23
24 **Abstract** In the present work, we conducted experiments of secondary organic aerosol (SOA) formation from urban cooking
25 and vehicular sources to characterize the mass spectral features of primary organic aerosol (POA) and SOA using an high-
26 resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS). Our results showed that the cooking styles have a greater
27 impact on aged COA mass spectra than oxidation conditions. However, the oxidation conditions affect the aged HOA spectra
28 more significantly than vehicle operating conditions. In our study, we use mass spectra similarity analysis and positive matrix
29 factorization (PMF) analysis to establish the POA and SOA mass spectra of these two sources. These mass spectra are used

30 as source constraints in a multilinear engine (ME-2) model to apportion the OA sources in the atmosphere. Comparing with
 31 the traditional ambient PMF results, the improved ME-2 model can better quantify the contribution of POA and SOA from
 32 cooking and vehicular sources. Our work, for the first time, establishes the vehicle and cooking SOA source profiles, and can
 33 be further used in the OA source apportionment in the ambient atmosphere.

36 1. Introduction

37 Organic aerosol (OA) is an important component of fine particulate matter and has significant
 38 environmental and health effects, especially in urban areas (Guo et al., 2012; Guo et al., 2014; Ying et al.,
 39 2020). Currently, real-time measurements of OA based on the aerosol mass spectrometer (AMS) has become
 40 an effective way to explore OA characteristics in the field campaigns and laboratory studies (Canagaratna et
 41 al., 2007; Ge et al., 2017; Hu et al., 2016a; Huang et al., 2011; Kim et al., 2017; Li et al., 2017; Sun et al.,
 42 2016; Zhang et al., 2011). Applying positive matrix factorization (PMF) and a multilinear engine (ME-2)
 43 (Paatero, 1999) to analyze the high-resolution mass spectrometry fragments, OA can be further identified as
 44 primary organic aerosol (POA) and secondary organic aerosol (SOA). POA includes a kind of hydrocarbon-
 45 like OA, (HOA), cooking (COA), and biomass burning (BBOA), which SOA includes low oxygenated OA
 46 (LO-OOA) and more oxygenated OA (MO-OOA)(Canonaco et al., 2013; Elser et al., 2016; Qin et al., 2017;
 47 Zhang et al., 2017a; Zhou et al., 2018). Many previous studies have been found that HOA is mainly associated
 48 with vehicle-related emissions in the urban atmosphere (Hu et al., 2017; Xu et al., 2016; Zhang et al., 2017a).
 49 Hereinafter, HOA will be referred to as the abbreviation for organic aerosol emitted by urban vehicles. As
 50 lifestyle sources in urban, cooking and vehicular sources emissions, that is COA and HOA mostly determine

51 ambient OA loadings. For example, primary cooking OA (COA) and vehicle exhaust OA (HOA) accounted
52 for 10-35 % and 6-26% of OA, respectively, in urban areas in China (He et al., 2011; Hu et al., 2017; Sun et
53 al., 2010; Sun et al., 2014; Sun et al., 2018; Wang et al., 2016; Xu et al., 2016; Zhang et al., 2014).

54 Besides the contribution to POA, many studies have found that cooking and vehicular sources may also
55 emit a large number of volatile organic compounds (VOCs) (Gentner et al., 2009; Katragadda et al., 2010;
56 Klein et al., 2016), semi-volatile organic compounds (SVOCs), and intermediate volatile organic compounds
57 (IVOCs) ($\geq C_{13}$ n-alkanes and fatty acids) (Louvaris et al., 2017; Schauer et al., 2002; Tang et al., 2021),
58 which may also play important roles in SOA formation (Wang et al., 2021; Yu et al., 2021). However, based
59 on collocated AMS measurements and factor analysis results, the SOA formed by vehicle and cooking sources
60 cannot be effectively resolved from the total SOA due to the lack of secondary mass spectral profiles. The
61 POA mass spectral profiles based on AMS including HOA (Collier et al., 2015), BBOA (Alfarra et al., 2007;
62 He et al., 2010; Xu et al., 2020), and COA (He et al., 2010; Liu et al., 2017; Mohr et al., 2012; Xu et al., 2020)
63 have been fully explored in laboratory studies and applied as constraint factors into the ME-2 model in the
64 ambient air. Some studies have made it possible to quantify biogenic secondary aerosol products of a single
65 precursor, such as isoprene oxidation products (IEPOX) (Budisulistiorini et al., 2013; Hu et al., 2016b), and
66 have been extended to the urban atmosphere to obtain an IEPOX-SOA factor via PMF analysis of OA spectra
67 (Zhang et al., 2017b). Although several studies explored the mass spectral characteristics of SOA from cooking
68 and vehicular sources, i.e., heated cooking oils, gasoline motors, and diesel engines (Kaltsonoudis et al., 2017;
69 Kroll et al., 2012; Liu et al., 2018; Presto et al., 2014), the spectral profiles of cooking SOA under actual
70 cooking conditions and vehicle SOA under different emission conditions are still uncertain. Besides, to date,
71 studies that used ME-2 for a better anthropogenic SOA source apportionment by inputting their SOA spectra
72 as constraints remain scarce. Therefore, the mass spectra of SOA from abundant cooking and vehicular sources
73 are urgent to characterize for conducting to acquire a better source apportionment of SOA.

74 In this study, cooking and vehicle experiments were carried out to investigate the variation in POA and
75 SOA spectra profiles emitted from vehicle emissions under different running conditions, and Chinese cooking
76 emissions under different cooking styles using high-resolution time-of-flight AMS (HR-ToF-AMS). The mass
77 spectral characterizations of POA and SOA from cooking and vehicle emissions were intercompared, and their
78 changes in some indicated ionic fragments were elucidated. Besides, we verified the mass spectral profiles by
79 applying POA and SOA profiles to ME-2 for source apportionment of OA in the winter observation with
80 various primary emissions and the summer observation with high oxidation conditions.

81 2. Materials and Methods

82 2.1 Simulation of POA emission and SOA formation from cooking and vehicular sources.

83 For cooking, we prepared four dishes including deep-frying chicken, shallow-frying tofu, stir-frying
84 cabbage, and Kung Pao chicken. The total cooking time for each experiment ranged from 40 to 66 min, which
85 was almost related to the features of each dish (**Table S1**). Each dish was continuously carried out 8 times in
86 parallel during the cooking process until the closed kitchen was full of fumes. The fumes produced by cooking
87 were introduced through the pipeline from the kitchen into the Gothenburg Potential Aerosol Mass (Go: PAM)
88 reactor (Li et al., 2019) in the laboratory after being diluted 8 times by a Dekati Dilutor (e-Diluter, Dekati Ltd.,
89 Finland). Heat insulation cotton was wrapped around the sampling pipelines to prevent fumes from condensing
90 on the wall of the pipe. We considered the emissions sampled after Go: PAM without OH radical as primary
91 emissions, and those monitoring after Go: PAM with given OH radicals as secondary formation. The sampling
92 time ranged from 58 to 90 min. ~~Each sampling was in parallel three times. The relative standard deviations~~
93 ~~were small, which were under 10% in most cases.~~ In addition, the background blank groups and the dilution
94 gas blank groups were separately completed using boiling water and dilution gas, according to the same steps
95 as experimental groups. More information on the experimental setup of cooking simulations has been given
96 in (Zhang et al., 2020).

97 For vehicle, experiments were performed by using a Gasoline direct engine (GDI) with a commercial
98 China V gasoline fuel (Emission: 998cc; Maximum power: 100KW 6000rpm; Peak torque: 205Nm 2000-
99 3000rpm). Vehicle operating under real-life conditions were dynamic rotating speed-torque combination. For
100 example, the combination of 1500 rpm rotating speed and 16Nm torque; ~~and 2000rpm;~~ rotating speed and
101 16Nm torque for the engine in this study reflect the realistic vehicle speed of 20km/h and 40km/h, respectively.
102 Five running conditions covering different speeds and torques, including 1500rpm_16Nm, 1750rpm_16Nm,
103 2000rpm_16Nm, 2000rpm_32Nm, and 2000rpm_40Nm, were used to characterize their POA and SOA mass
104 spectra in this study. Once the engine warmed up, it continued to work under one running condition. After the
105 three-way catalytic system, the exhaust from the engine tailpipe was diluted 30 times by the same dilution
106 system for the cooking experiment. Then the diluted exhaust entered the Go: PAM through the stainless pipe
107 wrapped by heat insulation cotton. For each running condition, five parallel experiments were conducted
108 (**Table S2**). The sampling time ~~with collecting three parallel data groups~~ was about 60 min for each experiment.

109 Go: PAM reactor consists of quartz tube that is 100 cm long and 9.6 cm in diameter, as described in
110 (Watne et al., 2018). The OH radicals in Go: PAM reactor is generated by the photolysis of ozone and the
111 reaction in the presence of water vapor. We adjusted input ozone concentrations ranging from ~0 to ~6.5 ppm
112 and ~0 to ~4.0 ppm to change the OH radicals in the Go: PAM for vehicle and cooking experiments,
113 respectively. The temperature, relative humidity, and the sampling residence time in Go: PAM for vehicle and
114 cooking experiments were documented in the supplement material (**Table S3**).

115 **2.2 Instrumentation and data analysis.**

116 The design drawing on vehicle and cooking experiments is presented in **Figure S1**. Two scanning
117 mobility particle sizers (SMPS; TSI Incorporation, USA) were set at the inlet and outlet of Go: PAM to correct
118 the wall loss (Zhang et al., 2020). The size distribution and number concentration of particles were scanned
119 every 2 (cooking) - 5 min (vehicle) before and after Go: PAM for cooking and vehicle experiment, respectively.

120 The mass concentrations of non-refractory submicron aerosol (NR-PM₁), and high-resolution ions fragments
121 of OA were recorded by HR-ToF-AMS (Aerodyne Research Incorporation, USA), synchronize with SMPS.

122 Before and after the two experiments, the ionization efficiency (IE) of HR-ToF-AMS was calibrated by
123 applying 300 nm mono-dispersed ammonium nitrate particles synchronization with SMPS. The collection
124 efficiency (CE) was obtained from comparing AMS and synchronous SMPS real-time measurement of particle
125 mass concentrations at the outlet of Go: PAM. Besides, the real-time measurements of CO₂ concentrations
126 (Model 410i, Thermo Electron Corporation, USA) were used to correct the influence of CO₂ on OA ion
127 fragments, refer to (Canagaratna et al., 2015). Other gas phase measurements included carbon monoxide (CO,
128 Thermo, Model 48i TL), NO_x (Thermo, Model 42i TL), and SO₂ (Thermo, Model 42i TL).

129 The mass concentration, size distribution, and the ion-specified mass spectra of NR-PM₁ species were
130 analyzed using the HR-ToF-AMS standard data analysis software (SQUIRREL version 1.57 and PIKA version
131 1.16). The elemental compositions (O/C, H/C, N/C, and OM/OC) were estimated by the “improved-ambient”
132 updated method (Canagaratna et al., 2015). The OH exposure and equivalent photochemical age (EPA) were
133 calculated by off-line methods according to SO₂ decay shown in (Zhang et al., 2020), which were validated
134 by a flow reactor exposure estimator using measured concentrations of reactive compounds such as VOCs,
135 CO, and NO_x (Peng et al., 2016). The OH exposure and photochemical age for all conditions in cooking and
136 vehicle experiments were listed in **Table S3**.

137 **2.3 OA source apportionment**

138 The PMF model can describe the variability of a multivariate database as a linear combination of static
139 factor profiles and their corresponding time series (Huang et al., 2020; Wang et al., 2017; Zhu et al., 2018). In
140 this study, we used the Igor-based PMF model with PMF2.exe algorithm (Paatero and Hopke, 2003) and the
141 PMF Evaluation Toolkit version 2.08D (Ulbrich et al., 2009) to split POA and SOA factors from cooking and
142 vehicle aged OA. The PMF model was also used to identify the source of OA for ambient atmosphere during

143 the summer and winter observations of Shanghai, following the procedure presented in the literature (Hu et
144 al., 2016a; Zhang et al., 2011), as described in section 3.3. In contrast to an unconstrained PMF analysis, ME-
145 2 algorithm allows the user to add prior information (e.g., source profiles) into the model to constrain the
146 matrix rotation and separated the mixed solution. In this study, we adopted the toolkit SoFi (Source Finder)
147 with an ~~in~~ a-value approach to perform organic HR-AMS datasets collected in Shanghai. The a-value can vary
148 between 0 and 1, which is the extent to which the output profiles can vary from the model inputs. The a-value
149 test was performed following the technical guidelines presented in (Crippa et al., 2014). The reference mass
150 spectral profiles that constrained in ME-2 analysis were derived from lab-based primary and secondary
151 cooking and vehicular factors of this study. Details of the algorithm could refer to previous studies (Canonaco
152 et al., 2013; Huang et al., 2020; Reyes-Villegas et al., 2016).

153 **2.4 Mass spectra similarity analysis.**

154 In this study, the angle θ was used to evaluate the correlation between the two AMS mass spectra features.

155 The angle θ between the two AMS mass spectra (MSa, MSb) is given by:

$$156 \cos \theta = \frac{MSaMSb}{|MSa||MSb|}$$

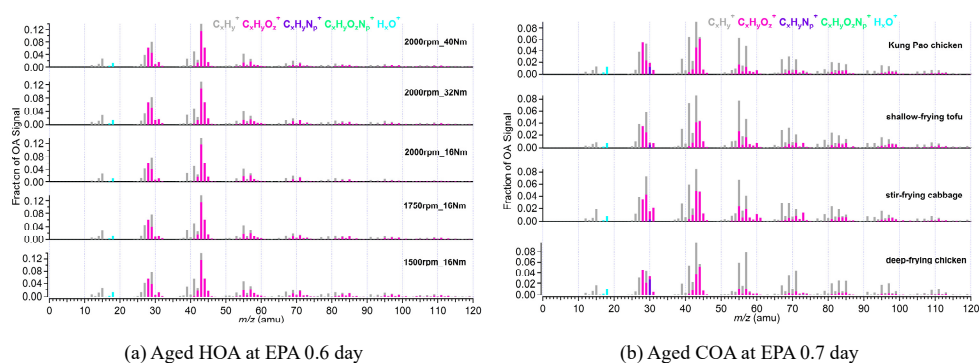

157 The θ angle between two mass spectra is 0-5, 5-10, 10-15, 15-30, and > 30 , which means excellent
158 consistency, good consistency, many similarities, limited similarities, and poor consistency, respectively;
159 (Kaltsonoudis et al., 2017; Kostenidou et al., 2009).

160 **3. Results and Discussion**

161 **3.1 Mass spectra of POA and aged OA from the cooking and vehicular sources.**

162 **Fig.1a** shows the mass spectra of aged HOA under different vehicle running conditions when EPA was
163 0.6 days. The mass spectra of aged HOA emission from different vehicle running conditions under other
164 various oxidation degrees are included in **Fig.S2**. All the aged HOA spectral profiles from different vehicle
165 running conditions showed a similar pattern, and the θ angles among the mass spectra of aged HOA were less

166 than 10° at EPA 0.6 days (**Table 1**), suggesting a little difference between the mass spectra. The mass spectra
 167 of aged HOA at 0.6 days were dominated by the ion series of C_nH^{+2n+1} (m/z 29, 43, 57, 71, 85...) and $C_nH_{2n-1}^+$
 168 (m/z 41, 55, 69, 83...), resulting from less oxidized components such as saturated alkanes, alkenes. As the
 169 highest proportion of ion fragments, m/z 43 and 29 consisted of oxygen-containing ions like CHO^+ and
 170 $C_2H_3O^+$, respectively, whose fractions were much larger than the hydrocarbon-like ion fragments at the same
 171 mass integers. Besides, there were also abundant tracer ion fragments for SOA (m/z 28 and m/z 44).

173
 174
 175 Fig.1. (a) The mass spectra of aged HOA emission from different vehicle running conditions at EPA 0.6 day; (b) The mass spectra of aged COA from four Chinese dishes at EPA 0.7 day. Five running conditions cover different speeds and torques, including 1500rpm_16Nm, 1750rpm_16Nm, 2000rpm_16Nm, 2000rpm_32Nm, and 2000rpm_40Nm. Four dishes include deep-frying chicken, shallow-frying tofu, stir-frying cabbage, and Kung Pao chicken.

176
 177 The mass spectra of aged COA at 0.7 days of EPA are presented in **Fig.1b**. Detailed mass spectra of aged
 178 COA under other various oxidation degrees are included in **Fig.S3**. The similarity of aged COA among
 179 different types of cooking was greater than that of aged HOA among different running conditions when the
 180 EPA was at the same level. Except for the θ angles of deep-frying chicken vs stir-frying cabbage (21°), and
 deep-frying chicken vs shallow-frying tofu (19°), the θ angles among other aged COA at EPA 0.7 day exhibited
 good agreement ($\theta < 15^\circ$) in mass spectra (**Table 1**). The mass spectra of cooking were dominated by the similar
 ion series as those of vehicle, which were mostly m/z 28, m/z 29, m/z 41, m/z 43, m/z 44, m/z 55, m/z 57, m/z

181 67, and m/z 69. However, the major mass spectral differences between cooking and vehicle were the
 182 abundance of m/z 41 and the ratio of oxygen-containing ions to hydrocarbon ions ($C_xH_yO_z^+/C_xH_y^+$). The four
 183 Chinese dishes had prominent peaks at m/z 41, m/z 43, and m/z 55 (generated from $C_3H_5^+$ and $C_3H_7^+$, $C_4H_7^+$)
 184 which was qualitatively consistent with mass spectra of primary COA in other studies (Xu et al., 2020). As
 185 described by (He et al., 2010), the most abundant ion fragments at m/z 41 and m/z 55 from primary Chinese
 186 cooking emissions associated with frying are resulting from unsaturated fatty acids

188 Table 1 The θ angles among the mass spectra of (a) aged HOA at EPA 0.6 day and (b) aged COA at EPA 0.7 day

(a) θ angles	1500rpm_16Nm	1750rpm_16Nm	2000rpm_16Nm	2000rpm_32Nm	2000rpm_40Nm
1500rpm_16Nm	0	3	3	8	4
1750 rpm_16 Nm		0	0.1	5	3
2000 rpm_16 Nm			0	5	3
2000 rpm_32 Nm				0	4
2000 rpm_42-40 Nm					0

(b) θ angles	deep-frying chicken	stir-frying cabbage	shallow-frying tofu	Kung Pao chicken
deep-frying chicken	0	21	19	14
stir-frying cabbage		0	10	13
shallow-frying tofu			0	12
Kung Pao chicken				0

190
 191 **Fig.2a** shows the mass spectra of aged HOA oxidation at different OH exposures under the same vehicle
 192 running condition (2000rpm, 16Nm). The changes in mass spectra of aged HOA under different conditions
 193 are provided in **Fig.S4**. It was worth noting that the source characteristics of vehicle POA were uncertain due
 194 to its low concentration emitted from the engine in this study. **(Table S4)**. A related study has found that the
 195 POA factor from vehicle emissions is similar to the HOA factor derived from environmental datasets (Presto
 196 et al., 2014). Therefore, we used the average HOA spectrum derived from unconstrained PMF analysis based

设置了格式: 字体: 加粗, 非突出显示

设置了格式: 非突出显示

197 on the ambient observations of Shanghai, Beijing, Dezhou, Shenzhen in China as an alternative to the mass
 198 spectrum of vehicle POA, as shown in **Fig.2a** and **Fig.S4**. Detail observation information of Shanghai, Dezhou,
 199 and Shenzhen referred to (Zhu et al., 2021a). The observations in Beijing have been given in (Hu et al., 2017).
 200 The HOA spectrum was similar to that reported in (Ng et al., 2011), which has been widely used as traffic
 201 emission profiles. As the oxidation degree increased, the ion fragments varied similarly with hydrocarbon-like
 202 ion fragments decreasing. The mass spectra at 2.9 days and 4.1 days had very similar patterns with the most
 203 abundant signals at m/z 28 and 44, respectively (**Fig.2** and **Fig.S4**), which showed good consistency with the
 204 mass spectra of MO-OOA resolved from ambient datasets ($\theta = 14^\circ$; compared with MO-OOA obtained during
 205 the spring observations in (Ng et al., 2011; Zhu et al., 2021b). When EPA was 1.7 days, there were different
 206 mass spectra patterns, with dominant signals at m/z 28 and m/z 44, yet contained a large signal at m/z 43,
 207 many similarities with the spectra of the ambient LO-OOA (**Fig.2** and **Fig.S4**) (Hu et al., 2017; Zhu et al.,
 208 2021b). Oxidation degrees greatly affected the similarity of mass spectra between POA and those of aged
 209 HOA. The mass spectra profile of HOA_ambient displayed poor agreement ($\theta > 30^\circ$) with all aged HOA
 210 spectra profiles (**Tables S6S7**). Besides, the mass spectra under the low oxidation degree (EPA was 0.6 day)
 211 was also poorly correlated with those mass spectra under the high oxidation degree (EPA were 2.9 and 4.1
 212 days) (**Table S6S7**).

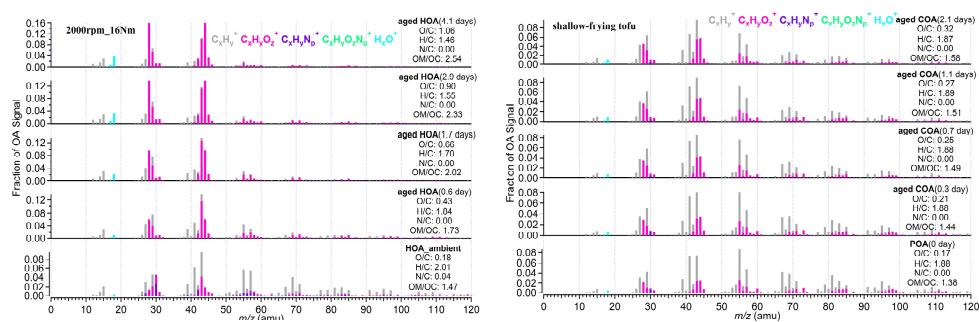

Fig.2. (a) The mass spectra of HOA and aged HOA oxidation under four different OH exposure at the same running

带格式的: 缩进: 首行缩进: 0 字符

condition (2000rpm, 16Nm). (b) The mass spectra of primary COA and aged COA oxidation of different OH exposure for shallow-frying tofu. The EPA was obtained from off-line methods according to SO₂ decay shown in Table S3. The elemental compositions were estimated by the “improved-ambient” updated method (Canagaratna et al., 2015).

214

215 The mass spectra of primary COA and aged COA showed great inter-correlations ($\theta < 15^\circ$), which were
216 smaller than that of vehicle OA (Table S7S8). The spectra of aged COA derived herein displayed good
217 consistency with those from cooking oils (Liu et al., 2018) (Fig.2b and Fig.S5). It should be noted that the
218 fractions of m/z 28 and m/z 44 signals in aged COA were lower than those of aged HOA at the similar EPA.
219 In addition, the aged COA had more hydrocarbon-like ions at the same mass integers than aged HOA.

220 All the above results imply that oxidation condition drives the variabilities in mass spectra of the vehicle
221 OA. In contrast, cooking styles instead of oxidation conditions significantly affected the mass spectra of
222 cooking OA. Here we concluded some possible explanations for these results. On one hand, under the same
223 oxidation conditions and different emission conditions, the similarity among the mass spectra of vehicles was
224 larger than that of cooking, which may be related to their precursors. Some studies have shown that the species
225 and the proportion of gaseous organic matter emitted by different dishes are quite different (Wang et al., 2018).
226 As described in the literature, alkanes and oxygenated volatile organic compounds (O-VOCs) contributed to
227 over 97% of the total VOCs for fried food, and O-VOCs were the dominant contributors for Sichuan and
228 Hunan cuisine where stir-frying is common (Wang et al., 2018). Different gaseous precursors cause
229 distinctions in the particle phase SOA formation, which is reflected in the variations of AMS ion fragments
230 between four dishes in our study. Compared to cooking, the precursors from vehicles are mainly hydrocarbons,
231 and the difference in emissions under different running conditions is inapparent (Robinson et al., 2007). On
232 the other hand, under the same emission conditions and different oxidation conditions, the similarity among
233 the mass spectra of cooking sources is larger than that of vehicle sources, likely due to the oxidation pathway
234 of precursors. As mentioned above, O-VOCs are important precursors of cooking sources, and their oxidation
235 mechanisms are mostly alcohol/peroxide substitution process. This conclusion was proved by a Van Krevelen

236 diagram, showing that the cooking data gather around the slope of approximately -0.1 (Zhang et al., 2020), in
237 agreement with that of heated oils OA (Liu et al., 2018). However, for vehicles, with the increase of oxidation
238 degrees, the reaction pathways of hydrocarbon precursors varied diversely. In Van Krevelen space, the vehicle
239 data fell along a line with a slope of -0.5 (Fig.S6), indicating oxidation processes involving the addition of
240 both carboxylic acid and alcohol or peroxide functional groups without fragmentation and/or the addition of
241 carboxylic acid functional groups with fragmentation.

242 3.2 Identification of the cooking and vehicular sources SOA mass spectra.

243 Although the f_{44} (proportion of m/z 44 in OA) of aged COA raised from 0.03 to 0.08 with oxidation
244 increasing (Fig.2b and Fig.S5), the high abundance of m/z 41, 55, and 57 in aged COA mass spectra for four
245 dishes may be a sign that aged COA identified in this study is a mixture of POA and SOA. PMF analysis was
246 performed on the high-resolution mass spectra to split SOA and POA factors from ~~integrated primary COA~~
247 ~~and~~ aged COA under each dish. Similarly, the same PMF procedure was also applied for vehicle ~~aged~~ datasets
248 for each running condition. The choice of the PMF solution can be found in the supplement material (Fig.S7-
249 S10 and Table ~~S8S9-S9S10~~; taken stir-frying cabbage for cooking, and 2000rpm_32Nm for vehicle as an
250 example).

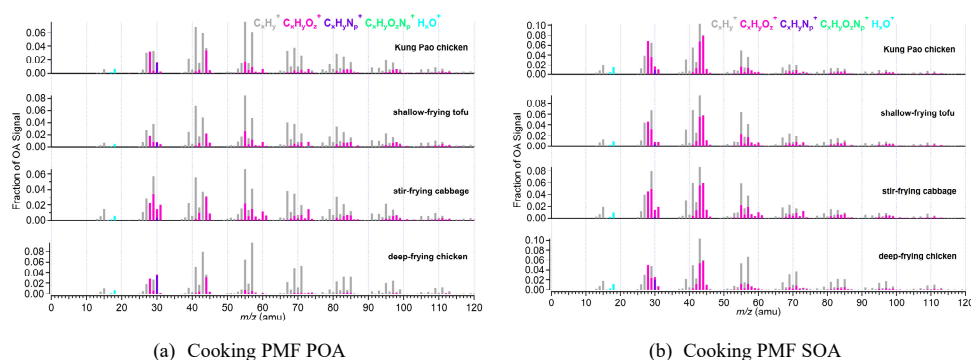

251 Some ions like m/z 41, 55, 57, 43, 28, and 44 are typically used as tracers of OOA, COA, HOA, LO-
252 OOA, and MO-OOA. Fig.3 shows the high-resolution mass spectra of POA and SOA from four Chinese dishes
253 and five vehicle running conditions. The cooking PMF POA of four Chinese dishes all showed obvious
254 hydrocarbon-like signals at m/z 41, 43, 55, ~~and~~ 57, 67, and 69 with ion fragments of $C_3H_5^+$, $C_3H_7^+$, $C_4H_7^+$,
255 $C_4H_9^+$, $C_5H_7^+$, and $C_5H_9^+$, respectively. The fraction of m/z 41 in cooking POA ranged from 0.051 to 0.069
256 The prominent fraction of m/z 43 ($f_{43}=0.068\sim 0.083$), 55 ($f_{55}=0.064\sim 0.084$), 57 ($f_{57}=0.041\sim 0.097$), 67
257 ($f_{67}=0.021\sim 0.40$), 69 ($f_{69}=0.034\sim 0.049$) were observed (Table S10). For mass spectra of cooking PMF SOA,
258 the ~~oxygen oxidation oxidized~~ ion fragments had higher signals than those of hydrocarbon-like ion fragments.

设置了格式: 非上标/下标

259 The dominate signals existed at m/z 28 ($f_{28}=0.045\sim 0.068$), 29 ($f_{29}=0.048\sim 0.080$), 41 ($f_{41}=0.050\sim 0.068$), 43
260 ($f_{43}=0.087\sim 0.103$), 44 ($f_{44}=0.058\sim 0.080$), 55 ($f_{55}=0.050\sim 0.064$) (Table S11).

261 Different from the cooking, two-vehicle PMF SOA factors were derived from aged HOA, rather than
262 integrated primary HOA and aged HOA datasets due to the low primary HOA emission (Table S4), as
263 described in sect. 3.1 due to higher OH exposure. Unfortunately, vehicle PMF POA factor cannot be separated
264 from aged HOA due to higher OH exposure. According to different O/C ratios, they were considered to be
265 low oxidized vehicle SOA (LO-SOA) and more oxidized vehicle SOA (MO-SOA). As indicated in Fig.3 and
266 **Table S12S13**, the prominent m/z 28 (average $f_{28}=0.045$), 41 (average $f_{41}=0.046$), 43 (average $f_{43}=0.158$), 44
267 (average $f_{44}=0.054$), 55 (average $f_{55}=0.039$), 57 (average $f_{57}=0.027$) of vehicle PMF LO-SOA were
268 comparable with those of cooking PMF SOA. The fraction of m/z 43 of vehicle PMF LO-SOA was higher
269 than that in cooking SOA by a factor of 2, which may be caused by the inability to separate vehicle PMF POA
270 factor in the PMF analysis. The abundant m/z 28 and 44 (mainly generated from CO_2^+) are widely used as the
271 ambient MO-OOA markers (Sun et al., 2018; Xu et al., 2017). We observed high fractions of m/z 28
272 ($f_{28}=0.110\sim 0.214$) and m/z 44 ($f_{44}=0.121\sim 0.224$) in vehicle PMF MO-SOA (Table S13) and high O/C ratios
273 (0.88~1.33), which were much higher than those of vehicle PMF LO-SOA (O/C=0.37~0.53) and cooking SOA
274 (O/C=0.29~0.41).

设置了格式: 字体: 加粗

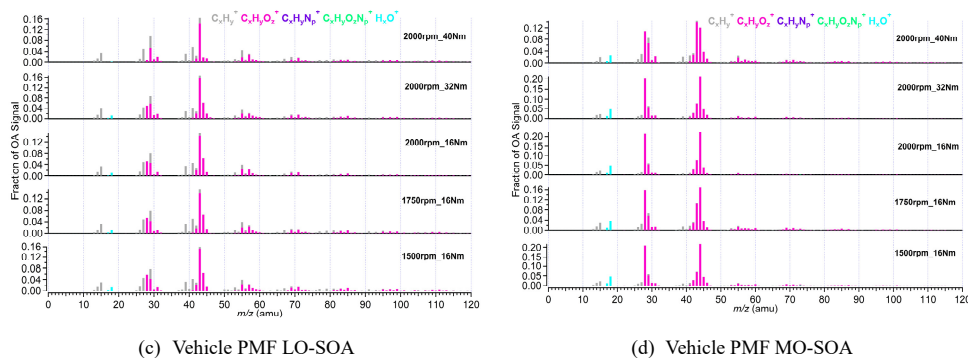

Fig.3. The mass spectra of PMF POA and SOA from vehicle and cooking. PMF analysis was performed on the high-resolution mass spectra to split two factors (cooking POA and SOA) from aged COA and two SOA factors (vehicle LO-SOA and MO-SOA) from aged HOA, respectively.

276
 277 Similarly, for the resolved SOA factors, the correlation of mass spectra among cooking groups under
 278 different cooking methods ($\theta = 8\sim 21^\circ$) was worse than that of vehicle groups (vehicle PMF LO-SOA; $\theta =$
 279 $3\sim 19^\circ$) under different running conditions (**Table S14-S15** and **Table S16-S17**). The mass spectra of the PMF
 280 POA factors for deep-frying chicken exhibited poor agreement with those of stir-frying cabbage, Kung Pao
 281 chicken, and shallow-frying tofu (**Table S15-S16**). In addition, we also found that the θ angles between vehicle
 282 PMF LO-SOA and vehicle PMF MO-SOA under five GDI running conditions were ranged from 36° to 50°
 283 (**Fig.S11**), indicating that the mass spectra profiles of vehicle PMF LO-SOA are poor consistency with those
 284 of vehicle PMF MO-SOA, consistent with the changes in the mass spectra characteristics of vehicles, under
 285 the same emission conditions and different oxidation conditions. Our results suggest that it is necessary to
 286 consider the cooking styles when constraining cooking and atmospheric oxidation conditions when
 287 constraining vehicle factors.

288 3.3 Application of established POA and SOA profile in ambient OA source apportionment.

289 The POA and SOA of the cooking as the primary and secondary spectrum constraints for ME-2 were
 290 obtained by averaging the high-resolution mass spectra datasets of the four dishes, which were identified from

291 aged COA using the PMF model. Similarly, combining different GDI running conditions, the averaged vehicle
 292 LO-SOA and vehicle MO-SOA which were resolved based on aged HOA by using the PMF model were used
 293 as the inputting mass spectra profiles of vehicles for ME-2. The mass spectral profiles for cooking and vehicle
 294 as constraints in the ME-2 model are shown in **Fig.S12**.

295 The θ angles between the mass spectral profiles from urban cooking and vehicular sources and ambient
 296 PMF-resolved factors were calculated and summarized in **Fig.4** and **Table S18S19**. The AMS mass spectra of
 297 ambient factors were obtained and averaged in Shanghai, Dezhou, Beijing, and Shenzhen in China (Hu et al.,
 298 2017; Zhu et al., 2021a). The θ angles among ambient COA, HOA, LO-OOA, and MO-OOA factors and the
 299 cooking POA, SOA, and the vehicle LO-SOA, vehicle MO-SOA were ranged from 18° to 52° (**Fig.4**),
 300 suggesting that the cooking POA, cooking SOA, and the vehicle LO-SOA, vehicle MO-SOA can be used as
 301 source constraints for ME-2 in ambient air.

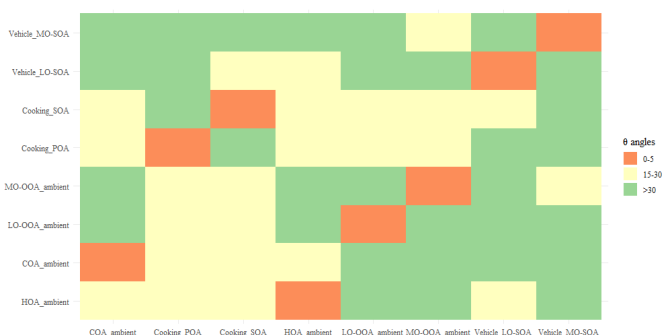

Fig.4. The θ angles between ambient COA, HOA, LO-OOA, and MO-OOA factors and the cooking PMF POA, SOA, and the vehicle LO-SOA, MO-SOA. The θ angle between two mass spectra is 0-5, 5-10, 10-15, 15-30, and > 30 indicates excellent consistency, good consistency, many similarities, limited similarities, and poor consistency, respectively. The ambient COA, HOA, LO-OOA, and MO-OOA factors were averaged the resolved factors which performed on Shanghai, Dezhou, Beijing, and Shenzhen datasets (Hu et al., 2017; Zhu et al., 2021a).

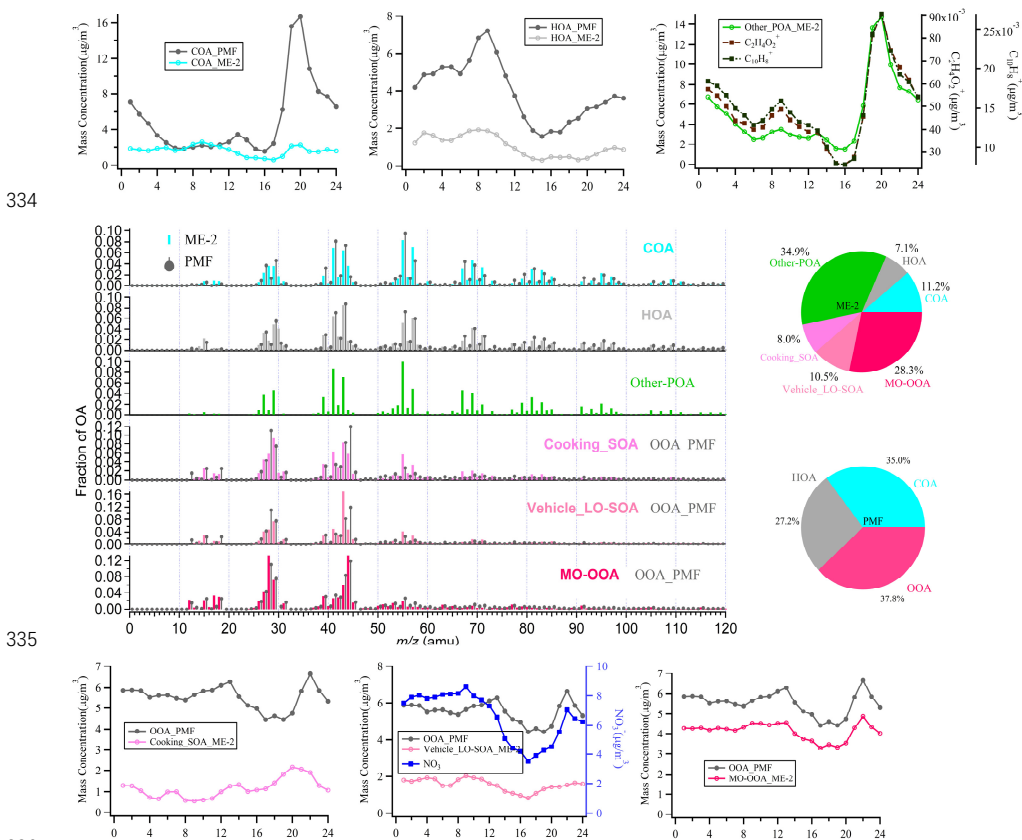

302
 303 ~~Constraining many SOA factors could be over-constraining the ME 2 runs, which leads to factor mixing~~
 304 ~~and reduces the number of factors. In addition, considering~~ Considering the actual oxidation conditions, that
 305 is the concentration of OH radicals, and the lacking vehicle POA due to its low emission (Table S4), and the

设置了格式: 字体: 加粗

306 SOA spectra constraining reasonably, the cooking POA, cooking SOA, vehicle LO-SOA, and ambient HOA
307 (instead of vehicle POA; derived from Beijing, Shenzhen, Dezhou, Shanghai ambient measurements) was
308 finally selected as the input source spectra of ME-2. We further demonstrated the feasibility of input primary
309 and secondary mass spectra for OA source apportionment in two field campaigns at the urban site of Shanghai
310 in summer and winter. The ambient measurements in Shanghai were taken in situ at the same location as ~~(Zhu~~
311 ~~et al., 2021a)~~, i.e., Shanghai Academy of Environmental Sciences (31.10°N,121.25°E), a typical urban site in
312 the Yangtze River Delta region from 23 August to 5 September 2016, and from 28 November 2016 to 12
313 December 2017 with HR-ToF-AMS at 4 min time resolution. For the tracers described below, the mass
314 concentration of chemical compositions e.g., sulfate, nitrate, and ion-speciated fragment were detected by HR-
315 ToF-AMS, as shown in (Zhu et al., 2021b). The detail measurements of black carbon (BC) and nitrogen oxides
316 (NOx) can also be found in Zhu et al., 2021b. In general, the ME-2 source analysis was performed by
317 constraining two primary OA factors (the cooking POA, HOA) and two secondary OA factors (the cooking
318 SOA, the vehicle LO-SOA) with the fixed α -value of 0.1 for HOA, 0.2 for cooking POA, 0.4 for vehicle LO-
319 SOA and cooking SOA based on the same ambient OA datasets of the summer and winter observations in
320 Shanghai. In ME-2 solutions from 1 to 7 factors, we found the solution of 6 factors (i.e., COA, HOA, Other-
321 POA, Cooking SOA, Vehicle LO-SOA) was most interpretable for the wintertime observations. For the 5
322 factors solution, in addition to the constraint four factors, factor 5 appeared to be mixed primary and secondary
323 features. However, Other-POA split into two factors with similar profiles in seven factors solution (**Fig.S13**).
324 Source apportionment on OA datasets by using the unconstrained PMF model was also examined to compare
325 with ME-2 analysis. The choice for the optimal solution for the PMF model was presented in the supporting
326 information (**Fig.S14-S16** and **Table ~~S19S20-S20S21~~**). Ambient PMF-resolved OA factors included POA
327 factors (i.e., HOA, COA), and SOA factors i.e., OOA (oxygenated OA) in the winter observations in Shanghai,
328 on average accounting for 27%, 35%, and 38% of OA mass. OOA resolved by PMF model did not separate

329 into two types of OOA including LO-OOA and MO-OOA. Besides, we observed that HOA and COA profiles
 330 (provided via PMF during the wintertime) contained high signals at the biomass burning tracer ion (m/z 73),
 331 and m/z 91 (PAH-related m/z), indicating that the mixing among HOA, COA, and other POA_{source} emissions
 332 (e.g., BBOA) (Fig.5).

333

337 Fig.5. The comparison of the mass spectra, the diurnal variation, and fraction between ME-2 and PMF resolved factors during
 338 the wintertime in Shanghai. The black lines in the spectra and diurnal pattern are the results of PMF analysis of the actual
 339 atmosphere in Shanghai winter. The others correspond to the ME-2 source analysis results by using two primary OA factors
 340 (the cooking POA, ambient HOA) and two secondary OA factors (the cooking SOA, the vehicle LO-SOA) as constraints
 341 based on the same ambient OA datasets as the PMF model during the winter observations of Shanghai. Note that in the mass
 342 spectra and daily patterns, the OOA_PMF factors which compared with vehicle LO-SOA and Cooking SOA respectively are
 343 the same, rather than the two resolved factors.

365

366

As shown in **Fig.5**, compared with PMF results, the proportions of HOA (7%) and COA (11%) obtained by source apportionment with ME-2 have significantly decreased to the expected value during the winter observation(Huang et al., 2020; Xu et al., 2020). As expected, other POA contributions were identified in the highly polluted season, correlated well with $C_2H_4O_2^+$ and $C_{10}H_8^+$, which are well-known fragments from biomass burning and coal combustion emissions (**Fig.5**, **Fig.S17** and **Table S24S22**) (Alfarra et al., 2007; Duan et al., 2020; Hu et al., 2016a; Lee et al., 2010). The diurnal patterns of HOA PMF were consistent with HOA_ME-2 during the winter observation, presenting low concentration during the daytime and high concentration at nighttime, likely due to the combined influence of boundary layer height and emissions from diesel vehicles during the nighttime. The temporal variation of two HOA factors showed a high correlation with NO_x (Pearson $r > 0.7$), suggesting two HOA factors are associated with vehicle emissions. Some variabilities existed between the diurnal cycle of COA_PMF and COA_ME-2. However, COA_ME-2 correlated better with $C_6H_{10}O^+$ than COA_PMF, which was considered a fragment tracer mainly from cooking emissions (Ge et al., 2012; Hu et al., 2016a; Sun et al., 2011; Xu et al., 2016). For SOA factors, the sum of cooking SOA and vehicle LO-SOA had a high correlation with nitrate (Pearson $r = 0.84$; **Fig.S17** and **Table S24S22**) and fragments of low-oxidizing substances ($C_2H_3O^+$; Pearson $r = 0.95$). In addition, we noticed that the vehicle SOA analyzed by ME-2 exhibited consistency with the diurnal variation of nitrate, especially the reasonable morning peak (~09:00) retained, implying that vehicle SOA is well separated by using ME-2 in winter. MO-OOA resolved via ME-2 was characterized by prominent signal at m/z 28 and m/z 44, consistent with those in OOA identified by using PMF and in other studies (Duan et al., 2020; Kim et al., 2017). Meanwhile, there was a strong correlation between MO-OOA time series and sulfate (Pearson $r = 0.93$), which was representative of regional aging species. Unfortunately, the SOA factor corresponding to other-POA (likely biomass burning OA) has not been resolved. Some studies have been found that OA emitted by biomass

367 burning will be rapidly oxidized in the ambient atmosphere, and the BBOA in the fresh plume is mostly aged
368 OA (Zhou et al., 2017). When the aged biomass burning OA is further oxidized, it is difficult to be identified
369 the biomass burning SOA from mixed within OOA without constraining its SOA factor. Overall, ME-2 source
370 analysis with the input of four source spectra profiles significantly improved the OA source apportionment
371 during the wintertime. In comparing the ME-2 analysis results with only two POA factors constraining to that
372 of the four factors constraining, the diurnal variations of HOA and COA obtained by constraining two primary
373 sources were more consistent with those of the ME-2 constraint four-factor than PMF. However, OOA and
374 POA were weakly separated, and the diurnal patterns of OOA were correlated with the case for the peak of
375 other-POA during the evening (20:00~21:00) (Fig.S18-S19). These phenomena imply that the SOA factor
376 constraint can be more environmentally meaningful factors to a certain extent.

377 For the source apportionment in summer with high oxidation conditions (Fig.S20), the fraction of COA
378 reduced from 21% (PMF result) to 12% (ME-2 result). Moreover, the diurnal patterns of ME-2 SOA factors
379 present more reasonable than PMF SOA factors. For example, the MO-OOA obtained based on ME-2 analysis
380 was in good agreement with the diurnal variation of O_x in summer. The Pearson r between MO-OOA_ME-2
381 and $CO_2^+(m/z\ 44)$, a marker of SOA was 0.95, higher than that of MO-OOA_PMF (0.79), which better reflects
382 the characteristics of the MO-OOA factor in ME-2 (Fig.S21 and Table S22S23). In general, the accurate
383 source apportionment results have significantly indicated that the reliability source profiles of the primary and
384 secondary of cooking and vehicles obtained in our study can be used as constraints for source apportionment
385 of OA with ME-2 in various primary emissions or high oxidation conditions.

386 4. Limitations and future work

387 POA emissions, and SOA formation in Go: PAM reactor from urban cooking and vehicular sources were
388 explored. The aged COA had higher hydrocarbon ions than aged HOA in mass spectra. The spectra profiles
389 of urban cooking and vehicular sources derived from the lab simulation were performed as constraints in ME-

2_model. The OA source apportionment using ME-2 compared with unconstrained PMF based on the HR OA datasets in Shanghai validated the reasonable of the primary and secondary source profiles of cooking and vehicles. It is noted that the vehicle experiments were solely conducted under a single engine with gasoline, and the cooking experiment only related to limited cooking styles. The variations of VOCs in diesel and gasoline vehicle emissions may lead to differences in the SOA characteristics (Wang et al., 2020). The POA and gas-phase precursor emitted from another cooking style - meat charbroiling can also form a large amount of SOA after photochemical oxidation (Kaltsonoudis et al., 2017). More work needs to be done to explore the POA and SOA mass spectrometric characteristics of emissions from vehicles and cooking sources. In addition, SOA mass spectra were split from aged COA and aged HOA by using the PMF model, and therefore provided limited information on dynamic SOA mass spectra; we suggested that further studies control the oxidation conditions to obtain a set of dynamic pure SOA spectral profile. Especially, the absence of primary HOA due to low emissions of engine, and the inability to separate vehicle PMF POA from aged HOA in the PMF analysis were major limitations of this study. In addition to obtaining pure vehicle POA through source experiments, further work can apply ME-2 model for constraining pure SOA profiles from experimental datasets to obtain the vehicle POA profiles. Constraining many SOA factors could be over-constraining the ME-2 runs, which leads to factor mixing and reduces the number of factors. Therefore, SOA source spectra can only be appropriately and reasonably limited in ME-2 model. Besides, measurements of accurate tracers for all factors that resolved by PMF or ME-2 model should be conducted in future work to improve source apportionment verification. For example, we had to combine vehicle LO-SOA and cooking SOA as LO-OOA due to the lack of the measurement tracers for vehicle and cooking SOA factor, and then we analyzed the time series-correlation of LO-OOA with nitrate and other tracer ions. Due to the limitation of Go: PAM, dilution and high concentration of OH radicals without other inorganic aerosol seeds were adopted to measure and simulate atmospheric aging of aerosols. Thus, the possible atmospheric transformations and the reaction pathway are

413 affected. In the future, it is still necessary to take further researches, for instance, use a quasi-atmospheric
 414 aerosol evolution study (QUALITY) chamber (Guo et al., 2020) to study the SOA formation under different
 415 actual oxidation conditions, like high/low NO_x and so forth. Moreover, ambient datasets obtained from
 416 different sites and seasons need to be analyzed to validate the application of POA and SOA profiles of cooking
 417 and vehicles in this study, noting selecting a loose constraint via a value in SOA factors due to their high
 418 variability. Our research found that SOA from the urban cooking and vehicular sources contributed 19% and
 419 35% of OA in the wintertime and summertime of Shanghai, implying the need to develop control measures to
 420 reduce emissions from cooking and vehicular sources in the future.

421

422 **Nomenclature table**

Abbreviations	Description
OA	organic aerosol
POA	primary organic aerosol
SOA	secondary organic aerosol
HOA	hydrocarbon-like organic aerosol; associated with vehicle-related emissions in urban
COA	cooking organic aerosol
LO-OOA	low oxygenated organic aerosol
MO-OOA	more oxygenated organic aerosol
PMF	positive matrix factorization
ME-2	a multilinear engine
HR-ToF-AMS	high-resolution time-of-flight aerosol mass spectrometer
SMPS	scanning mobility particle sizers
Go: PAM	Gothenburg Potential Aerosol Mass reactor
VOCs	volatile organic compounds
SVOCs	semi-volatile organic compounds
IVOCs	intermediate volatile organic compounds
O-VOCs	oxygenated volatile organic compounds
$f_{28, 29, 41, 43, \dots}$	fraction of m/z 28, 29, 41, 43... in total organic aerosol
aged HOA	organic aerosols oxidized by Potential Aerosol Mass reactor in vehicle experiments
aged COA	organic aerosols oxidized by Potential Aerosol Mass reactor in cooking experiments
LO-SOA	low oxidized vehicle secondary organic aerosol
MO-SOA	more oxidized vehicle secondary organic aerosol
