20  
21 **Key points**

- 22 1. The expected concentrations of trifluoroacetic acid (TFA) from the degradation of HFO-  
23 1234yf (CF<sub>3</sub>CF=CH<sub>2</sub>) emitted now and in the future by India, China, and the Middle East  
24 were calculated using GEOS-Chem and WRF-Chem models.  
25 2. We conclude that, with the current knowledge of the effects of TFA on humans and  
26 ecosystems, the projected emissions through 2040 would not be detrimental.  
27 3. We carried out various tests and conclude that the model results are robust.  
28 4. The major uncertainty in the knowledge of the TFA concentrations and their spatial  
29 distributions is due to uncertainties in the future projected emissions.  
30

31 **Abstract**

32 We have investigated trifluoroacetic acid (TFA) formation from emissions of HFO-1234yf, its dry  
33 and wet deposition, and rainwater concentration over India, China, and the Middle East with  
34 GEOS-Chem and WRF-Chem models. We estimated the TFA deposition and rainwater  
35 concentrations between 2020 and 2040 for four previously published HFO-1234yf emission  
36 scenarios to bound the possible levels of TFA. We evaluated the capability of GEOS-Chem to  
37 capture the wet deposition process by comparing calculated sulfate in rainwater with observations.  
38 Our calculated TFA amounts over the U.S., Europe, and China were comparable to those  
39 previously reported when normalized to the same emission. A significant proportion of TFA was  
40 found to be deposited outside the emission regions. The mean and the extremes of TFA rainwater  
41 concentrations calculated for the four emission scenarios from GEOS-Chem and WRF-Chem were  
42 orders of magnitude below the no observable effect concentration. The ecological and human  
43 health impacts now and continued use of HFO-1234yf in India, China, and the Middle East are  
44 estimated to be insignificant based on the current understanding, as summarized by Neale et al.  
45 (2021).

47 **Keywords:** HFO-1234yf, Trifluoroacetic acid, wet and dry deposition, India, China, the Middle  
48 East.

49

50 **1. Introduction**

51 The use of olefinic hydrofluorocarbons (HFCs) as substitutes for HFC-134a (1,1,1,2-  
52 tetrafluoroethane,  $\text{CF}_3\text{CFH}_2$ ) are increasing in both the developed and developing countries  
53 (Velders et al., 2009). HFC-134a is a replacement for chlorofluorocarbons (CFCs) and  
54 hydrochlorofluorocarbons (HCFCs), which were phased out under the Montreal Protocol and its  
55 many amendments and adjustments (WMO/UNEP Quadrennial Ozone Layer Assessment, 2007).  
56 HFC-134a is a potent greenhouse gas with a 100-year global warming potential (GWP) of 1600  
57 (Hodnebrog et al., 2020). HFO-1234yf (2,3,3,3-tetrafluoropropene,  $\text{CF}_3\text{CF}=\text{CH}_2$ ) with a 100-year  
58 GWP of <1 (IPCC report (Myhre et al., 2013)) is a replacement for HFC-134a in automobile air  
59 conditioners (MAC) (Papadimitriou et al., 2008). The atmospheric degradation of HFO-1234yf  
60 leads to trifluoro acetyl fluoride ( $\text{CF}_3\text{C}(\text{O})\text{F}$ ) (Young and Mabury, 2010).  $\text{CF}_3\text{C}(\text{O})\text{F}$  hydrolyzes  
61 rapidly to yield trifluoroacetic acid (TFA,  $\text{CF}_3\text{-C}(\text{O})\text{OH}$ ), which is removed from the atmosphere  
62 by dry and wet deposition (George et al., 1994). The chemical lifetime of HFC-134a (~14 years)  
63 is such that it is reasonably well-mixed globally upon emission into the atmosphere. Therefore, its  
64 degradation and the TFA formed will occur across the globe. Only about 30% of the emitted HFC-  
65 134a leads to TFA (Kotamarthi et al., 1998). Later research (Wallington et al., 1996) shows that  
66 hot  $\text{CF}_3\text{C}(\text{O})\text{H}$  formed in the degradation scheme would reduce the TFA yield from HFC-134a.  
67 This reduction is not explicitly considered here, but we acknowledge that the noted TFA yields  
68 from HFC-134a can be viewed as upper limits. A large fraction of the formed TFA is deposited  
69 into the oceans. The fraction of HFC-134a degraded per year from one year's emission would be  
70 small, leading to small TFA in rainwater concentrations at a given location. However, as HFC-

71 134a accumulates in the atmosphere, more TFA would be produced. HFO-1234yf has a shorter  
72 chemical lifetime of a few (~10) days (Myhre et al., 2013) and its degradation leads almost  
73 exclusively (~100%) to  $\text{CF}_3\text{C}(\text{O})\text{F}$ . Therefore, TFA deposition per year of emission will be higher,  
74 depending on the year, and more localized spatially.

75 Previous studies have focused on TFA formation from emissions of either HFC-134a at  
76 the current or previous levels (Kanakidou et al., 1995; Kotamarthi et al., 1998) or HFO-1234yf  
77 substituted for current levels of HFC-134a usage (Luecken et al., 2010); then, they have mostly  
78 scaled it for scenarios of HFO-1234yf emissions in the future over the continental U.S. and Europe  
79 (Henne et al., 2012; Pappasavva et al., 2009). Some works have distinguished between uses of HFC-  
80 134a in MAC versus total usage, while others have evaluated maximum use scenarios. These  
81 studies suggest that toxic levels of TFA in water bodies are not produced over Europe, North  
82 America, and China if HFO-1234yf replaces all the current use of HFC-134a (Henne et al., 2012;  
83 Kazil et al., 2014; Luecken et al., 2010; Wang et al., 2018). Russell et al. (2012) conducted a model  
84 study to determine TFA concentration in terminal water bodies in the contiguous U.S., with TFA  
85 deposition rates from Luecken et al. (2010). They found that after 50 years of continuous  
86 emissions, aquatic concentrations of 1 to 15  $\mu\text{g L}^{-1}$  are projected, with extreme concentrations of  
87 up to 50 to 200  $\mu\text{g L}^{-1}$  in the arid southwestern U.S.

88 Kazil et al. (2014) investigated, using the WRF-Chem model, the atmospheric turnover  
89 time of HFO-1234yf, the dry and wet deposition of TFA, and the TFA rainwater concentration  
90 over the contiguous U.S. between May and September 2006. They also examined where TFA  
91 deposited emissions of three specific regions in the U.S. They concluded that the average TFA  
92 rainwater concentration was 0.89  $\mu\text{g L}^{-1}$  for the contiguous U.S. Although Kazil et al. (2014) used  
93 emissions twice as large as that used by Luecken et al. (2010), the TFA rainwater concentrations  
94 were comparable. Kazil et al. (2014) used the measured HFC-134a to CO ratio from the Los  
95 Angeles area to obtain potential HFO-1234yf emissions. They also showed that TFA rainwater  
96 concentrations reached significantly higher values (7.8  $\mu\text{g L}^{-1}$ ) at locations with very low  
97 precipitation on shorter time scales. A comparably low TFA wet deposition occurred in the dry  
98 western U.S. The work of Wang et al. (2018) is similar to that of Henne et al. (2012) and used the  
99 GEOS-Chem model and examined the rainwater content and deposited amounts of TFA over  
100 Europe, the U.S, and China, with similar findings. Henne et al. (2012) is the only study that used  
101 two different models (FLEXPART and STOCHEM) to study the TFA deposition and rainwater  
102 concentration over Europe.

103 The above-noted studies focused on the U.S. and Europe, and most recently China. The  
104 U.S. and Europe emissions of the sum of HFC-134a and HFO-1234yf are expected to increase  
105 only in proportion to the population in the future since the per capita number of MAC, stationary  
106 AC, and other cooling units are unlikely to increase rapidly. India, China, and the Middle East are  
107 the regions with expected large increases in HFO-1234yf use. In these regions, the number of units  
108 and associated usage will increase rapidly as the economies grow. Perhaps Latin America and parts  
109 of Africa would also see similar increases. The above-noted studies from the U.S. and Europe do  
110 not allow us to draw firm conclusions about TFA's formation from realistic future emissions from

111 Asia (China and the Indian subcontinent), where the markets are not saturated, and meteorology  
112 is very different from North America and Europe. The rate of degradation of parent compounds  
113 and precipitation will differ in the warmer tropical and subtropical regions from those seen for the  
114 U.S. and Europe; the seasonality will also be different. The precipitation across Asia is associated  
115 with the Asian monsoon, which is stronger in comparison to the monsoon in the southwest U.S. It  
116 is also essential to look at the Middle East emissions since the studies of Kazil et al. (2014) and  
117 Russell et al. (2012) showed that TFA rainwater concentrations are larger over drier areas of the  
118 U.S., and there can be more accumulation in arid regions.

119 In 2019 the Kigali Amendment to the Montreal Protocol went into force. According to the  
120 amendment the production and use of HFCs has to be phased down in the coming decades. This  
121 should reduce the emissions of HFCs such as HFC-134a, but will likely increase emissions of  
122 HFO-1234yf.

123 A description of the models used (GEOS-Chem and WRF-Chem), HFO-1234yf emission  
124 scenarios, and the chemical scheme are given in section 2. In section 3, we compare the  
125 precipitation in GEOS-Chem and WRF-Chem with observations. We evaluate the GEOS-Chem  
126 model's ability to reproduce wet deposition by comparing sulfate rainwater concentrations with  
127 observations. We performed simulations using both the models for the three domains individually  
128 to calculate the TFA's dry and wet deposition and rainwater concentrations over India, China, and  
129 the Middle East. We performed two-year runs in GEOS-Chem to check for interannual variability.  
130 We compare our simulation results with other studies for the U.S., Europe, and China. The HFO-  
131 1234yf emissions from all the regions together were also simulated to assess the interregional  
132 effects. Major findings from this study are summarized in section 4.

133

## 134 **2. Methods**

### 135 **2.1. Model description**

136 **GEOS-Chem:** We used the GEOS-Chem (v12.0.3, [www.geos-chem.org](http://www.geos-chem.org)) global three-  
137 dimensional chemical transport model driven by GEOS-FP assimilated meteorological data.  
138 GEOS-Chem has a fully coupled tropospheric NO<sub>x</sub>-O<sub>x</sub>-hydrocarbon-aerosol chemistry. The  
139 simulations were made at 2°×2.5° resolution and 47 vertical levels from the surface to ~80 km.  
140 The wet deposition of aerosols and soluble gases by precipitation includes the scavenging in  
141 convective updrafts, in-cloud rainout, and below-cloud washout (Amos et al., 2012; Liu et al.,  
142 2001). The dry deposition was calculated using a resistance-in-series parameterization, which is  
143 dependent on environmental variables and lookup table values (Wesely, 1989). The simulations  
144 were conducted for 2015 and 2016 following a 2-month spin-up.

145 The global anthropogenic emissions were from Emissions Database for Global  
146 Atmospheric Research (version 4.3). The global emissions are superseded by regional emission  
147 inventories for India (Speciated Multi-pOllutants Generator (SMOG) and MIX) (Li et al., 2017;  
148 Pandey et al., 2014; Sadavarte and Venkataraman, 2014), China (MIX), Europe (EMEP), U.S.  
149 (National Emissions Inventory (NEI) 2011) (NEI2011, [http://www.epa.gov/air-emissions-](http://www.epa.gov/air-emissions-inventories)  
150 [inventories](http://www.epa.gov/air-emissions-inventories)), Canada (Criteria Air Contaminants (CAC), <http://www.ec.gc.ca/>), and Mexico

151 (BRAVO) (Kuhns et al., 2005). We used the biomass burning from Global Fire Emissions  
152 Database (GFED) version 4 (Giglio et al., 2013). The biogenic VOC emissions were from the  
153 Model of Emissions of Gases and Aerosols from Nature (MEGAN) version 2.1 inventory of  
154 Guenther et al (2012). The details on other emissions are described in David et al. (2018, 2019).  
155 **WRF-Chem:** The Weather Research and Forecast with Chemistry (WRF-Chem) model (Fast et  
156 al., 2006; Grell et al., 2005) version 4.1.3, was used to simulate meteorology and chemistry over  
157 India, China, and the Middle East individually. The WRF-Chem simulations were integrated for  
158 14 months, beginning 1 November 2014 and ending 31 December 2015, with the first two months  
159 of the simulation was used to spin up the model chemistry. The three model domains, shown in  
160 Figure 1, have a horizontal grid spacing of 30 km and 40 vertical levels reaching a model top of  
161 50 hPa. The vertical levels stretch in size with a fine resolution near the surface and a coarser  
162 resolution in the upper troposphere. The model meteorology was initialized with Global Forecast  
163 System (GFS) archived at 0.5° and a temporal resolution of 6 hours. Observational nudging is  
164 applied for temperature, moisture, and winds to keep large-scale features in line with the observed  
165 meteorology. The model physics and chemistry options that were used are summarized in Table  
166 S1 in the supplementary information. The Model for Ozone and Related chemical Tracers  
167 (MOZART) gas-phase chemical mechanism and the Global Ozone Chemistry Aerosol Radiation  
168 and Transport (GOCART) scheme for aerosols (MOZCART) (Pfister et al., 2011) were used to  
169 simulate ozone and aerosol chemistry. TFA chemistry was added to this chemical option. Six-  
170 hourly results from the Community Atmosphere Model with Chemistry (CAM-Chem), which has  
171 a similar chemistry mechanism as the WRF-Chem model configuration, were used (Tilmes et al.,  
172 2015) to initialize trace gas and aerosol mixing ratios as well as to provide lateral boundary  
173 conditions. HFO-1234yf and TFA were initialized with the GEOS-Chem results described above.  
174 The Model of Emissions of Gases and Aerosols from Nature (MEGAN v2.04; Guenther, 2007)  
175 was used to represent the net biogenic emissions for both gases and aerosols. Anthropogenic  
176 emissions were from the Emissions Database for Global Atmospheric Research – Hemispheric  
177 Transport of Air Pollution (EDGAR-HTAP) emission inventory (Janssens-Maenhout et al., 2015).  
178 The Fire Inventory from NCAR version 1 (FINNv1.6; Wiedinmyer et al., 2011) was implemented  
179 to provide daily varying emissions of trace species from biomass burning.

180 The wet removal scheme in WRF-Chem for MOZART chemistry, based on Neu and  
181 Prather (2012), was used to compute the dissolution of soluble trace gases into precipitation and  
182 their release into the gas phase upon evaporation of hydrometeors. Neu and Prather (2012) estimate  
183 trace gas removal by multiplying the effective Henry's law equilibrium aqueous concentration by  
184 the net precipitation formation (conversion of cloud water to precipitation, minus evaporation of  
185 precipitation). Dry deposition of trace gases was described with the Wesely (1989)  
186 parameterization. Diagnostic information on the wet and dry deposition of TFA was determined  
187 every time step and accumulated values were included in the output files.

188

## 189 **2.2. Emissions**

190 HFO-1234yf is just now entering the market driven by regional (e.g., the European Union’s  
191 MAC Directive 2006/40/EC), national (e.g., Japan and U.S.) F-gas regulations, and the Kigali  
192 Amendment to the Montreal Protocol. HFC-134a is currently the primary working fluid of MAC  
193 and other applications (refrigerant, insulating foams, and aerosol propellants). Therefore, we have  
194 to estimate the future emission levels from the three regions of interest. Unlike the developed  
195 countries, India, China, and the Middle East are growing rapidly and the use of air conditioning  
196 and refrigeration (and other uses of HFCs and HFOs) are expected to increase rapidly. Therefore,  
197 one has to consider the likely economic growth and other factors in estimating emissions levels.  
198 Here, we explore a few different potential scenarios for emissions of HFO-1234yf.

199 TFA production from HFO-1234yf increases linearly with the rise in HFO-1234yf  
200 emissions, i.e., there is no feedback on this process since the primary drivers for the degradation  
201 of this chemical, the OH radical, will not be altered by their relatively small emissions. In addition,  
202 the changes in the abundance of OH in the troposphere in the next few decades are unlikely to be  
203 different (say <13%) than the current levels based on the changes seen over the past few decades  
204 (Rigby et al., 2017). Therefore, we can estimate the extent of TFA formation from a set of  
205 modeling calculations that employed a fixed total amount of HFO-1234yf from each region. After  
206 that, we can calculate the extent of TFA formation for various possible emission scenarios.

207 We used four future HFO-1234yf emissions scenarios for the 2020 to 2040 period: (1)  
208 estimate of the upper range scenario HFO-1234yf emissions based on Velders et al. (2015)  
209 estimate; (2) lower range scenario of HFO-1234yf based on Velders et al. (2015) estimate; (3) the  
210 Greenhouse Gas Air Pollution Interactions and Synergies (GAINS) model (Amann et al., 2011)  
211 with maximum technically feasible reduction (MTFR) estimates of HFO-1234yf; and (4) the  
212 GAINS ‘maximum HFO’ (max HFO) scenario. Given the relatively short lifetime of HFO-1234yf,  
213 the TFA production per year is dependent only on the emissions in that year. Figure 2 shows the  
214 HFO-1234yf emission projection from India, China, and the Middle East for the four scenarios  
215 between 2020 and 2040. The scenario based on Kumar et al. (2018) is similar to the fourth scenario  
216 we considered. Therefore, we have not specifically included this possibility.

217 The emission estimates of HFO-1234yf in the GAINS model depends on when countries  
218 will comply with the Kigali Amendment, current and future emissions based on country-level  
219 activity data, uncontrolled emission factors, the removal efficiency of emission control measures,  
220 and the extent to which such measures are applied (Purohit and Höglund-Isaksson, 2017). The  
221 GAINS model uses the fuel input for the transport sector that is provided by the exogenous  
222 projections (e.g., International Energy Agency’s World Energy Outlook 2017). First, using the  
223 annual mileage per vehicle (veh-km) and specific fuel consumption (SFC), GAINS estimates the  
224 number of vehicles (by type, fuel). Second, using the penetration rate of a MAC, the number of  
225 vehicles with MAC is calculated. Next, using the specific refrigerant charge (different for MAC  
226 used in vehicle types), the HFO-1234yf consumption in mobile air conditioners is calculated. Note  
227 that the HFO-1234yf is assumed to be substituted for HFC-134a, one-to-one, in all vehicles. For  
228 HFO-1234yf use in MAC, HFO-1234yf emissions are estimated separately for “banked”  
229 emissions, i.e., leakage from equipment in use, and for “scrapping” emissions, i.e., emissions

230 released at the end-of-life of the equipment. The leakage rate in the GAINS model assumes a  
231 percentage of the charge per year. For example, if the refrigerant charge in MAC is 0.5 kg then the  
232 emissions from the bank will be 0.05 kg (= 0.5 kg×0.1) per year, where the leakage rate is 10%  
233 per year. This leakage rate is a steady refrigerant loss through seals, hoses, connections, valves,  
234 etc. from every MAC over the entire use-phase (annually). At the end-of-life, the scrapped  
235 equipment is assumed to be fully loaded with refrigerant, which needs recovery, recycling, or  
236 destruction. At the same time, if there are regulations in place (e.g., MAC Directive 2006/40/EC  
237 in European Union) - a package of measures including leak prevention during use and refill,  
238 maintenance, and end of life recovery, and recollection of refrigerants, GAINS consider these good  
239 practices as a control option with a removal efficiency of 50% for *in-use* and 80% for *end-of-life* -  
240 based on secondary sources (Purohit et al., 2020). However, no such measures are assumed for  
241 India, China, and the Middle East. Thus, these emissions can be considered the maximum likely  
242 emissions. The MTFR version of the GAINS scenario assumes that the maximum technically  
243 feasible reductions are applied across the sectors in India, China, and the Middle East. The Velders  
244 et al. (2015) emissions also follow the Kigali amendment. The ‘Shared Socioeconomic Pathways’  
245 (SSPs) SSP3 and SSP5 are the lower and upper range scenarios, respectively, used in Velders et  
246 al. (2015) calculated for 11 geographic regions and 13 use categories. Kumar et al. (2018) highlight  
247 that many applications in India will likely transition to something other than HFOs. These trends  
248 are not unique to India and will likely be replicated in China and the Middle East. Therefore, the  
249 four HFO-1234yf emission scenarios for the 2020 to 2040 period represent emissions that are  
250 higher than should be expected and, therefore, are upper limit estimates of the potential impact of  
251 TFA in these regions.

252 To minimize numerical errors (in using small emissions) and compare them with previous  
253 studies, we used HFO-1234yf emissions of ~40 Gg yr<sup>-1</sup> from each of these regions. This value  
254 corresponds to 2025 projected emissions from the GAINS model over India and the Middle East  
255 if all the applications were to use HFO-1234yf in place of HFC-134a for China, the emission values  
256 are for 2016 from Wang et al. (2018). Figure S1 in the supplementary information shows the annual  
257 spatial distribution of HFO-1234yf over India, China, and the Middle East as simulated in: (i)  
258 GEOS-Chem; and (ii) WRF-Chem models. We distributed this total emission across the  
259 country/region of interest by scaling the emission to known anthropogenic CO emissions used in  
260 the model. The anthropogenic CO is a good tracer for HFO-1234yf emissions since they originate  
261 from similar applications (especially the transport sector) and in proportion to the distribution of  
262 economic activities in the region/country of interest. We show the total emissions in each of the  
263 three regions in both the models in the figure. The distribution varies to a small extent with the  
264 season (shown in Figure S2 in the supplementary information), and the monthly variation in  
265 emission is similar in both models. We also simulated GEOS-Chem over the US and Europe using  
266 the total HFO-1234yf emissions from Wang et al. (2018) and Henne et al. (2012), respectively.

267

### 268 2.3. Chemical scheme

269 The chemical degradation of HFO-1234yf and the production of TFA were added to both  
 270 the GEOS-Chem NO<sub>x</sub>-O<sub>x</sub>-hydrocarbon-aerosol chemistry scheme and the WRF-Chem  
 271 MOZCART chemistry scheme. The detailed chemical scheme for the formation of TFA from  
 272 HFO-1234yf is shown in Burkholder et al. (2015) and, therefore, not repeated here. The simplified  
 273 representation of TFA production follows that of Kazil et al. (2014):

281  
 282 The conversion of HFO-1234yf to TFA includes OH-initiated reaction of CF<sub>3</sub>CF=CH<sub>2</sub>  
 283 (Equation 1) with a temperature-dependent rate coefficient of  $1.26 \times 10^{-12} \exp(-35/T) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$   
 284 to produce gas-phase CF<sub>3</sub>C(O)F (note that the initial OH reaction is the rate-limiting step in  
 285 the conversion). The gas-phase removal of CF<sub>3</sub>C(O)F is not rapid but hydrolyzes to TFA in water  
 286 (George et al., 1994) (Equation 2). The hydrolysis process is added to the heterogeneous chemistry  
 287 with a hydrolysis rate of 150 s<sup>-1</sup>, and Henry's Law solubility constant of 3 M atm<sup>-1</sup>. TFA is highly  
 288 soluble in cloud water. Upon cloud evaporation, the dissolved TFA is released into the gas phase  
 289 (Equation 4). The gas-phase TFA is expected to be deposited either via dry (Equation 6) or wet  
 290 deposition using Henry's Law solubility constant of  $9 \times 10^3 \text{ M atm}^{-1}$  at a standard temperature of  
 291 298.15 K,  $\Delta H/R = 9000 \text{ K}$ , dissociation coefficient of 0.65 mol L<sup>-1</sup> at 298.15 K, and  $\Delta E/R = -1562$   
 292 K. Thus, at cloud temperatures (generally <290 K) the effective Henry's Law of TFA is high,  
 293 characterizing TFA as a highly soluble gas. The dry deposition rate for TFA is assumed to be the  
 294 same as that for nitric acid (Henne et al., 2012; Kazil et al., 2014; Luecken et al., 2010). We also  
 295 included the potential loss of gas-phase TFA by its reaction with OH radicals (Equation 5) with a  
 296 rate coefficient of  $9.35 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ . Other potential losses of HFO-1234yf via reaction  
 297 with Cl, O<sub>3</sub>, and NO<sub>3</sub> are very small and all yield the same set of products. Therefore, we have not  
 298 included them in the model. We also examined the possible removal of gas phase TFA by its  
 299 reaction with Criegee intermediate (CI). We used the Bristol group's calculated concentrations of  
 300 the Criegee intermediates (Chhantyal-Pun et al., 2017; Khan et al., 2018).

301

### 302 **3. Results and Discussion**

#### 303 **3.1. Sulfate concentration in rainwater**

304 Wet deposition is one of the primary removal processes for TFA. This deposition depends  
 305 on precipitation amounts and how well our model captures the wet deposition process, making it  
 306 crucial to evaluate the models used here to capture these two factors.

307 First, we compared the annual total precipitation amounts calculated by GEOS-Chem and  
308 WRF-Chem with the observed daily total accumulated precipitation from the Tropical Rainfall  
309 Monitoring Mission (TRMM\_3B42\_daily product) in the three regions (Figure S3a in the  
310 supplementary information). The TRMM product is at a  $0.25^{\circ} \times 0.25^{\circ}$  resolution. The spatial  
311 distribution of seasonal total precipitation in the three domains from the two models and TRMM  
312 is shown in Figure S4 in the supplementary information. Both the models captured the seasonal  
313 precipitation patterns. As seen in Figure S3a, the total precipitation amounts were a factor of 1.5-  
314 2 higher in GEOS-Chem compared to WRF and TRMM. (The ratio of total precipitation between  
315 GEOS-Chem and WRF-Chem(TRMM) were 2.6 (1.5), 2.2 (1.5), and 2.2 (1.4) for India, China,  
316 and the Middle East, respectively). WRF-Chem underestimated the precipitation amounts  
317 compared to TRMM in the three regions. Kumar et al. (2012; 2018) have addressed the  
318 precipitation biases in WRF-Chem compared to TRMM over South Asia. We attribute the higher  
319 precipitation in GEOS-Chem to: (a) the different model physics used; (b) the effects of a  
320 meteorology-driven chemistry transport model (GEOS-Chem) versus an “online” chemistry  
321 transport model (WRF-Chem) where chemistry is solved at the same time step as the meteorology;  
322 (c) and to the different grid spacings used by the two models, noting that the coarse GEOS-Chem  
323 grid cells contain several convective storms compared to that in WRF-Chem. The monthly  
324 variation in total precipitation is shown in Figure S3b (supplementary information), and both  
325 models have similar trends as that observed by TRMM.

326 To evaluate the accuracy of the TFA wet deposition, it is useful to compare sulfate wet  
327 deposition amounts produced by the oxidation of  $\text{SO}_2$ . The emissions of  $\text{SO}_2$  are comparable in  
328 both the models (shown in Figure S5 in the supplementary information). We have measurements  
329 of sulfate rainwater concentrations in some of the regions. Further, the lifetime of  $\text{SO}_2$  in the  
330 troposphere is comparable to that of HFO-1234yf. We hasten to add that while the HFO-1234yf  
331 degradation is controlled by gas phase OH reactions, that of  $\text{SO}_2$  includes both gas and condensed  
332 phase processes. However, the removal of both sulfate and TFA are due to condensed phase  
333 reactions. The WRF-Chem model has been shown to capture the sulfate rainwater concentration  
334 over the continental U.S. by Kazil et al. (2014); we expect it to do well over this study's regions.  
335 However, GEOS-Chem has not been evaluated previously. There are no networks for measuring  
336 sulfate rainwater concentration in India and the Middle East. Yet, there are some observations of  
337 rainwater sulfate in the published articles in all three domains. The available data are sparse, and  
338 the observations for 2015 (the modeled year) are even fewer to make a comparison with WRF-  
339 Chem simulations. However, GEOS-Chem simulations were available from our previous work for  
340 2000-2015. We used those results to compare with observations during that period. The  
341 observation locations (over land only) in the three domains are shown in Figure S6 in the  
342 supplementary information. Figure 3 shows the scatter plot of simulated and observed sulfate  
343 rainwater concentration in the three domains. Table 1 lists the statistics of the comparison between  
344 GEOS-Chem and the observations. Rainwater sulfate amounts calculated by GEOS-Chem  
345 correlate well ( $R > 0.80$ ) with observations. We see a bias of -13, -13, and -3% in India, China, and  
346 the Middle East domains, respectively. The negative bias in GEOS-Chem sulfate rainwater

347 concentration could be because the model integrates over a large area while the observations are  
348 point locations. It could also be, as noted earlier, because GEOS-Chem yields higher amounts of  
349 precipitation and thus could lead to smaller rainwater concentrations. We suggest that these values  
350 are good to at least a factor of two. In summary, the GEOS-Chem model shows considerable skill  
351 in reproducing mean sulfate rainwater concentrations and spatial variability of sulfate rainwater  
352 concentrations; therefore, it can be utilized to calculate TFA wet deposition.

353

### 354 **3.2. Comparison of calculated TFA with previous studies**

355 Before presenting the results of the calculations for India, China, and the Middle East from  
356 the present study, we note that our models agree with the previous studies over the U.S. (Kazil et  
357 al., 2014; Luecken et al., 2010), China (Wang et al., 2018), and Europe (Henne et al., 2012). Figure  
358 4 shows the comparison of annual mean (a) TFA deposition (dry and wet combined), and (b) TFA  
359 rainwater concentration over the U.S., China, and Europe. We have normalized the emissions to  
360 match those of the previous studies for meaningful comparisons. (The emissions used to compare  
361 TFA from the U.S., China, and Europe are 24.5, 42.7, and 19.2 Gg yr<sup>-1</sup>, respectively.) We note that  
362 average deposition rates differ in the model because of the differences in calculations' domain  
363 sizes. Given that the models vary in their versions, meteorology, physics, and the expected model  
364 variabilities, the observed agreement is reasonable. The TFA rainwater concentration in GEOS-  
365 Chem than in WRF-Chem simulations because the total precipitation amounts were factors of 1.5-  
366 2 higher in GEOS-Chem compared to WRF and TRMM as mentioned in section 3.1. We also show  
367 the comparison with our calculations over the U.S. for the summer months with previous studies  
368 (Kazil et al., 2014; Luecken et al., 2010; Wang et al., 2018) (Figure S7 in the supplementary  
369 information).

370

### 371 **3.3. Atmospheric mixing ratios**

372 Figure 5 shows the annual mean mixing ratios of HFO-1234yf over India, China, and the  
373 Middle East as simulated by GEOS-Chem and WRF-Chem. We present here only results with  
374 emissions in GEOS-Chem(WRF-Chem) of 41.3(41.9), 40.6(39.9), and 37.8(38.1) Gg yr<sup>-1</sup> from  
375 India, China, and the Middle East, respectively. Expected TFA for other emissions can be simply  
376 scaled to the emissions of interest. The annual mean mixing ratio of HFO-1234yf in India, China,  
377 and the Middle East as simulated by GEOS-Chem(WRF-Chem) were 2.87(3.94) ppt, 2.49(3.70)  
378 ppt, and 1.82(2.49) ppt, respectively, and below 1 ppt (as seen in GEOS-Chem) outside of the three  
379 regions. The annual mean mixing ratio in the China domain was comparable to Wang et al. (2018).  
380 The highest (>40 ppt) simulated annual mean HFO-1234yf mixing ratio for India was in the Indo-  
381 Gangetic Plain (IGP), for China in the northeast region, and for the Middle East in northern Iran.  
382 The emission hotspots (Figure S1 in the supplementary information) in the three regions led to the  
383 largest annual mean HFO-1234yf mixing ratios in those regions. The WRF-Chem simulated higher  
384 annual mean HFO-1234yf mixing ratios compared to GEOS-Chem. Differences in annual mean  
385 HFO-1234yf mixing ratios between models for the same amount of emissions have been reported  
386 also by Henne et al. (2012). However, the overall spatial patterns are comparable between GEOS-

387 Chem and WRF-Chem. It should be noted that the change of HFO-1234yf emissions in any of the  
388 three regions would change the HFO-1234yf mixing ratio within that region and will have minimal  
389 effect on other regions.

390

### 391 **3.4. TFA deposition**

392 GEOS-Chem simulated mean total deposition rates (dry and wet deposition combined) to  
393 be 0.874, 0.501, and 0.477 kg km<sup>-2</sup> yr<sup>-1</sup>, respectively, in India, China, and the Middle East domains  
394 for emissions of 41.3, 40.6, and 37.8 Gg yr<sup>-1</sup>, respectively. WRF-Chem simulated mean deposition  
395 rates (dry and wet) were 0.802, 0.342, and 0.284 kg km<sup>-2</sup> yr<sup>-1</sup> in India, China, and the Middle East  
396 domains, respectively (Figure S8 in the supplementary information). Figure 6 shows the annual  
397 total dry and wet TFA deposition rates in the three domains. The total annual dry deposition in  
398 GEOS-Chem and WRF-Chem over the India domain was largest in eastern India and Bangladesh,  
399 reaching up to 2 kg km<sup>-2</sup> yr<sup>-1</sup>. The wet deposition in the India domain mostly occurred in the  
400 Himalayas' foothills, eastern IGP, parts of central India, and southwest India and was >3.5 kg km<sup>2</sup>  
401 yr<sup>-1</sup>. In the China domain, the total dry and wet deposition rates in GEOS-Chem and WRF-Chem  
402 were highest in southeast China. The total dry deposition rate in the Middle East domain was  
403 highest in northern Iran. The wet deposition rate was the largest in parts of Iran, with differences  
404 between the models. The wet deposition dominated the total TFA deposition. The combined annual  
405 total deposition pattern was similar to that of wet deposition in the three domains (Figures 6 and  
406 S8 in the supplementary information). The seasonal total deposition rates of TFA from dry and  
407 wet depositions in the three domains are shown in Figure S9 in the supplementary information.  
408 The seasonal deposition rates were highest for June-September, June-August, and April-October  
409 in India, China, and the Middle East domains, respectively.

410 Figure 7 shows the percentage contribution of dry and wet deposition to total TFA  
411 deposition between GEOS-Chem and WRF-Chem in the three domains. It should be noted that the  
412 sum of the two (dry and wet) percent contributions do not add up to exactly 100% because of  
413 transport in and/or out of the domains. For the total amount of HFO-1234yf emissions mentioned  
414 in Figure S1(supplementary information) and discussed in section 2.2, the total TFA deposition  
415 (dry and wet combined) in India, China, and the Middle East domains from GEOS-Chem were  
416 23.4, 20.5, and 18.7 Gg yr<sup>-1</sup>, respectively. The total annual dry(wet) deposition amounts account  
417 for 21(36)%, 20(31)%, and 20(29)% of the annual emissions of HFO-1234yf in GEOS-Chem. In  
418 WRF-Chem, the annual total TFA deposition was 19.4, 12.1, and 9.9 Gg yr<sup>-1</sup>, respectively, in India,  
419 China, and the Middle East domains. The dry(wet) TFA deposition was 10(37)%, 3(23)%, and  
420 4(26)% of the emissions in India, China, and the Middle East domains, respectively. Table S2  
421 (Supplementary Information) shows the seasonal TFA deposition (dry and wet) calculated from  
422 GEOS-Chem and WRF-Chem models in the three domains. The lower TFA deposition in WRF-  
423 Chem compared to GEOS-Chem is due to the venting of surface emissions into the free  
424 troposphere (Grell et al., 2004; Kazil et al., 2014) that leads to lower dry deposition in WRF-Chem  
425 (Figure 7a). The differences in deposition between models can also be attributed to differences in  
426 model resolutions, model transport, meteorological conditions (e.g., precipitation), and cloud

427 treatment. These differences highlight the need for multi-model simulations to estimate the likely  
428 variation in these parameters.

429 Figure 8 shows the total TFA deposition (dry and wet combined) for the four emission  
430 scenarios (Figure 2) calculated from GEOS-Chem and WRF-Chem. Our results show that the  
431 differences in the calculated extent of TFA formed and deposited are about a factor of two between  
432 the models. In all cases, the computed TFA dry and wet deposition varies linearly with the  
433 emissions. Therefore, we can calculate the amounts of TFA formed and deposited for any  
434 envisioned emission of HFO-1234yf.

435

### 436 **3.5. Rainwater concentrations**

437 Figure 9 shows the monthly variation in mean TFA rainwater concentration in the three  
438 domains calculated from GEOS-Chem and WRF-Chem. The TFA rainwater concentration also  
439 varies linearly with the emissions. Figure 9 shows the following: (a) higher concentrations are to  
440 be expected when there is little rain/precipitation (Figure S10 in the supplementary information)  
441 to remove TFA. This point has been noted in previous studies (Kazil et al., 2014; Russell et al.,  
442 2012; Wang et al., 2018). So, if all the TFA were concentrated into a small amount of rain, the  
443 concentrations have to be larger. Such events are infrequent. They are, relative to the rainier  
444 regions, more frequent in the Middle East. The large rainwater concentration does not mean that  
445 the amount of deposited TFA is larger; (b) The rainwater concentrations varied inversely with the  
446 precipitation amount, as seen by comparing the rainwater TFA levels with the total precipitation  
447 (Figure S10 in the supplementary information). A clear signal for the rainfall variation was seen  
448 over India, where the monsoon season (June, July, August, and a part of September) bring large  
449 and almost constant precipitation. This large precipitation makes the TFA rainwater concentrations  
450 extremely small. In other words, this is simply a dilution effect; (c) When the rainfall is small,  
451 there are considerable variations as one would expect. Lesser total precipitation arises because of  
452 fewer showers and often in spatially and temporally sporadic events. So, the concentrations can  
453 vary a great deal. This was also evident over China during dry seasons; and (d) the calculated TFA  
454 rainwater concentrations were comparable to previous calculations for China (scaled to emissions,  
455 Figure 4b). The variation of rainfall amounts and their geographical distribution as climate changes  
456 are uncertain, but there are some estimates. For example, Terink et al., (2013) suggest that there  
457 could be a ~20% decrease in precipitation over the Middle East region over the next 20 years. A  
458 20% decrease in precipitation will correspond to TFA rainwater concentration less than 40  $\mu\text{g/L}$   
459 (95<sup>th</sup> percentile). The annual mean precipitation over China is likely to increase; for example,  
460 estimates are roughly increases of 0.078 mm/d in the 2020s and 0.218 mm/d in 2050s, with larger  
461 changes in the summer months (rainy season) (Guo et al., 2017). The projected rainfall changes  
462 across the Indian monsoon region could increase by 6% (RCP4.5) and 8% (RCP8.5) in the mid-  
463 21<sup>st</sup> century (Krishnan et al., 2020).

464 It is important to know the regions of high TFA rainwater concentrations. Therefore, we  
465 plotted the spatial pattern of annual mean TFA rainwater concentration in the three domains from  
466 both models (Figure S11 in the supplementary information). It is noticeable that most of the regions

467 in all three domains did not have high TFA rainwater concentrations. There were some grids with  
468 TFA rainwater concentrations that exceeded  $50 \mu\text{g L}^{-1}$  for emissions of  $\sim 40 \text{ Gg yr}^{-1}$ . The high TFA  
469 rainwater concentration seen in the western part of India and China domains is because of input at  
470 the lateral boundaries from a global model. As mentioned in section 3.1, the precipitation in GEOS-  
471 Chem was higher, resulting in lower TFA rainwater concentration. Focusing on the highest  
472 possible rainwater concentrations is misleading since that does not tell us the amount of wet TFA  
473 deposition, which is shown in Figure 6. However, it is clear that if the emissions of HFO-1234yf  
474 reach the large numbers noted by the IIASA/GAINS model (max HFO, Figure 2d) for 2040, there  
475 will be significant areas with larger TFA rainwater concentrations. The wet deposition does not  
476 tell the whole story either since a substantial fraction of the rainwater ends up in the oceans every  
477 year. The estimation of the TFA retained on land will be critical for further estimating the long-  
478 term impact. Such a hydrology study is warranted but beyond the scope of this work.

### 479 **3.5.1. Comparison of expected TFA rainwater levels with No Observable Effects** 480 **Concentrations**

481 The primary reason for carrying out these calculations was to estimate the potential impact  
482 of HFO-1234yf usage in the three regions of the study for the current and future emissions. The  
483 effects of interest here are TFA formation from HFO-1234yf and its consequences to human and  
484 ecosystem health. Figure 10 shows the mean TFA rainwater concentration for the four emission  
485 scenarios calculated from GEOS-Chem and WRF-Chem. In all the scenarios, the annual mean  
486 TFA rainwater concentration was well below the no observed effect concentration (NOEC) for  
487 aquatic species, which is  $>10,000 \mu\text{g L}^{-1}$  (Solomon et al., 2016), with an outlier for the most  
488 sensitive alga as  $120 \mu\text{g L}^{-1}$  (Boutonnet et al., 2011). The negligible impact of TFA formation  
489 during the atmospheric oxidation of HFCs, HCFCs, and HFOs has been established for some time.  
490 The WMO/UNEP Quadrennial Ozone Assessment (2007) concluded that TFA from the  
491 degradation of HCFCs and HFCs would not result in environmental concentrations capable of  
492 significant ecosystem damage. Hurley et al., (2008) concluded in their study that the products of  
493 the atmospheric oxidation of  $\text{CF}_3\text{CF}=\text{CH}_2$  will have a negligible environmental impact. Solomon  
494 et al., (2016) also concluded in their study that the concentrations of TFA and its salts in the  
495 environment that result from degradation of HCFCs, HFCs, and HFOs in the atmosphere do not  
496 present a risk to humans and the environment.

497 Neale et al. (2021) have summarized the impact of TFA on human and ecosystem health.  
498 Their conclusion suggests that the NOEC on aquatic systems is  $>10,000 \mu\text{g L}^{-1}$ . As shown in  
499 Figures 9, 10, and S11 (supplementary information), the expected rainwater concentrations are at  
500 least two orders of magnitude lower than the NOEC. Also, the rainwater concentrations of TFA,  
501 even for the 2040 emissions, are roughly comparable to those currently observed in China (Chen  
502 et al., 2019) and about ten times greater than those presently observed over Germany (Freeling et  
503 al., 2020). They also note that large TFA concentrations have been observed in people's blood in  
504 China with no ill effects on the endpoints measured in that work (Duan et al., 2020).

505 TFA quantities deposited via dry deposition to land and vegetation would be much smaller  
506 than those noted in Neale et al. (2021) to have any significant detrimental health effect. Indeed,

507 they note that there are other sources of TFA that are much higher than those expected from HFO-  
508 1234yf degradation. Neale et al. (2021) also point out that the TFA deposited to snow in the Arctic  
509 would not significantly contribute to marine water bodies even if it all melted down since the  
510 volume of the melt would be much smaller than those of the receiving water bodies.

511 Lastly, since TFA can accumulate over land and water bodies, we can estimate the  
512 influence of accumulation on the potential future impacts. The total TFA amount in rainfall would  
513 not change. However, the amounts in water bodies could increase. For the 20 years modeled here,  
514 the total TFA in water bodies would be larger than those observed for 2020 if TFA merely  
515 accumulates. It is hard to calculate precisely where the water bodies would accumulate TFA  
516 without a hydrological model. However, these values would still be orders of magnitude smaller  
517 than the NOEC of  $>10,000 \mu\text{g L}^{-1}$ . For example, if all the TFA produced in these regions were to  
518 end up in the top 15 meters of the world's oceans, we expect the TFA levels to increase by about  
519  $0.015 \mu\text{g L}^{-1}$  by 2040.

520 Based on these observations, and assuming that the NOEC concentration holds, it appears  
521 that the TFA from the expected emissions of HFO-1234yf in these three regions would not  
522 constitute a health threat to plants or humans (even if we assume that there is no water treatment  
523 to remove TFA in drinking water).

524

### 525 **3.6. Interannual variability**

526 The model results discussed in the previous sections are for one year, 2015. To assess the  
527 influence of interannual variability in meteorology, we simulated the TFA deposition and  
528 rainwater concentration for 2016 with the GEOS-Chem model for the total HFO-1234yf emissions  
529 described in section 2.2. Figure 11 shows the fraction of TFA in the three domains for 2015 and  
530 2016 that is: (a) dry deposited; (b) wet deposited; and (c) the annual mean TFA rainwater  
531 concentrations. The total precipitation in both years was comparable (shown in Figure S12 in the  
532 supplementary information). The results of our two-year simulations lead us to conclude that the  
533 interannual differences are small. Therefore, we suggest that the results of 2015 are applicable  
534 going forward to 2040.

535

### 536 **3.7. Simultaneous emissions from multiple regions**

537 It is important to note that most TFA is deposited outside of the domains, even though the  
538 estimated lifetime of HFO-1234yf is about ten days. Therefore, TFA is dispersed significantly  
539 from the source region. Figure 12a shows that roughly 25-50% of the HFO-1234yf emitted from  
540 a given region was converted and deposited (via dry and wet deposition) as TFA within the domain  
541 (see Figure 1 for domain boundaries). Figure 12b shows the percentage of TFA deposition (dry  
542 and wet combined) calculated from GEOS-Chem and WRF-Chem within the three domains over  
543 land. The remaining TFA was transported outside the domain. It is difficult to quantify the exact  
544 locations of these depositions outside the domain since the concentrations get very small even  
545 though in the aggregate that accounts for somewhere between 30% and 45%. The fraction that was  
546 deposited within the region of emission was even smaller and ranged between 7% and 27%.

547 Therefore, it can be concluded that a significant fraction ended up in the oceans. This is especially  
548 true for India and the Middle East emissions. Interestingly, a substantial amount of the TFA from  
549 the Middle East emissions are deposited in the Arabian Sea. Therefore, we conclude that even  
550 though HFO-1234yf is short-lived, it is still sufficiently long-lived to travel thousands of  
551 kilometers. Such an expectation is in accord with the calculated distances traveled by an air mass  
552 for even about  $2 \text{ m s}^{-1}$ .

553 The deposition outside of the region and domains also means that the emitting regions are  
554 not the only area affected by their emission of HFO-1234yf. This is in spite of the relatively short  
555 turnover time of HFO-1234yf. (Note: We call this the turnover time because of the way we  
556 calculate it in the model.) Since the three countries/regions studied here are adjacent to each other  
557 and their domains overlap (Figure 1), it is possible to estimate the impact of the neighbors'  
558 emissions on each other. We consider the emissions over the rest of the world (excluding India,  
559 China, the Middle East, the US, and Europe) from Fortems-Cheiney et al. (2015) assuming HFC-  
560 134a is substituted with HFO-1234yf on a mole-per-mole basis (the maximum likely emissions  
561 scenario). Figure S13 in the supplementary information shows the annual spatial distribution of  
562 HFO-1234yf emissions from all the regions as simulated in GEOS-Chem. The percentage  
563 deposition of TFA (dry and wet combined) from global and regional (individual regions) emissions  
564 of HFO-1234yf is shown in Figure 13. The TFA deposition increased by 7-18% in the three  
565 domains because of the emissions from its neighbors. Figure 13 suggests that if the entire world  
566 switches to HFO-1234yf, the impact of TFA from the near and far neighbors would be noticeable,  
567 but still be at most a factor of 2 or 3 larger. Figure S14 in the supplementary information shows  
568 the spatial pattern of the annual total TFA via (a) dry and (b) wet deposition rates from global  
569 emissions of HFO-1234yf. The dominant TFA deposition regions were most parts of India,  
570 southeast China, parts of Iran, and the southern Arabian Sea. We discussed in section 3.5.1 the  
571 potential impacts of such a global switch.

572

### 573 **3.8. Reaction of TFA with Criegee intermediates**

574 We examined the influence of CI's potential reactions with TFA on its tropospheric levels.  
575 We used the CI concentrations in the boundary layer (0-2 km) from Chhantyal-Pun et al. (2017)  
576 in GEOS-Chem and simulated the model for seven months (January to July) using 2015  
577 meteorology. Figure S15 in the supplementary information shows the mean surface CI  
578 concentration for those seven months calculated at  $2^\circ \times 2.5^\circ$  spatial resolution. The CI  
579 concentrations in the three regions of our study were less than  $2500 \text{ molecules cm}^{-3}$ . We calculated  
580 the percentage decrease in total TFA deposition within the three domains by including the CI  
581 chemistry. We assumed at all the CI reactions with TFA have the rate coefficient measured for  
582 that of  $\text{CH}_2\text{OO}$  with TFA, i.e.,  $5 \times 10^{-18} T^2 e^{1620/T} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ . Figure 14 shows the  
583 spatial pattern of decrease in total TFA deposition (dry and wet combined) for seven months by  
584 including CI reaction with gas phase TFA for emissions of HFO-1234yf by (a) India, (b) China,  
585 and (c) the Middle East. In most of the locations within the three domains, the decrease in total  
586 TFA deposition was  $<2.5\%$ . At a few places in southeast Asia (Figure 14a), western China (Figure

587 14b), and northern Africa (Figure 14c), the TFA deposition decreased by 7-25%. The decrease in  
588 TFA deposition due to CI was 0.03, 0.32, and 0.08 Gg (total for seven months) for India, China,  
589 and the Middle East domains, respectively. Figure S16 shows the percentage decrease in mean  
590 surface TFA mixing ratio by including the reaction of CI with TFA following the emissions of  
591 HFO-1234yf emissions from (a) India, (b) China, and (c) the Middle East. The decrease in the  
592 mean surface TFA mixing ratio is less than 2% (0.01 ppt). Overall, the impact of CI on TFA  
593 deposition/mixing ratio was small in the regions of study.

594

#### 595 **4. Summary**

596 We have investigated TFA formation from emissions of HFO-1234yf, its dry and wet  
597 deposition, and rainwater concentration over India, China, and the Middle East with GEOS-Chem  
598 and WRF-Chem models. We estimated the TFA deposition and rainwater concentrations between  
599 2020 and 2040 for four HFO-1234yf emission scenarios. The models were simulated for a year  
600 (2015), with additional 2016 simulations to understand the interannual variability. We also  
601 simulated the model using global emissions to assess interregional effects on TFA deposition. The  
602 main results of the study are summarized below:

- 603 • Using two models at different spatial resolutions helped us assess the variation in model  
604 transport, precipitation, and cloud treatment. These variations yield slightly different  
605 calculated TFA levels from the emission of HFO-1234yf. Even though there are discernable  
606 differences, the overall conclusions are the same and point to this study's robustness.
- 607 • The accuracy of the GEOS-Chem model's ability to calculate wet deposition over the regions  
608 of interest was tested by comparing calculated sulfate rainwater concentration with  
609 observations. The model reproduces well the multiyear sulfate rainwater concentration (-3%  
610 to -13% bias) and its spatial variability ( $R > 0.80$ ) in the three domains.
- 611 • Our calculated TFA amounts over the U.S., Europe, and China were comparable to those  
612 previously reported when normalized to the same emissions.
- 613 • The controlling factor for the amount of TFA from HFO-1234yf is its emissions. The  
614 uncertainties in the models and chemistry are secondary to the extent of emissions.
- 615 • The TFA deposition was largest over eastern India, southeast China, northern Iran, and the  
616 southern Arabian Sea. The TFA wet deposition was comparable between the two models.
- 617 • There are large variations in TFA rainwater concentrations associated with rainfall extent. The  
618 mean TFA rainwater concentration calculated for the four emission scenarios from GEOS-  
619 Chem and WRF-Chem was below the no observable effect concentration (NOEC), suggesting  
620 the ecological and human health impacts to be not significant.
- 621 • With a chemical turnover time of HFO-1234yf of 10 days, its impact is not local and extends  
622 well beyond the region of emissions. This study highlights the enhanced TFA formation by the  
623 simultaneous use of HFO-1234yf by neighboring regions. If all the Northern Hemisphere  
624 countries were to use HFO-1234yf, the impact would be higher by a factor of 2 or 3. However,  
625 these amounts are still much lower than the NOEC noted above.

- 626 • We estimate that continued use of HFO-1234yf in India, China, and the Middle East are  
627 unlikely to lead to detrimental human health effects based on the current understanding of the  
628 effects of TFA in water bodies, as summarized by Neale et al. (2021). (Note we do not assume  
629 the water is treated specifically to remove TFA before consumption.)
- 630 • We note that a hydrology model of the water flow and TFA concentrations in them would be  
631 beneficial to quantify the extent of TFA accumulation in pools and flow out to large water  
632 bodies.

633

#### 634 **Acknowledgement:**

635 We are grateful to Jan Kazil (NOAA/CSL) and Rajesh Kumar (NCAR) for help with the WRF-  
636 Chem. We are thankful to Jared Brewer and Viral Shah for helping with TFA chemistry in GEOS-  
637 Chem. We are thankful to Kirpa Ram for providing the sulfate rainwater concentration data over  
638 India. We are grateful to Anwar Khan, Rabi Chhantyal Pun, Dudley Shallcross, and Andrew Orr-  
639 Ewing for providing their calculated Criegee intermediate concentrations. The work at CSU was  
640 funded by the Global Forum for Advanced Climate Technologies. NCAR is supported by the U.S.  
641 National Science Foundation. Pallav Purohit and Lena Höglund-Isaksson gratefully acknowledge  
642 funding from IIASA and the National Member Organizations that support the institute.

862 **Tables**

863 **Table 1.** The slope, correlation coefficient (R), intercept (c), mean bias (MB), and the number of  
864 points (N) of simulated (GEOS-Chem) and observed sulfate rainwater concentration over the three  
865 domains.

<b>Region</b>	<b>Slope</b>	<b>R</b>	<b>c</b>	<b>MB</b>	<b>N</b>
India	0.771	0.816	0.210	-0.255±0.778	54
China	0.799	0.911	0.655	-1.07±2.700	89
Middle East	1.42	0.880	-2.81	-0.187±2.71	5

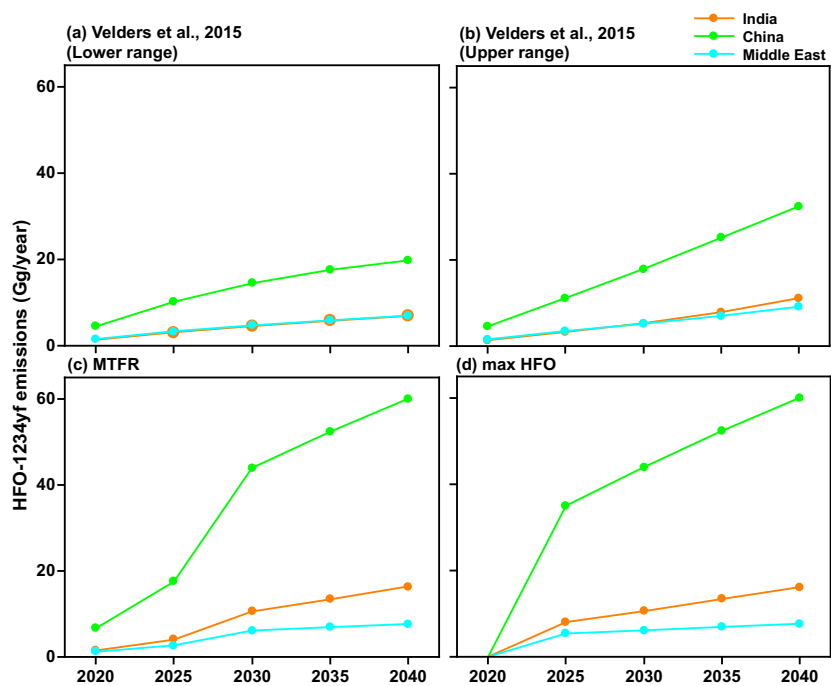

866

867 **Figures**

868  
869 **Figure 1.** The model domains for India, China, and the Middle East used in the present study and  
870 also for WRF-Chem simulations. The land regions for the emissions are shown in color.  
871

872

873  
874 **Figure 2.** The projected HFO-1234yf emissions scenarios between 2020 and 2040 from Velders  
875 et al. (2015) (a) lower and (b) upper ranges, IIASA GAINS model for (c) Maximum Technically  
876 Feasible Reduction (MTRF) and (d) max HFO in India, China, and the Middle East.  
877

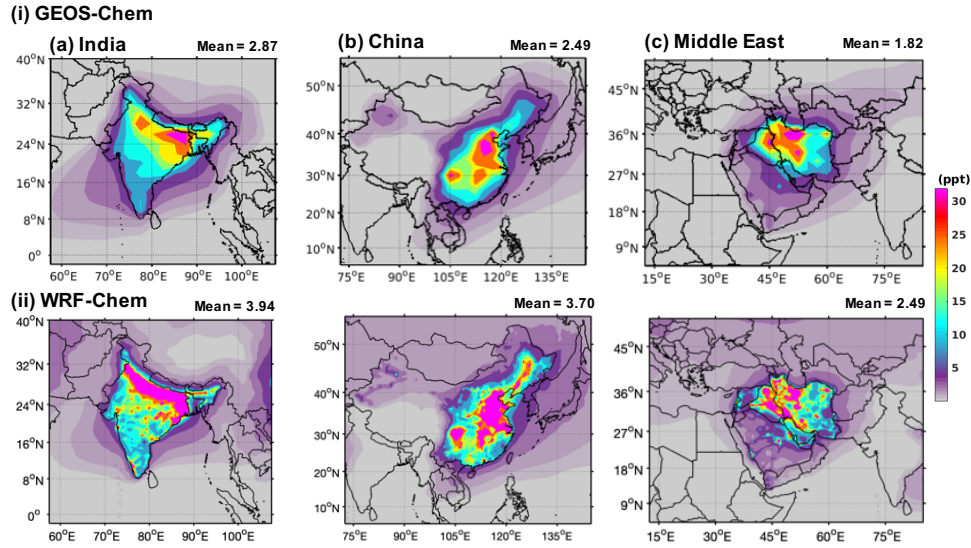

878  
 879 **Figure 3.** Scatter plot of simulated and observed sulfate rainwater concentration in (a) India, (b)  
 880 China, and (c) the Middle East for 2000-2015. The linear regression line is shown in red. The black  
 881 dashed line corresponds to slope = 1. The data for the Middle East is very limited.  
 882

883

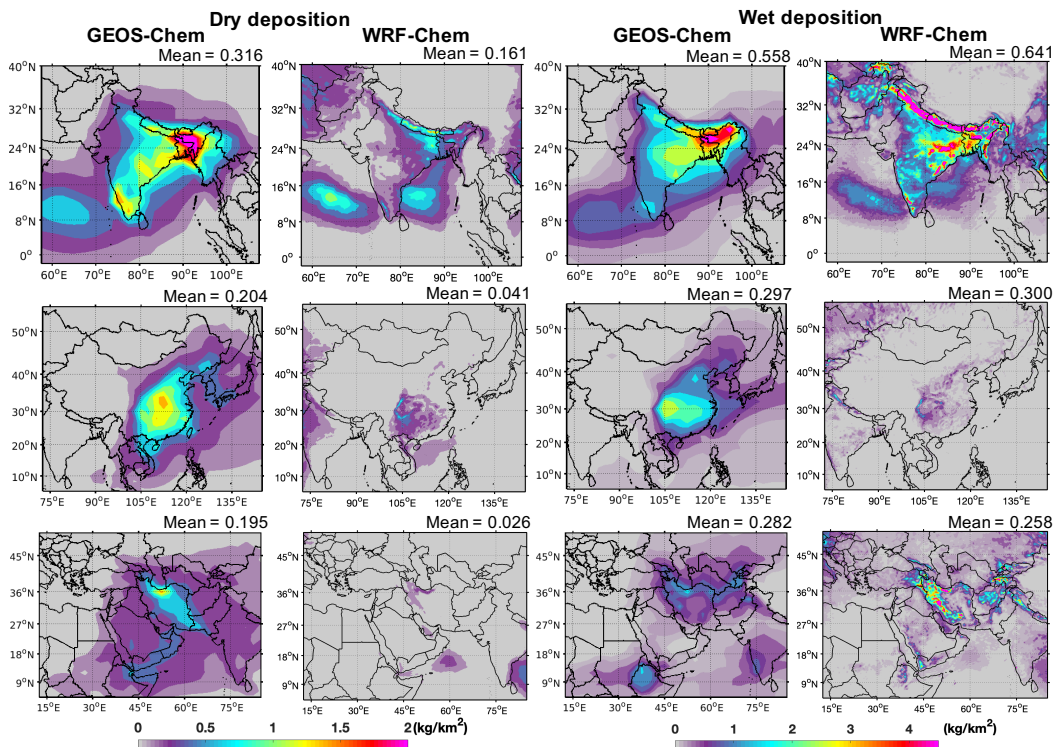

884  
 885 **Figure 4.** Comparison of the present study with other studies over the U.S., China, and Europe for  
 886 (a) TFA deposition, and (b) TFA rainwater concentration. Note the emissions are 24.53 Gg yr<sup>-1</sup>,  
 887 42.65 Gg yr<sup>-1</sup>, and 19.16 Gg yr<sup>-1</sup> for the U.S., China, and Europe, respectively.  
 888

889  
890  
891  
892  
893  
894

**Figure 5.** Annual mean surface mixing ratios of HFO-1234yf simulated in (i) GEOS-Chem and (ii) WRF-Chem over (a) India, (b) China, and (c) the Middle East. The number at the top of each panel gives the mean HFO-1234yf mixing ratios within the domains.

895  
896  
897  
898  
899

**Figure 6.** GEOS-Chem and WRF-Chem simulated annual total deposition rates of TFA ( $\text{kg km}^{-2} \text{yr}^{-1}$ ) from (a) dry and (b) wet deposition in India, China, and the Middle East domains. The number at the top of each panel gives the mean dry and wet deposition rates within the domains.

900  
 901 **Figure 7.** Percentage contribution of (a) dry and (b) wet deposition to total annual TFA deposition  
 902 simulated in GEOS-Chem and WRF-Chem in the three domains.  
 903

904  
 905 **Figure 8.** Total TFA deposited (dry and wet combined) in four emission scenarios for 2020 to  
 906 2040 within India, China, and the Middle East domains calculated using GEOS-Chem (solid lines)  
 907 and WRF-Chem (dashed lines). The values from the two models are reasonably close for India  
 908 and the Middle East, while they differ by almost a factor two for China.  
 909

910  
 911 **Figure 9.** Box and whisker plot of TFA rainwater concentration calculated from GEOS-Chem and  
 912 WRF-Chem in the three domains. In the box plot, the inside line and square are the median and  
 913 mean, respectively. Box boundaries are 25<sup>th</sup> and 75<sup>th</sup> percentiles, and whiskers indicate the 5<sup>th</sup> and  
 914 95<sup>th</sup> percentiles. The dashed horizontal line is the No Observable Effect Concentration (NOEC)  
 915 level. It is important to note that these values, including the 95<sup>th</sup> percentile values are at least 100  
 916 times lower than the NOEC for harming aquatic bodies even when normalized for higher projected  
 917 emissions in 2040.  
 918

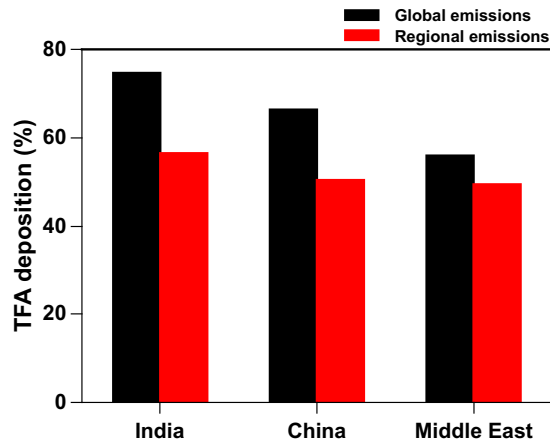

919  
 920 **Figure 10.** Mean TFA rainwater concentration in four scenarios for 2020 to 2040 for India, China,  
 921 and the Middle East domains calculated using GEOS-Chem (solid lines) and WRF-Chem (dashed  
 922 lines). The NOEC is denoted above, and it is two orders of magnitude larger than calculated TFA  
 923 concentrations for any of the scenarios.  
 924

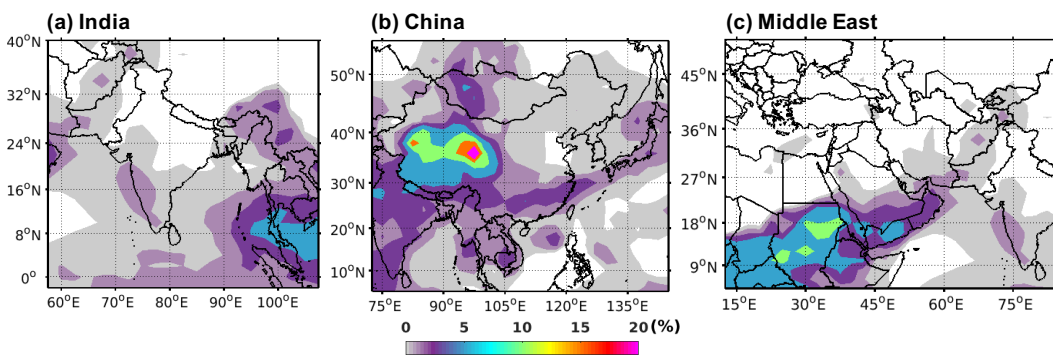

925  
 926 **Figure 11.** Annual percentage of total TFA (a) dry and (b) wet deposition, and (c) annual mean  
 927 TFA rainwater concentrations in India, China, and the Middle East domains from GEOS-Chem  
 928 for 2015 and 2016. The dashed horizontal line is the NOEC level.  
 929

930  
 931 **Figure 12.** Annual percentage of total TFA deposition (dry and wet combined) calculated from  
 932 GEOS-Chem and WRF-Chem within the three (a) domains and (b) regions (land).  
 933

934  
 935 **Figure 13.** Annual percentage of total TFA deposition (dry and wet combined) in India, China,  
 936 and the Middle East from global and regional (individual regions) emissions.  
 937

938  
 939 **Figure 14.** Percentage decrease in TFA deposition (dry and wet combined) by adding Criegee  
 940 intermediate chemistry to HFO-1234yf emissions over (a) India, (b) China, and (c) the Middle  
 941 East domains.  
 942
