products that are highly reactive and have wide range of volatilities (Hallquist et al., 2009).

60 A number of studies have shown that SOA volatility is largely dependent on the functionality through control of the vapour pressures (and to a lesser extent, the activity coefficients) of the individual organic compounds in the mixtures (McFiggans et al., 2010; Barley et al., 2009; Topping et al., 2011). Condensed phase reactions may further alter the SOA volatility (Kroll and Seinfeld, 2008). Therefore, the chemical reactions in both the gas and condensed phases determine the aerosol volatility, which in turn drives the partitioning of the species and the subsequent  
65 transformation pathways.

Recently, the formation of highly oxygenated organic molecules (HOM), defined as organic compounds with at least 6 oxygen atoms through the autoxidation of peroxy radicals ( $\text{RO}_2$ ) (Bianchi et al., 2019), has been shown to be a critical process affecting the growth of newly formed particles (Tröstl et al., 2016; Stolzenburg et al., 2018). The fate of  $\text{RO}_2$ , which can participate in autoxidation or other explicit termination reactions such as  $\text{RO}_2 + \text{HO}_2$ ,  
70  $\text{RO}_2 + \text{NO}$  and  $\text{RO}_2$  cross-reactions, has a determinant role for the HOM formation and volatility (Schervish and Donahue, 2020). HOM volatility is thought to range from the semi-volatile to the ultra-low volatility range.

Chamber studies have mainly focused on studying the formation and the resulting properties of the SOA formed from a single VOC precursor. Recently however, McFiggans et al. (2019) showed that upon mixing bVOC precursors, the SOA formation is governed by the molecular interactions of the products. Specifically, it was shown  
75 that upon mixing a high and a low yield bVOC ( $\alpha$ -pinene and isoprene, respectively), the overall SOA formation was suppressed due to i) the hydroxyl radical (OH) scavenging by the lower yield isoprene and ii) due to product scavenging. In the second process, the peroxy radical ( $\text{RO}_2$ ) oxidation products of isoprene were scavenging the highly oxygenated  $\text{RO}_2$  oxidation products (HOM- $\text{RO}_2$ ) of the higher yield precursor, leading to higher volatility products than if their termination partners had been other HOM- $\text{RO}_2$ . This demonstrates that product interactions  
80 in mixed precursor systems will alter the product distribution with consequent implications to the SOA formation and properties.

In this work, we extend the system studied by McFiggans et al. (2019) with the investigation of the interactions of an aVOC with a bVOC. We selected *ortho*-cresol (hereafter *o*-cresol), a product of toluene oxidation and also a directly emitted aromatic species, as a representative aVOC. In each system, the initial concentrations of the  
85 reactants were adjusted to have equal reactivity towards OH at the beginning of each experiment such that the

mixtures were initially iso-reactive towards the dominant oxidant in the system. *o*-cresol is a convenient choice, enabling similar concentrations of VOC to be used in initially iso-reactive mixtures, owing to its relatively high reactivity with OH and moderate SOA yield (Atkinson, 2000; Henry et al., 2008). This choice of precursors and contributory reactivities enabled investigation of SOA formation with mixed systems containing a low, a moderate and a high yield precursor (i.e., isoprene, *o*-cresol and  $\alpha$ -pinene, respectively) with equal initial chances of reacting with the dominant oxidant and contributions of first-generation oxidation products. This manuscript focuses on demonstrating the ability of the available tools to explore the SOA particle volatility using the  $\alpha$ -pinene and *o*-cresol subset of the system as a proof of concept. Subsequent manuscripts will focus on the SOA formation dynamics and other aspects of the binary and ternary mixtures.

90

95 The SOA particle volatility in single precursor systems has been investigated based on the aerosol evaporation after heating (Lopez-Hilfiker et al., 2015; Donahue et al., 2006), by isothermal dilution (Yli-Juuti et al., 2017) or a combination of the two (Louvaris et al., 2017; Cain et al., 2020). Previous works have showed that the oxidation of  $\alpha$ -pinene results in low volatility and semi-volatile components (Zhang et al., 2015). The oxidation of *o*-cresol has been studied to much lesser extent and the resulting SOA is thought to be composed of lower volatility species compared to that derived from biogenic precursors (Baltensperger et al., 2005). Low and extremely low volatility material formed from oligomerisation reactions might contribute considerably to the  $\alpha$ -pinene-derived SOA particle mass (Lopez-Hilfiker et al., 2015). Aromatic oxidation proceeds through rapid multiple generations of OH oxidation resulting in more oxygenated and less volatile material compared to biogenic precursors (Garmash et al., 2020; Wang et al., 2020).

100

105 In this study, we employ two independent thermal techniques (thermal denuder and FIGAERO coupled to a high resolution time of flight chemical ionisation mass spectrometer) and we aim to provide the first observational quantification of the volatility of SOA formed from an aVOC and bVOC precursor mixture with modest and high yields, respectively. Additionally, we use detailed gas and particle phase composition measurements to contextualise our volatility estimations and identify the main drivers of the SOA particle volatility in such mixtures.

110 We further aim to investigate the ability of the instrumentation used in exploring the SOA particle volatility and discuss their implications to the interpretation of the results.

## 2. Materials and methods

### 2.1. Manchester Aerosol Chamber

115 The experiments were conducted at the University of Manchester Aerosol Chamber (MAC) facility (Alfarra et al.,  
2012). MAC is an 18 m<sup>3</sup> fluorinated ethylene propylene (FEP) bag mounted on three rectangular frames, enclosed  
in a temperature and relative humidity (RH) controlled housing, operating as a batch reactor. The central frame is  
fixed whereas the lower and upper frames are free to move, allowing the bag to collapse and expand as chamber  
air volume changes, maintaining atmospheric pressure without dilution. Light is generated by a series of halogen  
120 lamps (Solux 50 W/4700 K, Solux MR16, USA) and two 6 kW Xenon arc lamps (XBO 6000 W/HSLA OFR,  
Osram) over the range of 290-800 nm. Quartz glass filters were used in front of each arc lamp in order to reduce  
the radiation flux below 300 nm and mimic the atmospheric radiation spectrum as closely as possible. The  
photolysis rate of NO<sub>2</sub> ( $J_{\text{NO}_2}$ ), as computed from steady-state actinometry experiments, was 0.11-0.18 min<sup>-1</sup>. The  
O<sub>3</sub> formed by NO<sub>2</sub> photolysis was itself photolysed in the moist chamber atmosphere (RH ≈ 50%) to yield a OH  
125 concentration from primary production, as calculated by the decay rate of solely OH reacting VOCs (e.g., toluene,  
*o*-cresol), of around 1×10<sup>6</sup> molecules cm<sup>-3</sup>. Liquid VOC precursors (*α*-pinene and *o*-cresol; Sigma Aldrich, GC  
grade ≥99.99% purity) were added to the chamber by injecting the desired amount into a heated glass bulb and  
transferred into the chamber using gentle electronic capture device-grade nitrogen stream. Seed particles were  
nebulised using an aerosol generator (Topaz model ATM 230) from aqueous solutions of ammonium sulfate  
130 (Puratonic, 99.999% purity). NO<sub>x</sub> concentration was controlled by adding the desired amount of NO<sub>2</sub> from a  
cylinder using ECD N<sub>2</sub> as carrier gas. All the reactants (VOC, NO<sub>x</sub> and seed) were introduced to the chamber at  
high flow rate (~3 m<sup>3</sup> min<sup>-1</sup>) during the final fill cycle, resulting in rapid mixing. The mixing and temperature  
control throughout the experiment was effected through the use of conditioned air circulated at high flowrate around  
the chamber housing, continually agitating the chamber walls without physical contact.

135

### 2.2. Experimental procedure

The experiments conducted in this study were representative of “daytime” photo-oxidation in the presence of O<sub>3</sub>  
and OH. This study, as also described above, is part of a broader project investigating SOA derived from mixtures  
of precursors with distinct yields and properties. Here, we focus on the *α*-pinene and *o*-cresol system, as  
140 representative biogenic and anthropogenic VOC precursor sources (Hallquist et al., 2009; Schwantes et al., 2017),

both with appreciable SOA yields (e.g., Henry et al., 2008; Kristensen et al., 2014). In order to study the effect of mixing anthropogenic and biogenic precursors on SOA particle volatility, two types of experiments were conducted: (a) single precursor experiments, where the photo-oxidation of each precursor was studied individually and (b) mixture experiments, where both precursors were added to the chamber simultaneously. Since *o*-cresol is practically unreactive towards O<sub>3</sub> within our experimental timescales and because  $\alpha$ -pinene's lifetime with respect to OH is shorter than towards O<sub>3</sub> at the expected oxidant concentrations in our experiment (5.2 vs 6.3 h; Atkinson, 2000), the concentrations of the reactants were selected based on the reactivity of each precursor with OH. As such, each VOC has equal initial chances of reacting with the dominant oxidant in the mixture experiments, while the overall initial reactivity (defined as the product of the VOC concentration and the reaction rate coefficient with OH) in both single-precursor and mixture experiments was the same. Therefore, our systems are "iso-reactive" at the beginning of each experiment, though not necessarily thereafter. The ozone concentration at the beginning of each experiment was zero. Ozone is formed rapidly from the photolysis of NO<sub>2</sub> after the lights are turned on to establish photostationary state and then continuously produced through the oxidation of VOC in the presence of NO<sub>x</sub> (Atkinson, 2000). All the experiments were conducted under modest NO<sub>x</sub> conditions (VOC/NO<sub>x</sub> 6±2 ppb/ppb) by adding NO<sub>2</sub>, and moderate RH and temperature conditions (50±5% and 24±2 °C, respectively). Ammonium sulfate seed particles (53±12 μg m<sup>-3</sup>) were added to provide a medium for condensation of the condensable VOC oxidation products to successfully compete with the walls, to reduce the influence of vapour wall-losses and also to suppress nucleation (Zhang et al., 2014). The initial experimental conditions are summarised in Table 1.

Each experiment was comprised of a common set of procedures shown in Fig. S1a. Briefly:

- i) The "pre-experiment" procedure entailed flushing of the chamber with clean air at a high flow rate of 3 m<sup>3</sup> min<sup>-1</sup> for ~1.5 h.
- ii) The "chamber background" was established by stabilising the chamber with clean air without reactants. This phase lasted for ~1 h and the established baselines were thereafter subtracted from the measurements.
- iii) The "dark unreactive" phase commenced after the addition of the VOC precursor(s), NO<sub>2</sub> and seed aerosol to the chamber in the dark. During this period (also ~1 h), the initial conditions of the chamber were established.
- iv) The "experiment" phase commenced when the chamber lights were turned on, initiating the photo-oxidation and consequent SOA formation. Each "experiment" phase lasted for 6 h.

- 170 v) A “post-experiment” cleaning procedure normally comprised the high flowrate flushing of the chamber with clean air for ~1.5 h, subsequently filling with high concentration of O<sub>3</sub> (≥1 ppm) and soaking overnight to oxidise any remaining gas-phase organic species. All the results given below correspond to the “experiment” phase only.

175 **Table 1: Summary of the initial conditions for each of the experiments conducted in this study.**

Experiment No.	Experiment type	NO <sub>x</sub> (ppb)	VOC (ppb)	VOC/NO <sub>x</sub> (ppb/ppb)	Seed Concentration (µg m <sup>-3</sup> )
<b>Single VOC</b>					
1	<i>α</i> -pinene	40	309	7.7	72.6
2	<i>α</i> -pinene	43	309	7.2	67.6
3	<i>α</i> -pinene	37	309	8.4	62.0
4	<i>α</i> -pinene	50	309	6.2	39.4
6	<i>o</i> -cresol	71	400	5.6	36.0
7	<i>o</i> -cresol	44	400	9.1	47.8
8	<i>o</i> -cresol	56	400	5.0	51.3
<b>Mixture</b>					
9	<i>α</i> -pinene+ <i>o</i> -cresol	n.a.*	355 (155+200) <sup>a</sup>	n.a.*	42.5
10	<i>α</i> -pinene+ <i>o</i> -cresol	30	355 (155+200) <sup>a</sup>	11.8	57.0
11	<i>α</i> -pinene+ <i>o</i> -cresol	52	355 (155+200) <sup>a</sup>	6.8	48.3

\*n.a. values correspond to corresponding instrument failures at the day of the experiment.

<sup>a</sup>Sum of the VOC added in the mixture the individual concentrations of *α*-pinene and *o*-cresol added are shown in the brackets, respectively.

## 180 2.3. Instrumentation

### 2.3.1. TD- AMS/SMPS

A scanning mobility particle sizer (SMPS; DMA 3081 and CPC 3776, TSI Inc., USA) was used to measure aerosol size distributions in the range of 10-670 nm, operating at 0.3 L min<sup>-1</sup> (1:10 sample/sheath flow). The non-refractory aerosol chemical composition and mass were measured by a high-resolution time of flight aerosol mass spectrometer (HR-ToF-AMS, ARI Inc., USA hereafter HR-AMS) (DeCarlo et al., 2006), sampling at 0.1 L min<sup>-1</sup>.  
185 The HR-AMS was calibrated regularly using previously published procedures (Jimenez et al., 2003; Allan et al., 2004).

The TD unit employed here was designed based on the recommendations of Fuentes and McFiggans (2012). Briefly, sample flow enters and exits the TD unit via a cylindrical 0.12 m long and 36.6 mm inner diameter (ID) stainless steel compartment. The heating section which is placed in a housing with insulating material, has a length  
190 of 0.51 m and an ID of 151 mm, and its temperature is controlled by four PID controllers (Watlow EZ-ZONE). A cooling section with a length of 0.2 m and an ID of 20 mm, allows the sample to cool down to ambient temperature with minimal re-condensation (Fuentes and McFiggans, 2012). In our configuration, the TD was operating at temperatures ranging from 25 to 90 °C in 13 steps and the HR-AMS and SMPS sampling alternated between the  
195 bypass and TD every 4 and 6 min, respectively, using a 3-way electronic valve. The alternating sampling through the TD unit was initialised at the final 2 h of each experiment where minimal changes in the aerosol composition over time are expected (i.e., SOA formation rate < wall loss rate). The resulting mass fraction remaining (MFR) in each temperature step was calculated as the ratio of the total aerosol mass passing through the TD to the average bypass concentration obtained before and after each step. The sample flow rate through the TD and bypass was  
200 adjusted to 1 L min<sup>-1</sup>, resulting in an average residence time of the aerosol in the heating section of 31 s, using a vacuum line and a mass flow controller. All the TD data were corrected for particle losses as a function of particle size and temperature, based on characterisation experiments conducted using sodium chloride particles and the same instrument configuration.

### 2.3.2. FIGAERO-ToF-CIMS

205 Near-real time gas and particle composition was measured using the Filter Inlet for Gas and Aerosols (FIGAERO) (Lopez-Hilfiker et al., 2014) coupled to an Iodine high-resolution time of flight chemical ionisation mass spectrometer (Lee et al., 2014) (hereafter FIGAERO-CIMS). Briefly, the FIGAERO manifold allows the

determination of both particle and gas phases by collecting particles on membrane filter while sampling the gas phase. After a period of time, the deposited aerosol is thermally desorbed using high purity N<sub>2</sub> as a carrier gas. In our setting, particles were sampled from the middle of the chamber through a 2 m long, 0.635 cm OD stainless steel tube at 1 sL min<sup>-1</sup> and deposited on a PTFE filter (Zefluor, 2.0 μm pore size). The flow over the filter is continually monitored by an MKS mass flow meter (MFM) after the sample has passed over the filter so ensure a known volume is sampled in each cycle. The gas phase was sampled through a separate line, using a 2 m long, 0.635 cm OD PTFE tubing, in order to minimise any potential gases losses into the lines (Sulyok et al., 2002;Mittal et al., 2013), at 2 sL min<sup>-1</sup>. This gas phase sample flow is again constantly measured a MFM at the exhaust of the IMR pump which included the reagent ion flows. The instrument was run in negative-ion mode with I<sup>-</sup> reagent ion in all the experiments. The reagent ions were produced by passing a known concentration mix of CH<sub>3</sub>I and UHP N<sub>2</sub> over a PO<sub>210</sub> radioactive source and passed directly into the IMR.

The FIGAERO-CIMS was configured in operating in cyclic mode with 30 min of gas sampling and simultaneous particle collection, followed by 15 min of thermal desorption from ambient to 200 °C (~12 °C min<sup>-1</sup>; temperature ramp period) and then kept at a constant temperature for another 10 min (i.e., soak period) to ensure that all the remaining mass is evaporated. Last, the FIGAERO was cooled down to ambient temperature within 10 min (i.e., cooling period). An example of the FIGAERO cycle is shown in Fig. S1b. Further details on the FIGAERO-CIMS employed in this study can be found in Bannan et al. (2019) and Priestley et al. (2018). In order to account for any potential instrument contamination during the gas-phase sampling, the instrument was flushed with UHP N<sub>2</sub> for a period of 0.2 min every 2 min, thus a gas phase instrument background value was regularly established and applied to the final data by linear interpolation (Fig. S1b).

As a result of the low organic particles concentration in the first hours of the *o*-cresol experiment and for comparison with the concurrent TD measurements, all the results shown by the FIGAERO-CIMS here correspond to the data obtained during the last two hours of the experiment.

It should be noted that quantification from the FIGAERO-CIMS in both the particle and gas phase remains challenging as a result of a lack of available standards and the experimental limitations (Riva et al., 2019). Despite a number of studies attempting to constrain those limitations (Lopez-Hilfiker et al., 2016a;Aljawhary et al., 2013), this remains extremely challenging. Therefore, here, we assumed uniform instrument sensitivity across the whole range of the detected products and an assessment of the impact of increased sensitivity to particular functional group additions on the reported results is probed in Section 4.2.

## 2.4. Data analysis

### 2.4.1. FIGAERO-ToF-CIMS

240 The FIGAERO-CIMS data were analysed using the Tofware package in Igor Pro (v. 3.2.1., Wavemetrics<sup>®</sup>) (Stark  
et al., 2015). The peak fitting was conducted in the region of 190-550 m/z, where the vast majority of the total  
signal occurred (>70%; excluding the reagent ions;  $I^-$   $I_2^-$   $I_3^-$  and  $I.H_2O$ ). The mass to charge calibration was  
performed in the range of 127-380 m/z using four known masses,  $I$ ,  $CH_2O_2I$ ,  $I_2^-$  and  $I_3^-$  and the resulted calibration  
error was within 3 ppm. The remaining ions were sorted based on their contribution to the total signal and the HR  
245 formula identification was conducted until more than 80% of the total fitted signal was assigned. All the elemental  
formulae were assigned to the HR spectrum according to Kendrick's mass defect, all within ~6 ppm error. Only  
the particle phase data collected during the temperature ramp were considered here due to signal interferences  
observed during the soak period. These interferences could be attributed to the prolonged period of flushing the  
instrument with high temperature gas and/or burning off inorganic/involatile material from the filter (Wang and  
250 Hildebrandt Ruiz, 2018). The gas-phase data obtained during "instrument background" mode (see Section 2.3 and  
Fig. S1b) were subtracted from the measured values in each cycle by linear interpolation. To account for any  
potential chamber contamination, the data obtained during the "chamber background" phase were also subtracted  
from the data obtained during the "experiment" phase (see Section 2.2 and Fig. S1b). For the particle-phase data,  
a similar procedure was followed. In certain cases, a high initial particle phase signal was observed that  
255 subsequently decreased over time (Fig. S2a). To correct for these interferences a corresponding particle-phase  
"instrument background" period was assumed. We selected the 30-60th second of each desorption cycle as a  
particle-phase "instrument background" period (Fig. S1b) because (i) the desorption temperature was still at  
ambient levels (<22°C; Fig. S2b), implying that the thermal desorption process had not yet started and (ii) this  
period avoided the "noisy" signal that appeared during the first 10-15 s of each desorption cycle produced by the  
260 IMR pressure change due to the actuator shifting position (Fig. S2a). The average signal of the particle-phase  
"instrument background" period was then subtracted from the raw desorption data and the resultant thermograms  
(signal vs. desorption temperature) were integrated using the trapezoid rule. Subsequently, the integrated area of  
each peak obtained during the "dark unreactive" phase (see Section 2.2; Fig. S1a) was subtracted from the data to  
remove any seed and/or filter effect. All the subsequent analysis presented in this work is using the background-  
265 corrected data.

In order to identify the products that are uniquely formed in the mixed VOC systems, we computed the signal contribution of each of the unique precursor products, as identified in the single VOC experiments, to the total signal of the FIGAERO-CIMS of the mixture in each phase. The contributions of products with assigned formulae which were common among all systems and CIMS is unable to resolve (i.e., isomers) were also computed, while the remaining were considered as unique to the mixture products. In order to take into account any potential products which were not identified in single experiments but still uniquely correspond to either of the two precursors and were potentially miscounted as unique to the mixture products, we compared the resultant products categorised as unique to the mixture with the Master Chemical Mechanism (MCM v3.2; Saunders et al., 2003; Jenkin et al., 2003). The unique to the mixture products that were matched with the products of either precursor from the MCM or were found as common, were subsequently assigned to the corresponding lists.

#### 2.4.2. Volatility retrieval from TD-AMS

The Mass Fraction Remaining (MFR) data obtained from the SMPS/AMS were used to calculate the volatility distributions of the bulk SOA. The volatility distributions here were expressed as effective saturation concentration at 298 K ( $C^*$ ;  $\mu\text{g m}^{-3}$ ) bins in the Volatility Basis Set (VBS) framework (Donahue et al., 2006) and were calculated by the algorithm of Karnezi et al. (2014). Briefly, the approach uses the thermodynamic mass transfer model of Riipinen et al. (2010) to fit the MFR measurements of the thermodenuder selecting appropriate volatility distributions and effective enthalpies of vaporization. The model neglects any temperature gradients in the TD and assumes monodisperse aerosol population, equal to the mean volumetric diameter. The inputs of the model, in addition to the MFR measurements, were the average residence time in the heating section (31 s), the length of the heating section (0.51 m), the average volumetric diameter of the particles entering the TD (calculated from SMPS data for the by-pass line), the average organic mass concentration bypassing the TD and the particles' density (assumed as  $1.4 \text{ g cm}^{-3}$ ). The volatility distribution was expressed in six volatility bins spanning from  $C^*=10^{-3}$  to  $10^2 \mu\text{g m}^{-3}$ .

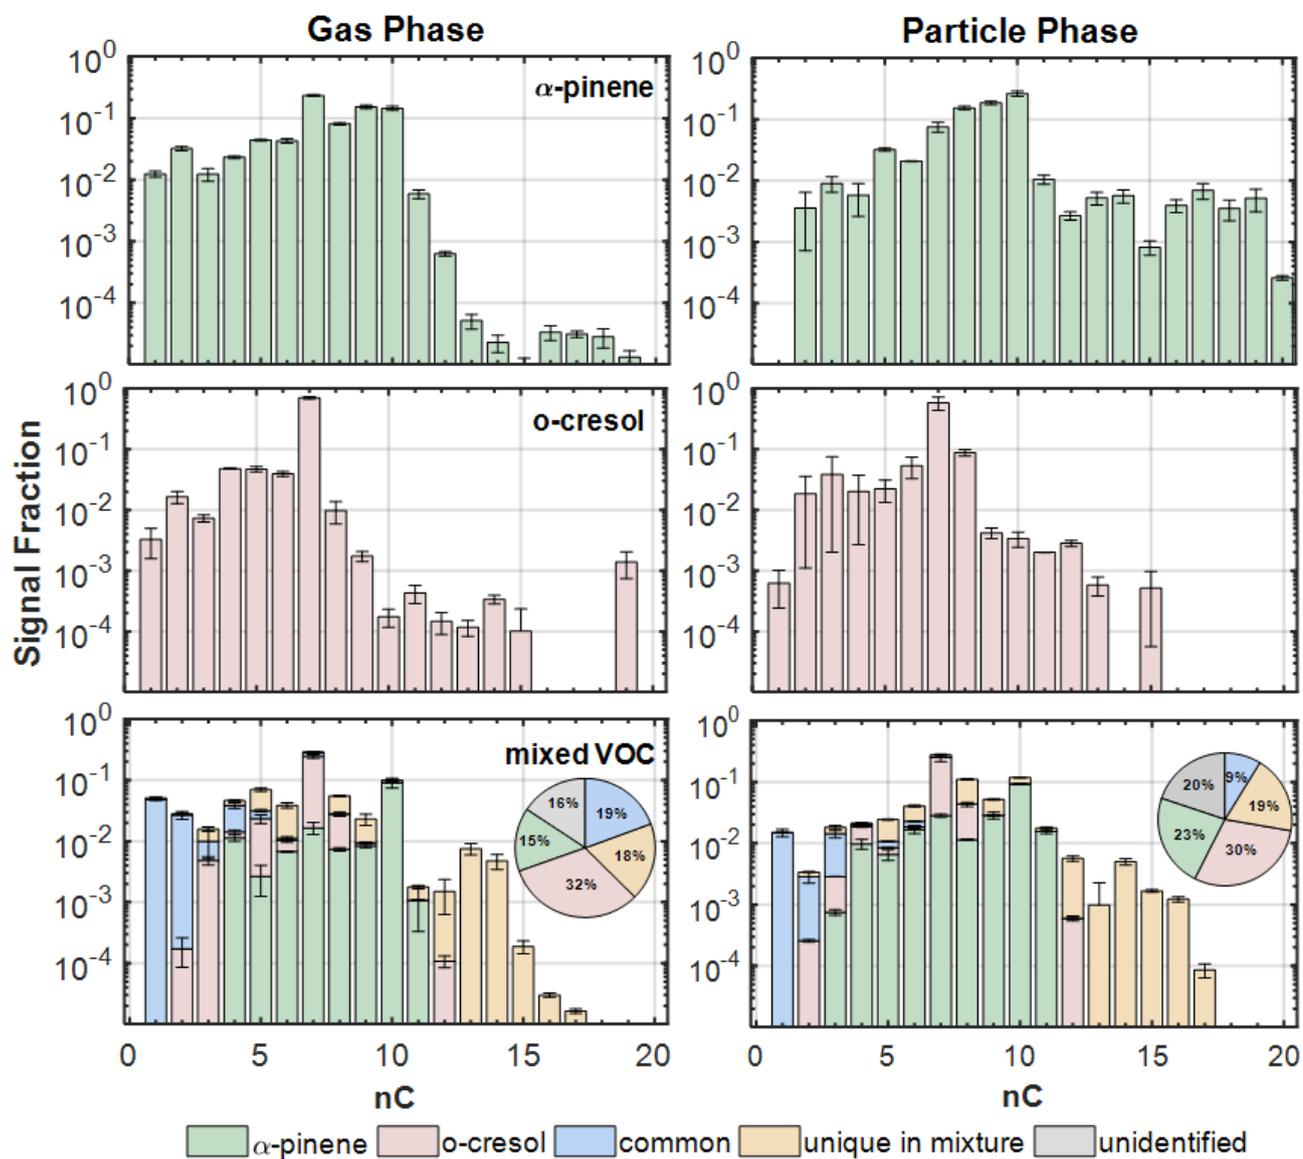

### 3. Results

#### 3.1. Gas and particle phase composition

Figure 1 shows the average ( $\pm 1 \sigma$ ) distribution of carbon number of all the products identified by the FIGAERO-CIMS in each phase and system investigated. The distributions in the mixed VOC system show the contributions

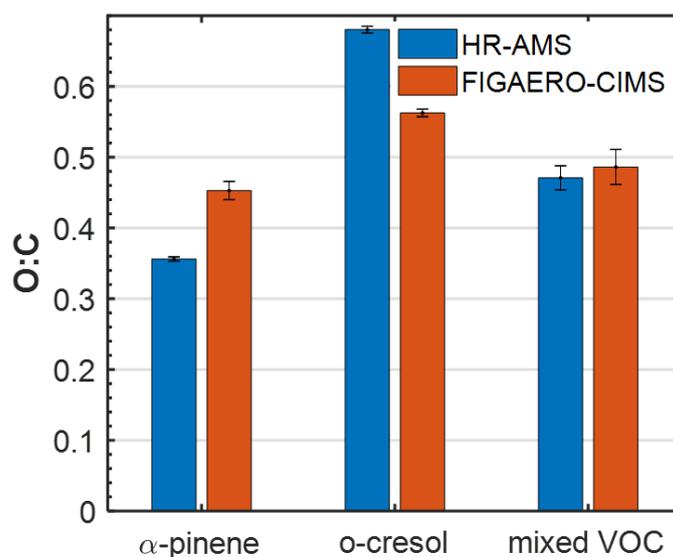

- from the products of either precursor, the common products and the products unique to the mixture, in addition to the unidentified fraction (see Section 2.4).
- 295 Each individual precursor system exhibited distinct features. For example, in the  $\alpha$ -pinene single precursor system, the majority of the products identified by the FIGAERO-CIMS both in the gas and particle phase had the same or fewer carbon atoms than the parent molecule (81 and 73% of the total signal in each phase, respectively; Fig. 1). More specifically, in the particle phase, the highest contribution was found for products with 10 carbon atoms while in the gas phase for products with 7 carbon atoms. In contrast, in the *o*-cresol single precursor system, the vast
- 300 majority of the identified products in either phase showed a narrow distribution centred around the carbon number of the precursor (ie.,  $nC=7$ ). This can be associated with the large signal contribution of two individual products in each phase, assigned as  $C_7H_8O_2$  (50%) and  $C_7H_7NO_4$  (40%) in the gas and particle phase, respectively. In the particle phase of both single precursor systems, a greater fraction of the signal is associated with products having more carbon atoms than each precursor, compared to the respective gas phase contributions.
- 305 In both gas and particle phases in the mixed VOC system, the largest fraction of the total signal was found for products with 7 carbon atoms. In the gas phase, the remaining signal was distributed in the region of  $nC=4-10$  with stronger contributions at  $nC=5$  and  $nC=10$ , while in the particle phase, products with  $nC=8$  and  $nC=10$  contributed considerably to the total signal. Unlike the single precursor systems, the contributions of products with larger than 10 carbon atoms are not substantially different between the gas and particle phases.
- 310 The majority of the products that were common between all systems have low carbon numbers ( $nC<5$ ) and account for a higher fraction of the total gas than the particle phase signal of the mixed VOC system (18% vs. 8%). In both phases, *o*-cresol products appear to contribute most to the total signal of the mixed VOC system with the majority of the signal in products with 7 carbon atoms, similar to the single precursor system. The products that were classified as unique products of the mixture account for approximately the same fraction in both phases and were
- 315 found mostly in the  $nC=5-10$  range, with appreciable fractions in the  $nC>10$  range.

320 **Figure 1:** Average ( $\pm 1\sigma$ ) distributions of carbon number (nC) of all individual products identified in the three systems for the gas (left panels) and the particle phase (right panels). In the mixed VOC system, the bars are separated to show the contributions of products that were associated with either precursor, the common ions as well as those that were found unique in the mixture. The above are summarised in inset pie charts to show to overall contributions to the total signal in each phase.

The O:C ratios in the particle phase show the contributions to SOA mass per condensed carbon attributable to O. The average ( $\pm 1\sigma$ ) of O:C ratio for all the products identified in each system from the FIGAERO-CIMS, weighted to the contribution of each product to the total signal along with O:C ratio derived from the HR-AMS are shown in the Figure 2. Both HR-AMS and FIGAERO-CIMS showed comparable results, with the O:C being highest in the *o*-cresol system (0.68 vs 0.56, respectively), followed by the mixed VOC (0.47 vs 0.49, respectively) and the  $\alpha$ -pinene system (0.35 vs 0.45, respectively). Although N:C ratios might provide similarly useful information, their quantification with FIGAERO-CIMS and HR-AMS has been proven challenging as a result of sensitivity effects (Iyer et al., 2016) and the extensive fragmentation which is not readily characterised for the N-containing fragments (Farmer et al., 2010), respectively.

**Figure 2: Average ( $\pm 1\sigma$ ) oxygen to carbon (O:C) ratio for all the products identified in the particle phase from the FIGAERO-CIMS and the HR-AMS for each system.**

### 3.2. SOA particle volatility

Our experimental setup allows the estimation of the SOA particle volatility distribution using two independent techniques. The TD measurements with the approach of Karnezi et al. (2014) allow the retrieval of the SOA particle volatility distribution in the VBS framework. For comparison, the thermal desorption of the SOA particles collected

340 on the FIGAERO provides an indirect measure of the volatility as a function of the FIGERO-CIMS total particle phase signal (Lopez-Hilfiker et al., 2014; Lopez-Hilfiker et al., 2016b).

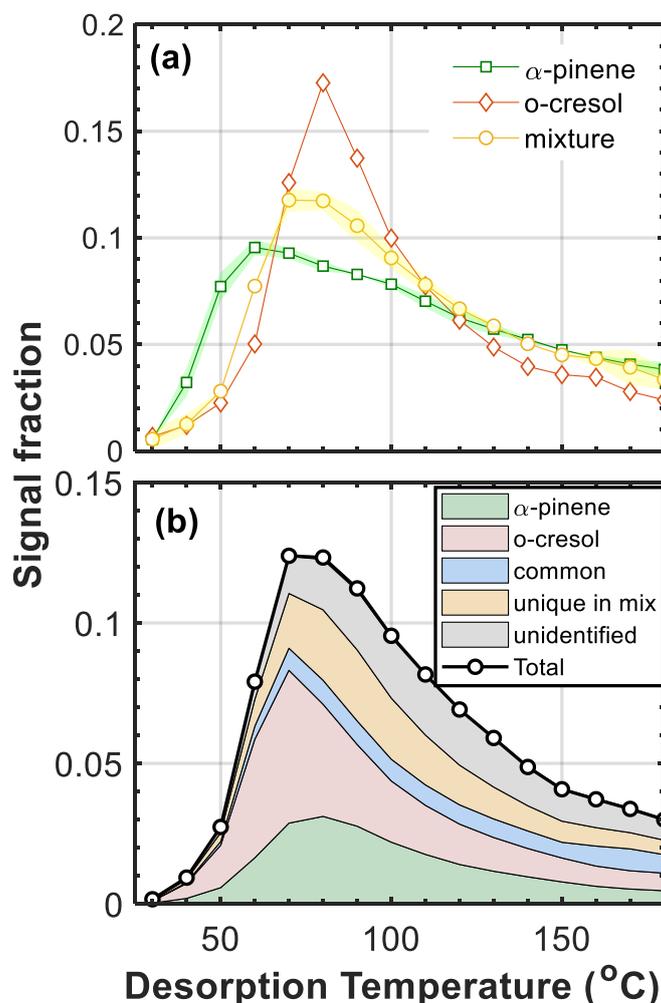

### 3.2.1. Insights on the SOA particle volatility from the FIGAERO-CIMS

Figure 3, shows the average sum thermograms for each system ( $\pm 2\sigma$  as shaded areas). For the mixture, the contributions from the products of either precursor, the common products, the unique to the mixture products in addition to the unidentified fraction are shown in Figure 1b as areas for a characteristic experiment (Exp. no. 10; Table 1). Furthermore, here, we define the products evaporating at  $\leq 50^\circ\text{C}$  as “more volatile”, those evaporating between 50 and  $90^\circ\text{C}$  as “moderately volatile” and those evaporating above  $90^\circ\text{C}$  to be “less volatile” (e.g., Saha and Grieshop, 2016; D'Ambro et al., 2019; Lopez-Hilfiker et al., 2014). Figure 4 shows the corresponding signal fraction that evaporated in each of these desorption temperature bins in three characteristic experiments (Exp. No. 2, 5 and 10; Table 1). The sum thermogram in the  $\alpha$ -pinene system is broader compared to the other systems and peaked at relatively low temperature ( $60^\circ\text{C}$ ). Characteristically, the fraction of the signal evaporated at the  $\leq 50$ , 50-90 and  $\geq 90^\circ\text{C}$  range was 11, 27 and 62%, respectively. In contrast, the sum thermogram in the *o*-cresol experiment was narrower, peaking at  $80^\circ\text{C}$ , while the corresponding fractions evaporated were 4, 35 and 61%. The sum thermogram in the mixed VOC system peaked in the mid-temperature range ( $70^\circ\text{C}$ ), while its distribution appeared to have similar features as those from the single precursor experiments. More specifically, the sum thermogram of the mixture exhibited similar fraction of products desorbing at lower temperatures as the *o*-cresol experiment (4% of the total signal desorbed at  $\leq 50^\circ\text{C}$ ) and similar fraction of products desorbing at higher temperatures as those in the  $\alpha$ -pinene experiment (64% of the total signal desorbed at  $\geq 90^\circ\text{C}$ ). This suggests that the SOA particles from  $\alpha$ -pinene photo-oxidation have higher contributions of both higher and lower volatility material, those from *o*-cresol oxidation have narrower volatility distribution and modest volatilities, and those formed from the photo-oxidation of the mixture of both precursors to be moderate to less volatile.

350

355

360

365 **Figure 3: (a) FIGAERO-CIMS average ( $\pm 2\sigma$  as shaded areas) sum thermograms in each system and (b) Example sum thermogram from a mixed VOC experiment (Exp. No. 10; Table 1) where the contributions of products that were associated with either precursor, the common products, those that were found unique in the mixture, in addition the unidentified fractions are shown as areas.**

The products from the *o*-cresol oxidation contribute substantially to the total signal in the 50-90 °C and  $\geq 90$  °C range of the mixed VOC experiment (12 and 10%, respectively), whereas those deriving from the oxidation of  $\alpha$ -pinene contribute most to the  $\geq 90$  °C range and to a lesser extent to 50-90 °C range (12% and 8%, respectively).  
370 The common products mostly contribute to the  $\geq 90$  °C range (7%), with smaller contributions to the 50-90 °C bin

(2%). The products that were unique to the mixture contribute mostly to the  $\geq 90$  °C range (12%) and considerably to the 50-90 °C range (6%). Notably, the unidentified ions were contributing 21% of the signal in the  $\geq 90$  °C range. This shows that the products from either precursor as well as those that were common in both systems have moderate to low volatilities, while those that were classified as unique products of the mixture mostly have lower volatilities.

It should be noted however that the high contribution from the *o*-cresol products in the mixture at the 50-90 °C range, as well as the narrow desorption temperature distribution observed in the single *o*-cresol system, was significantly influenced by the dominant product (i.e.,  $C_7H_7NO_4$ ). The implications of this in the interpretation of the results will be further discussed in Section 4.2.

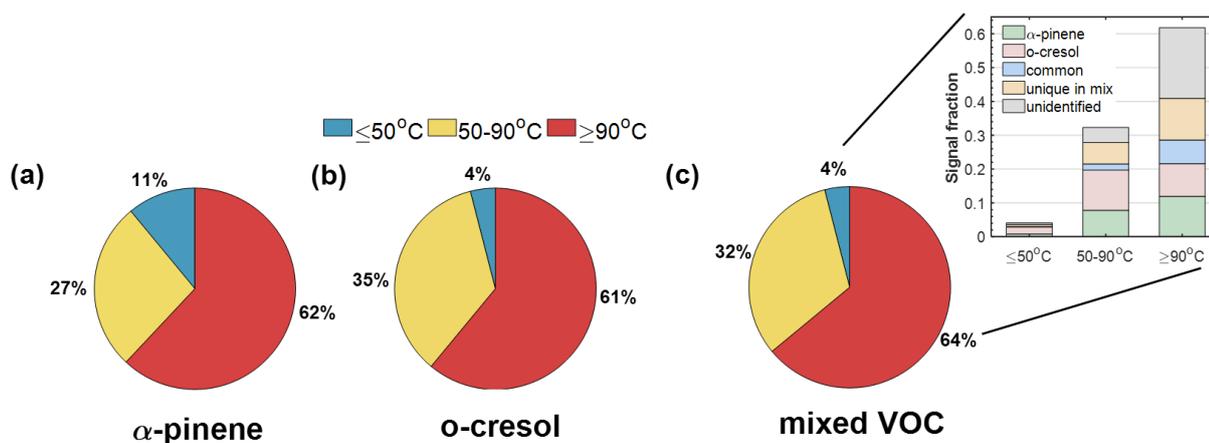

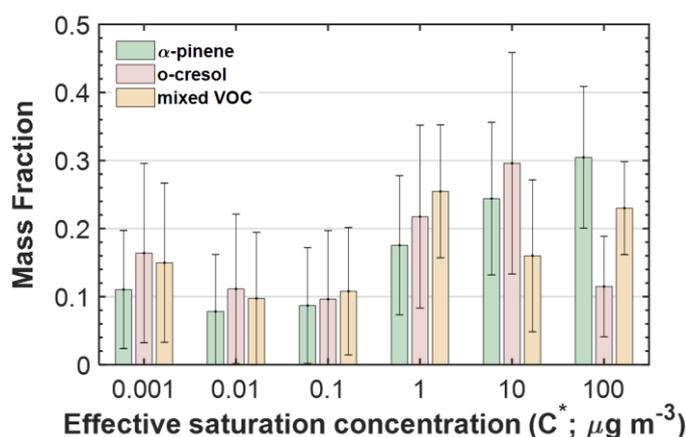

Figure 4: FIGAERO-CIMS signal fraction that evaporated at  $\leq 50$ , 50-90 and  $\geq 90$  °C in a characteristic (a)  $\alpha$ -pinene, (b) *o*-cresol and (c) mixed VOC experiments (Exp. No. 2, 5 and 10, respectively). For the mixed VOC experiment, the inset bar chart shows the contributions of the products of each precursor, the common and the unique to the mix products as well as the unidentified fraction.

### 3.2.2. Insights on the SOA particle volatility from the TD-AMS

The predicted SOA particle volatility distributions from the TD measurements for the same characteristic experiments (Exp. No. 2, 5 and 10; Table 1) are presented in Figure 5, expressed in effective saturation concentration at 298 K ( $C^*$ ) bins in the VBS framework. The bin with  $C^*=10^{-3}$   $\mu\text{g m}^{-3}$  includes also the less volatile material (extremely low volatility organic compounds) and the bin with  $C^*=10^2$   $\mu\text{g m}^{-3}$  may also include more

volatile material. The material with  $C^* \geq 1 \mu\text{g m}^{-3}$  is characterized as semi-volatile organic compounds (SVOCs) while that with  $C^* \leq 0.1 \mu\text{g m}^{-3}$  has low volatility (LVOCs). The volatility distribution of the SOA formed in the  $\alpha$ -pinene experiment, indicates a higher contribution of species with  $C^* \geq 100 \mu\text{g m}^{-3}$ , compared to *o*-cresol and mixture experiments. Conversely, in the *o*-cresol and in the mixture experiments the bins with  $C^* \leq 0.1 \mu\text{g m}^{-3}$  exhibited relatively higher values compared to the single precursor  $\alpha$ -pinene system, suggesting a higher contribution of less volatile material. More specifically, the mass fraction of the LVOC and SVOC was 28 and 72% for the  $\alpha$ -pinene SOA, 39 and 61% for the *o*-cresol SOA and 37 and 63% for their mixture, respectively.

400 **Figure 5: SOA particle volatility distributions retrieved from the TD measurements for three characteristic experiments (Exp. No. 2, 5 and 10; Table 1).**

The volatility distribution inversion algorithm employed here (Karnezi et al., 2014) can also provide the enthalpy of vaporisation and the mass accommodation coefficient for each of the experiments investigated. The enthalpy of vaporisation was found to be higher in the  $\alpha$ -pinene experiment ( $120 \text{ kJ mol}^{-1}$ ) and lower at the *o*-cresol ( $106 \text{ kJ mol}^{-1}$ ). This qualitatively consistent with the larger size of the molecules in the  $\alpha$ -pinene SOA. The mass accommodation coefficients were close to unity in both systems (0.36 for the  $\alpha$ -pinene and 0.23 for the *o*-cresol SOA; Fig. S3) suggesting only small resistances to mass transfer in the temperature range of the TD. The respective values for the mixed VOC experiment were found to be intermediate of those for the individual single-precursor systems ( $109 \text{ kJ mol}^{-1}$  and 0.27, respectively). Nonetheless, due to the corresponding uncertainties which were  $\pm$  20% for the enthalpy of vaporisation and much higher for the mass accommodation coefficient, these differences may not reflect the reality.

The relationship between the O:C and the MFR can provide indirect additional information about the volatility of the species in each system. Figure 6 shows the O:C enchantment ratio (i.e., O:C at the TD line divided by the corresponding O:C at the BP line) as a function of the particle MFR for a number of experiments in each system. The increasing O:C enhancement ratio as the MFR decreases in all systems is indicating that as the temperature in the TD increases, the remaining SOA particles are less volatile and more oxygenated, consistent with previous observations in chamber experiments (e.g., Huffman et al., 2009). All systems appeared to behave similarly at low TD temperatures (<40 °C), with the O:C enhancement ratio being between 1 and 1.04 and MFR>80%, implying the existence of products with similar degree of oxygenation and similarly high volatility. However, at higher TD temperatures (>40 °C), each system showed distinctive features. The SOA particles from the *o*-cresol system showed the highest O:C enhancement ratio, reaching up to 1.16, followed by those from the mixed VOC and the  $\alpha$ -pinene system which exhibited similar maximum values (1.097 and 1.091, respectively). More specifically, the slope between the highest O:C enhancement ratio and the MFR was twice as high in the *o*-cresol compared to  $\alpha$ -pinene systems, whereas that of the mixed system was approximately between. These results indicate that the less volatile SOA particles from the *o*-cresol system are considerably more oxygenated compared to the average than those of the  $\alpha$ -pinene system.

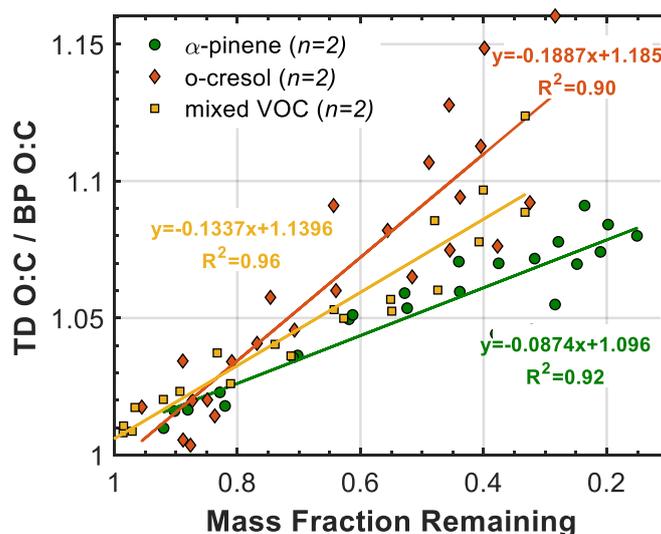

Figure 6: O:C enchantment ratio (i.e., O:C at the TD line divided by the corresponding O:C at the BP line) as a function of the particle MFR in each system investigated.

### 3.2.3. Comparison of the SOA particle volatility between FIGAERO-CIMS and TD-AMS

The FIGAERO-CIMS is able to detect a subset of the total SOA (Lee et al., 2014; Lopez-Hilfiker et al., 2014), whilst the TD technique is able to derive bulk estimations. The increased material in the  $C^* \leq 0.1 \mu\text{g m}^{-3}$  bins in the *o*-cresol and mixed VOC systems compared to that of  $\alpha$ -pinene are consistent with the increased number of products having relatively higher maximum desorption temperatures. Similarly, the increased  $C^* = 100 \mu\text{g m}^{-3}$  content observed in the  $\alpha$ -pinene system compared to the other systems is consistent with the increased fraction of its products desorbing at relatively lower temperatures (i.e.,  $\leq 50^\circ\text{C}$ ; Fig. 4). The SOA volatility distribution of the mixed VOC system appeared to be between those of *o*-cresol and  $\alpha$ -pinene (Fig. 5), which is also consistent with the sum thermograms of its products (Fig. 3). This broad consistency between the volatility inferred from TD inversion and FIGAERO-CIMS provides some confidence that the analysis presented here may be representative of the bulk SOA particle composition.

## 4. Discussion

### 4.1. Linking the gas and particle chemical composition to SOA volatility

The gas and particle phase composition, as can be obtained by the FIGAERO-CIMS, can provide indications about the systems chemical behaviour and thereby the potential effect on SOA volatility. Oligomerisation is a process that increases the products' molar mass decreasing their volatility while tending to maintain their O:C. Functionalisation also decreases a compound's volatility by the addition of oxygenated functional groups and thus increasing their O:C ratio. Fragmentation (i.e., cleavage of carbon-carbon bond) will increase component volatility due to the decrease of the product's molar mass, though in some cases the fragmented products are subsequently functionalised (e.g.,  $\text{O}_2$  addition after the scission of a double bond) leading to a decrease of their vapour pressure, with the net effect on vapour pressure not immediately predictable.

The FIGAERO-CIMS results described above indicate that fragmentation is a major process occurring in all the systems due to the significant fraction of products having lower carbon numbers than their precursors (Fig. 1). Of course, it should be noted that the interpretation of FIGAERO data is dependent on the components that are readily accessible using the chemical ionisation scheme. The iodide CIMS (I-CIMS) has a wider range of sensitivity than acetate or  $\text{NO}_3^-$  instruments although each detects a subset of those components that are present at varying sensitivity (Riva et al., 2019). The I-CIMS is efficiently detecting compounds in the IVOC and SVOC range with

modest carbon and oxygen numbers while  $\text{NO}_3^-$ -CIMS is more sensitive towards compounds in the LVOC and ELVOC range with higher carbon and oxygen numbers, such as HOM (Priestley et al., 2021). This suggests that the observed relatively lower contributions of higher molecular weight compounds might be related to the sensitivity of the technique employed here. Nonetheless, considering that previous studies have showed that the contribution of HOM to the SOA mass is minor (Rissanen et al., 2014; Jokinen et al., 2014), and the general agreement between the FIGAERO-CIMS and the TD-AMS might indicate that the I-CIMS might be able to capture the bulk SOA composition.

Given the above, the effect of fragmentation is more pronounced in the  $\alpha$ -pinene system, in agreement with previous findings (Eddingsaas et al., 2012b; Eddingsaas et al., 2012a) potentially explaining the higher fraction of more volatile products with  $C^* \geq 100 \mu\text{g m}^{-3}$  compared to the other systems (Fig. 5). This is also consistent with the increased fraction of products desorbing at relatively lower temperatures (Fig. 4). On the other hand, the increased number of products in the  $nC > 10$  region compared to the other systems, shows that gaseous and/or condensed phase oligomerization/dimerisation reactions are also taking place during the  $\alpha$ -pinene SOA formation (Lopez-Hilfiker et al., 2015). Their relatively low contribution to the total FIGAERO-CIMS signal might indicate that they will make little contribution to the mass of the  $C^* \leq 1 \mu\text{g m}^{-3}$  volatility bin considering that the  $\alpha$ -pinene SOA mass is lower in these bins than in other systems (Fig. 5). These dimers probably are not responsible for the majority of the LVOCs in the SOA formed in the corresponding experiments.

In *o*-cresol experiments, the OH addition via hydrogen abstraction pathway which mainly leads to low volatility ring-retaining products (Olariu et al., 2002; Schwantes et al., 2017), contributes substantially to the total FIGAERO-CIMS signal, considering that the largest fraction of its signal is found for products with 7 or more carbon numbers (Fig. 1). Additionally, the elevated O:C in the *o*-cresol system and its stronger O:C enhancement ratio compared to the other systems (Fig. 2 and Fig. 6) is consistent with its overall low volatility (Fig. 4). The oxygen addition pathway, leading to bicyclic intermediates that subsequently decompose to smaller multifunctional compounds (Schwantes et al., 2017), may be also responsible for the presence of the smaller molecules. This latter pathway can have complex effects in both directions for the resultant SOA volatility.

The SOA formed in the mixed system may comprise i) products of either precursor, ii) cross-products formed in the particle or gas phase (with sufficiently low volatility to partition to the particle phase) and iii) individual precursor products resulting from the alteration of the oxidation mechanism of each precursor due to the interactions. It should be noted that our formula separation technique is unable to identify any new individual

490 precursor products from (iii) that are not listed in the MCM (see 2.4.) and would classify them as products unique  
to the mixture. Products unique to the mixture with  $nC=5-10$  represent the largest fraction of the corresponding  
total signal (Fig. S2). The formation of these products, as well as those with  $nC>10$ , could be both attributed to  
processes described above for each individual VOC and/or interactions between the resultant products (such as  
 $RO_2+R'O_2$  termination reactions, with R and R' from *o*-cresol and  $\alpha$ -pinene respectively). The volatility of these  
495 products, as inferred from their maximum desorption temperatures, is on average, lower than that of the respective  
products of the bulk with the same carbon numbers (i.e., individual precursor's plus common products in the  
mixture; Fig. 7). This decrease in volatility of the products unique to the mixture may be partly attributed to  
increased O:C content of those products compared to those of the bulk (Fig. S4). This suggests that the mixing of  
 $\alpha$ -pinene and *o*-cresol results in unique products that are more oxygenated than the respective products of the bulk,  
500 and consequently have lower volatilities.

The unique products to the mixture that have lower carbon numbers ( $nC<5$ ) were likely formed from small organic  
radical termination reactions deriving from each individual precursor and/or from the fragmentation/dissociation  
of larger cross- products and/or from the thermal decomposition of products in the FIGAERO (Stark et al., 2017).  
The vast majority of those products were found to be common between all experiments and contribute a higher  
505 fraction of the signal in the gas compared to the particle phase, making thermal decomposition unlikely to be the  
source of the largest fraction of these products. These products exhibit high O:C, consistent with their high  
desorption temperature and lower volatility (Fig. 7 and Fig. S4). Comparing their characteristics to the respective  
products of the bulk, similar conclusions can be drawn as for the corresponding larger products ( $nC\geq 5$ ), i.e., the  
unique to the mix products with  $nC<5$  appear to have higher O:C and desorption temperatures than those of the  
510 bulk. It should be noted that these products contribute minimally to the total signal of the particle phase (Fig. 1),  
thereby their effect of the overall SOA volatility is expected to be correspondingly low. Nonetheless, this  
demonstrates that the unique to the mix products are, on average, less volatile than the individual products of both  
precursors and those that were common that are found in the mixed VOC system, across the whole range of carbon  
numbers.

515 The retrieved SOA particle volatility from the mixed VOC system showed an increased content of lower volatility  
components compared to the  $\alpha$ -pinene system while being comparable with that from the *o*-cresol system. The  
compositional information obtained suggest significant signal contributions from the unique products of *o*-cresol  
in the mixed system, which are of lower volatility compared to  $\alpha$ -pinene's (Figs. 4-6). Furthermore, it is apparent

that the higher carbon number products that were formed in the  $\alpha$ -pinene system and are expected to have lower volatilities (Kroll and Seinfeld, 2008), are absent in the mixed VOC experiment (Fig. 1), suggesting that molecular interactions can also increase the volatility in mixtures (McFiggans et al., 2019). Meanwhile, the products that were only formed in the mixture are also contributing considerably to the total signal and are lowering the overall volatility (Fig. 7). This shows that upon mixing SOA precursors, the underlying molecular interactions can increase or decrease the SOA particle volatility in mixtures and the resultant particle volatility in mixed systems cannot be readily deduced.

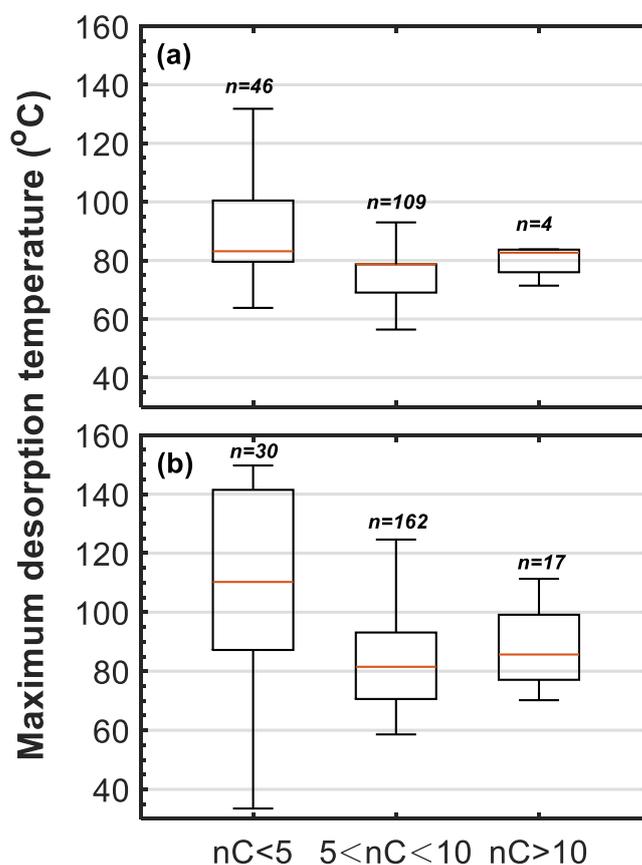

Figure 7: Boxplots of the maximum desorption temperatures of (a) the bulk products found in the mixed VOC system (i.e., unique products of  $\alpha$ -pinene, *o*-cresol and common) and (b) products that were found unique in the mixed VOC system, weighted to their contribution to the total signal. Red lines represent the median values, each boxes' upper and lower limits represent the 75<sup>th</sup> and 25<sup>th</sup> percentile, respectively, while the errorbars represent the minimum and maximum values.

## 4.2. Interpretation of FIGAERO-CIMS data

As has been shown here and elsewhere (e.g., Lopez-Hilfiker et al., 2016b; D'Ambro et al., 2017), linkages between  
535 the chemical composition and the particle volatility are possible using the FIGAERO-CIMS, while the individual  
product's volatility can be inferred qualitatively (Wang and Hildebrandt Ruiz, 2018) or quantitatively within an  
uncertainty (e.g., Bannan et al., 2019). Here we show for the first time that the technique can be used to distinguish  
the SOA products deriving from the oxidation of multiple precursors in environmental chambers, while being able  
to assess the potential role of product interactions in altering the SOA particle volatility. However, some limitations  
540 impact on results derived from the technique, such as the thermal desorption of the SOA collected in filters and the  
differential instrument sensitivity toward classes of compounds (Huang et al., 2018; Stark et al., 2017; Wang and  
Hildebrandt Ruiz, 2018; Lopez-Hilfiker et al., 2014).

We observed that the dominant *o*-cresol derived product,  $C_7H_7NO_4$ , exhibited different maximum desorption  
temperatures in the *o*-cresol single precursor experiments and the mixed VOC experiments (72.2 vs. 61.1 °C,  
545 respectively). This difference may result from differences in filter loadings between the experiments which were  
recently shown to affect the desorption profiles of the products due to matrix and/or saturation effects (Wang and  
Hildebrandt Ruiz, 2018; Ylisirniö et al., 2021). Expanding this to various characteristic products, we observe that  
their desorption profiles can have either a positive or negative relationship to the filter loading (Fig. S5). As also  
discussed in Schobesberger et al. (2018), a number of processes such as the thermal decomposition, isomerization,  
550 sample distribution in the filter and the uniformity of the heating may play a crucial role in the evaporation kinetics  
and parameters such as the enthalpy of vaporisation may have a determinant role in the shape of the thermograms.  
Consequently, comparing the desorption profiles of the products across systems with varying amounts of SOA  
formed and consequently filter loadings can be considered ambiguous. Here we qualitatively aim to establish the  
consistency of the overall shape of the sum thermograms with the volatility derived from independent quantitative  
555 techniques for the bulk of the SOA, but the quantitative retrieval of volatility distributions from the desorption  
temperature data is quite uncertain. A qualitative comparison of the shape of the maximum desorption temperature  
distributions may therefore be acceptable for the estimation of the bulk SOA particle volatility even when it is not  
possible to control filter loading.

Another characteristic of the CIMS technique is the varying instrument sensitivity toward different classes of  
560 compounds (Iyer et al., 2016; Lee et al., 2014). Recently, Hammes et al. (2019) showed that the sum of the 10

highest product signals accounted for ~50% of the acetate FIGAERO-CIMS signal in limonene photo-oxidation experiments. Here, in all the systems examined we also find that >45% of the total signal of the FIGAERO-CIMS can be attributed to the top 10 products (Fig. S6). Particularly, in the *o*-cresol experiments ~50% and ~40% of the total signal in the gas and particle phase respectively can be attributed to a single product ( $C_7H_8O_2$  and  $C_7H_7NO_4$ ,  
565 respectively; Fig. S6). These results may indicate either that the aerosol composition is dominated by those few products or that the technique is overly sensitive to these compounds or a combination of both explanations.

The sum thermograms (defined as the sum of the individual ion thermograms), have been widely used to infer the volatility of the aerosols (e.g., Lopez-Hilfiker et al., 2015; D'Ambro et al., 2017; Huang et al., 2018; Lopez-Hilfiker et al., 2016b). However, a large fraction of the total signal is due to as few as 10 products (out of hundreds or  
570 thousands typically found in the mass spectra) which in turn will largely define the shape of the sum thermogram (Fig. S7). Similarly, a number of studies have used various methods for estimating the saturation concentrations of the ions from CIMS data and expressed those results in the logarithmically spaced volatility bins as a function of their contribution to the total signal of the CIMS (e.g., Huang et al., 2019; Ylisirniö et al., 2020; Mohr et al., 2019; Tröstl et al., 2016). Conceivably, care should be taken in such an approach, since the major products will  
575 have a determinant role at the resulting volatility distributions and may be related to the instrument used and the characteristics of each experiment, in turn resulting in a specific range of detected products.

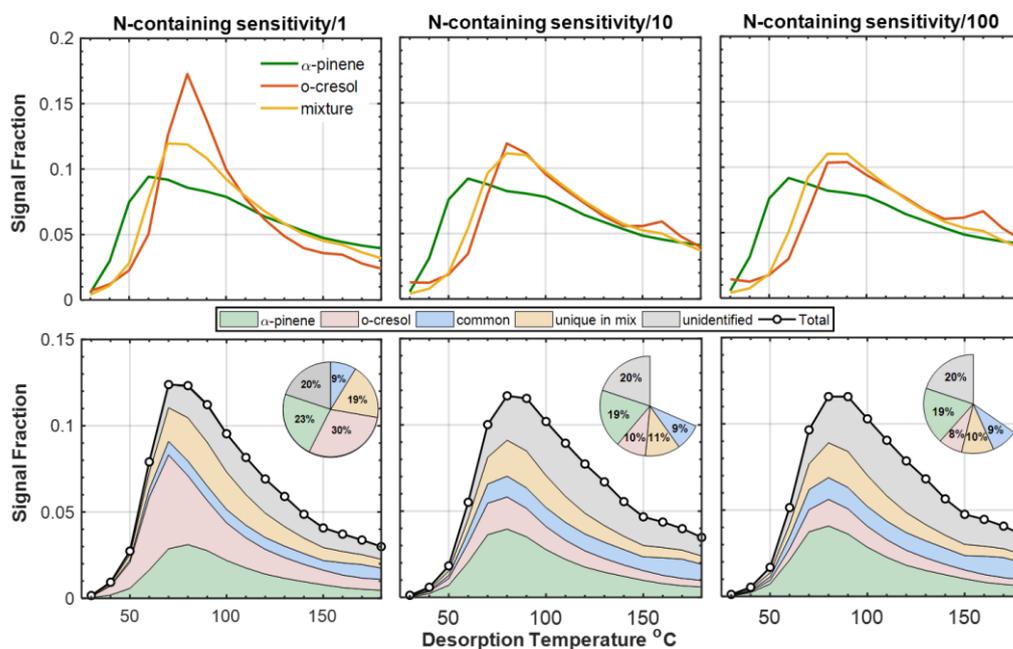

Figure 3 shows that the sum thermogram of the *o*-cresol experiment is narrow owing to the dominant product accounting for 40% of the total particle phase signal. Meanwhile, the resultant volatility distributions from the TD measurements suggest wider volatility distribution in this system (Fig. 5). Figure 1 suggests that a large fraction of  
580 the total particle phase signal of the FIGAERO-CIMS in the mixed VOC system is ostensibly related to *o*-cresol products (33%) with the signal from two products dominating this fraction ( $C_7H_7NO_4$  =26% and  $C_8H_{11}NO_3$ =3%; Fig. S6). Therefore, caution should be exercised when attributing the contributions of individual precursor products to the mixed precursor products as the expression of FIGAERO-CIMS results in terms of the signal fraction can be misleading. Below we further explore the implications of the instrument sensitivity on our conclusions.

585 It is widely known that the I-CIMS is highly sensitive to polar organic compounds with hydroxyl functional groups (Lee et al., 2014), while previously reported sensitivities resulting from calibrations of the I-CIMS with various compounds showed to be spanning in orders of magnitude difference (Aljawhary et al., 2013). Iyer et al. (2016) using experimental data and performing quantum calculations showed that the nitrogen as an element, and particularly if an  $ONO_2$  group is added to a compound containing a hydroxyl group, had a substantial effect on the

590 I-CIMS sensitivity. Particularly, the predicted and measured sensitivities of N-containing products investigated by  
Iyer et al. (2016) and Lee et al. (2014), respectively, might differ to up to two orders of magnitude compared to  
other compounds containing carboxylic and hydroxyl groups. Considering that *o*-cresol oxidation largely yields  
OH- containing products (Schwantes et al., 2017), in conjunction with the observed particularly high contributions  
of N-containing products to the total signal in all *o*-cresol-containing experiments (Fig. S8), it is likely that  
595 differential sensitivity plays a role in this apparent dominance.

In order to assess this while taking account the above, we reduced the calibration factor of all N-containing products  
by a factor of 10 and 100 and we observed the changes in the sum thermograms, shown on Figure 8. Interestingly,  
the overall shape of the distribution is not substantially changing in either case, while we did not observe any  
substantial differences between the two sensitivity scenarios. Considering the broad agreement between the  
600 volatility distributions derived from TD measurements with the shape of the sum thermograms derived from the  
FIGAERO, these results further suggest that regardless of the instrument sensitivity the latter can be used to  
qualitatively assess the particle volatility.

605 **Figure 8: FIGAERO-CIMS sum thermograms for three characteristic experiments in each system (Exp. No. 2, 5 and 10; Table 1) while varying the signal of the N-containing products (top panels) and corresponding sum thermogram from the mixed VOC experiment where the contributions of products that were associated**

with either precursor, the common products, those that were found unique in the mixture, in addition the unidentified fractions are shown as areas (bottom panels). Inset pie charts are showing the contribution of each product class to the total signal. The missing fraction appearing the sensitivity scenarios is attributed to the fraction of the total signal that was reduced.

It should be noted however, that the sensitivity effects could affect the linkage between the chemical composition and particle volatility. By altering the signal of N-containing products, we observe changes in the product distribution of the mixed VOC system. More specifically, the signal contribution of the unique *o*-cresol products to the mixture reduces from 30 to 10%, assuming a reduction in the sensitivity of N-containing products by a factor of ten and then to 8% for a reduction of a factor of a hundred. Conversely, the respective reduction is much lower for the  $\alpha$ -pinene products, which account 23% of the total signal assuming uniform sensitivity and 19% for both sensitivity scenarios. The signal fraction of the unique to the mix products is reduced roughly by half in both sensitivity scenarios compared to that assuming uniform sensitivity (19 to ~10%, respectively). The level of reduction is associated well with the fraction of the signal corresponding to products with CHON elemental formula in each system, where *o*-cresol showed the highest values, followed by the mixed VOC and the  $\alpha$ -pinene (71, 35 and 19%, respectively; Fig. S8a). Interestingly however, each system exhibited comparable number fraction of products containing C, H, O and N atoms (Fig. S8b), suggesting either that the nitrogen-containing oxidation products of *o*-cresol actually contribute substantially to the SOA mass and/or that there is a significant differential sensitivity of the instrument towards molecules containing C, H, O and N. Because of the lack of information regarding the I-CIMS sensitivity towards aromatic and nitrogen-containing compounds, this cannot be directly investigated here but should be an area for future research.

However, further consideration of the increased SOA formation potential of  $\alpha$ -pinene and the corresponding modest SOA yield of *o*-cresol (Fig. S9), might suggest that the domination of *o*-cresol products in the particle phase is unlikely. Therefore taking into account:

- i) our observations in all the sensitivity scenarios examined showed that the unique to the mix products contribute considerably to the total signal (Fig. 1 and Fig. 8) and are of lower volatility than the average (Fig. 7);
- ii) in all sensitivity scenarios the products of *o*-cresol, which are of lower volatility (Fig. 3 and Fig.4), also contribute appreciably to the total signal;

635 iii) the products of  $\alpha$ -pinene, whose products are likely contributing substantially to the SOA particle mass (both  
due to the large portion of the total signal and the increased nC; Fig. 1) and are of relatively higher volatility  
(Fig. 3 and Fig.4),

we can argue that the products of the higher yield precursor (i.e.,  $\alpha$ -pinene) may contribute substantially to the  
volatility of the mixture, while the contributions of the *o*-cresol products as well as those resulting from the mixing  
640 of the precursors are lowering the overall volatility.

## 5. Conclusions

Many climate/air quality prediction models express SOA volatility based on single-precursor experiments and  
neglecting the potential interactions of the oxidation pathways of the different precursors leading to the SOA  
645 formation (Yahya et al., 2017;Tsimpidi et al., 2018). However, more and more studies are showing that these  
results, obtained under simplified conditions and using single VOC precursor systems, might not represent  
accurately the ambient atmosphere in which hundreds of VOC are oxidized together (McFiggans et al.,  
2019;Shilling et al., 2019). Here, we investigate the SOA composition and volatility upon mixing characteristic  
anthropogenic and biogenic VOC precursors, using independent techniques.

650 Previously, Emanuelsson et al. (2013) observed an increase in the volume fraction remaining on SOA formed from  
the mixing various anthropogenic and biogenic precursors reacting sequentially. Here, we find the SOA particle  
volatility upon simultaneously mixing anthropogenic and biogenic precursors under initially iso-reactive mixing  
ratios appeared to be between the volatilities obtained in single precursor experiments. This is due to multiple  
processes taking place with some of them increasing the volatility, such as the scavenging of higher molecular  
655 weight products, or decrease the volatility, such as the formation of new, more oxygenated and less volatile  
products.

There is some ambiguity in interpreting the FIGAERO-CIMS data owing to the different filter loadings as well as  
the a priori selectivity of the instrument towards certain products, defined by the instrument setup (Lee et al.,  
2014;Riva et al., 2019). In order to overcome these limitations, we have explored the impact of various scenarios  
660 on the reported results and we show that the shape of the sum thermograms can be an acceptable qualitative measure  
of the SOA particle volatility. This was further confirmed by its broad agreement with the SOA particle volatility  
retrieved from an independent quantitative technique.

The results presented here call for further studies exploring the mechanisms that are driving these observations. Furthermore, the formation of new products in mixtures as well as the differential contribution of each precursor's product to the particle phase implies a range of potential changes on the SOA properties and thereby their subsequent interactions with water vapour and other particles and gases (Champion et al., 2019; Riipinen et al., 2015; Pankow et al., 2015). Further, the potential effect of mixing anthropogenic and biogenic products might significantly affect the predicted SOA radiative forcing (Gordon et al., 2016; Kelly et al., 2018).

### Data availability

All the data used in this work can be accessed on the open dataset of the EUROCHAMP programme (<https://data.eurochamp.org/data-access/chamber-experiments/>).

### Acknowledgements

The Manchester Aerosol Chamber received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement no. 730997, which supports the EUROCHAMP2020 research programme. AV acknowledges the Presidents Doctoral Scholarship from the University of Manchester and the support from the Natural Environment Research Council (NERC) EAO Doctoral Training Partnership. MRA acknowledges funding support from the Natural Environment Research Council (NERC) through the UK National Centre for Atmospheric Science (NCAS). Instrumentational support was funded through the NERC Atmospheric Measurement and Observational Facility (AMOF).

### Competing interests

The authors declare that they have no conflict of interest.

### Author contributions

GM, MRA, AV, YW and YS conceived the study. AV, YW, YS and MD conducted the experiments. SNP provided the volatility retrieval algorithm. TJB provided on-site help deploying the FIGAERO-CIMS and discussing the data analysis procedure. AV conducted the data analysis and wrote the manuscript with inputs from all co-authors.
