Abstract: Rate coefficients for the reaction of NO₃ radicals with a series of aromatic aldehydes were measured in a 7300-liter simulation chamber at ambient temperature and pressure by relative and absolute methods. The rate coefficients for benzaldehyde (BA), ortho-tolualdehyde (O-TA), meta-tolualdehyde (M-TA), para-tolualdehyde (P-TA), 2,4-dimethyl benzaldehyde (2,4-DMBA), 2,5-dimethyl benzaldehyde (2,5-DMBA) and 3,5-dimethyl benzaldehyde (3,5-DMBA) were: $k_1 = 2.6 \pm 0.3$, $k_2 = 8.7 \pm 0.8$, $k_3 = 4.9 \pm 0.5$, $k_4 = 4.9 \pm 0.4$, $k_5 = 15.1 \pm 1.3$, $k_6 = 12.8 \pm 1.2$ and $k_7 = 6.2 \pm 0.6$, respectively, in the units of $10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at $298 \pm 2 \text{ K}$. The rate coefficient k_{13} for the reaction of the NO₃ radical with deuterated benzaldehyde (benzaldehyde-d₁) was found to be half that of k_1 . The end product of the reaction in an excess of NO₂ was measured to be C₆H₅C(O)O₂NO₂. Theoretical calculations of aldehydic bond energies and reaction pathways indicate that NO₃ radical reacts primarily with aromatic aldehydes through the abstraction of an aldehydic hydrogen atom. The atmospheric implications of the measured rate coefficients are briefly discussed.

40

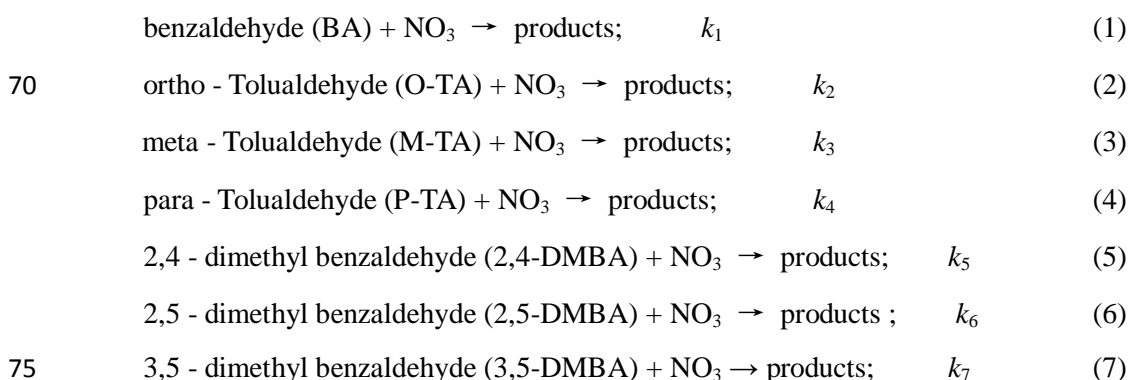

Keywords: rate coefficient, NO₃ radical, aromatic aldehydes, mechanism

1. Introduction

Aromatic aldehydes are a family of organic compounds emitted into the atmosphere from anthropogenic and pyrogenic sources. For example, benzaldehyde (BA) has been detected in the incomplete combustion of fuels (Legreid et al., 2007). Methylated benzaldehydes (ortho, meta, para-tolualdehydes) are present in wood smoke and biomass burning plumes (Koss et al., 2018). Benzaldehyde also has extensive industrial usage in perfume, soap, food and drink production, and as a solvent for oils and resins (OECD, 2002). Benzaldehyde and ortho/meta/para-tolualdehyde could also be formed from the atmospheric degradation of aromatic hydrocarbons, although their yields in the atmosphere are expected to be small (Calvert et al., 2002; Obermeyer et al., 2009).

It is known that the tropospheric removal of aromatic aldehydes occurs through photolysis (Clifford et al., 2011; Thiault et al., 2004) and their reactions with the OH radical. During daytime, photolysis and reaction with OH dominate the atmospheric loss of the aromatic aldehydes. (We assume that the aromatic aldehydes photodissociate akin to aliphatic aldehydes) Yet, oxidation of aromatic aldehydes via their reaction with the nitrate radical, NO₃, may be important in NO_x-rich locations at night since both the aromatic aldehydes and the nitrate radical can arise from anthropogenic emissions and biomass burning. Therefore, aromatic aldehydes can be degraded at night with consequences for ozone and secondary organic aerosol (SOA) formation. The reactions of aromatic aldehydes with NO₃ likely lead to acyl peroxy nitrates (APNs, often referred to as PANs) in the NO_x-rich regions with characteristically high NO₃ abundances. The APNs would then transport nitrogen oxides and the aromatic moieties from the polluted to cleaner parts of the globe (Wayne, 2000), with consequences for ozone production and particle formation away from the polluted regions. Therefore, quantifying the kinetics and understanding the mechanism of the reaction of NO₃ with aromatic aldehydes is needed.

In this study, the rate coefficients k_1 - k_7 at 298 K for the reactions of NO₃ radical with the following seven aromatic aldehydes were measured:

The rate coefficient for Reaction (1) has been previously reported by Carter et al. (1981),

Atkinson et al. (1991), Clifford et al. (2005), and Bossmeyer et al. (2006). The rate coefficients for Reactions 2-4 were reported only by Clifford et al. (2005). There are no previous reports on k_5 - k_7 , to the best of our knowledge. The results from earlier studies are compared with our data in the section of Results and Discussions.

We report the rate coefficients at 298 K for the above reactions, and we have determined the stable products formed in Reaction (1). We also have attempted to elucidate the mechanism of these reactions via studies of isotopic substitution, quantum chemistry calculations, and an examination of the linear free energy relationship.

2. Experimental setup and procedures

The kinetics and products were studied in a 7300-liter indoor simulation chamber described in detail previously (Zhou et al., 2017); therefore, it is described only briefly here. The chamber was made of Teflon foil. Two Teflon fans located inside the chamber rapidly mixed the contents of the chamber within about 30 s. Purified air was used as a bath gas and to flush the chamber to clean it in between experiments. Upon flushing, the levels of NO₂ and O₃ were less than 50 pptv (detection limit of our instruments). A proton transfer reaction time-of-flight mass spectrometer (PTR-TOF-MS) and a Fourier transform infrared spectrometer (FT-IR, Nicolet 5700) coupled to a White-type multipass cell (143 m optical path length) were employed to monitor the organic compounds in the chamber. The white cell was located within the chamber. An inlet situated in the center of the chamber fed the PTR-ToF-MS. The masses in PTR-ToF-MS and IR bands in the FTIR used to measure the aldehydes are listed in the SI (Table S1). The PTR-ToF-MS and/or FTIR signals were measured by expanding a known mass of liquid aldehyde in to the chamber to determine hydrocarbons concentrations. Calibration plots for the quantification of the aromatic aldehydes and the reference gases were constructed using these measurements. They are shown in Figure S1 in the SI. The concentrations of NO₃ and N₂O₅ were determined using a cavity ring down spectrometer (CRDS). The NO₃ radical was detected using its strong 662 nm absorption. The sum of NO₃ and N₂O₅ were detected simultaneously by thermally dissociating N₂O₅ in a second channel. The time resolution of CRDS was 1s, and detection limits for NO₃ and N₂O₅ were approximately 0.5 pptv (1.23×10^7 molecule cm⁻³ at atmospheric pressure) for a 5 s integration (Brown et al., 2002; Dub  t et al., 2006). NO₃ radicals were generated from the thermal decomposition of N₂O₅ in the chamber.

2.1 Rate coefficient measurements

Relative Method: The temporal profiles of a reference compound and the aromatic aldehyde

of interest were monitored simultaneously using the PTR-TOF-MS and/or FTIR in the
115 presence of NO₃ radical.

120 We accounted for the dilution of the chamber necessitated by the addition of air to keep
the pressure constant while we continually withdrew the chamber's contents for analysis.
Similarly, we also accounted for the depletion of the hydrocarbons due to the loss to the walls.
The two processes together are represented as a first-order loss process with a rate coefficient
 k_d :

125 aromatic aldehydes/references \rightarrow wall loss/dilution; k_d

Above, k_{1-7} and k_{ref} are the rate coefficient for the reaction of NO₃ with studied aromatic
aldehydes (BA, O-TA, M-TA, P-TA, 2,4-DMBA, 2,5-DMBA, and 3,5-DMBA) and the
130 reference compound (methyl methacrylate, MMA), respectively. The dilution rate coefficient
was measured by adding a small amount of unreactive SF₆ into the chamber and monitoring
its temporal decay. We quantified the rate coefficient (ranging from $5.5 \times 10^{-7} \text{ s}^{-1}$ to $1.6 \times 10^{-6} \text{ s}^{-1}$)
for the removal of the aldehydes and reference compound due to loss on the walls by
monitoring their decay in the absence of the NO₃ reactant

135 The typical experimental procedure for relative rate measurements consisted of a
sequence of three steps: (1) SF₆ was added at the beginning of the experiment and monitored
to measure the dilution rate. During this time, as noted above, air was continually added to
make up for the loss due to the withdrawal for analysis; (2) VOCs (aromatic aldehydes,
reference compounds) were introduced into the chamber and monitored for roughly 30
140 minutes to obtain k_d ; and (3) N₂O₅ was then continually introduced to the chamber using pure
air as a carrier gas, and the consumption of VOCs was monitored using PTR-TOF-MS for 1-2
hours. The typical initial VOC concentrations were $(0.9-4.5) \times 10^{12} \text{ molecule cm}^{-3}$ (Table S2).
Typical NO₃ concentrations were $(0.25-2.5) \times 10^9 \text{ molecule cm}^{-3}$.

Assuming that the aromatic aldehydes and reference compounds were lost by reaction
145 with NO₃ radical and dilution/loss to the walls, it can be shown that:

$$\ln\left(\frac{[\text{aro}]_0}{[\text{aro}]_t}\right) - k_d \times t = \left(\frac{k_{1-7-RR}}{k_{\text{ref}}}\right) \times \left[\ln\left(\frac{[\text{ref}]_0}{[\text{ref}]_t}\right) - k_d \times t\right] \quad \text{I}$$

Where $[\text{aro}]_0$ and $[\text{aro}]_t$, and $[\text{ref}]_t$ and $[\text{ref}]_0$, are the corresponding concentrations of aromatic

150 | aldehydes and reference compound at the initial time and time t, respectively. According to Equation I, plots of $\{\ln(\frac{[aro]_0}{[aro]_t}) - k_d \times t\}$ against $\{\ln(\frac{[ref]_0}{[ref]_t}) - k_d \times t\}$ are straight lines of slope equal to k_{1-7}/k_{ref} , with zero intercepts.

155 | **Absolute method:** Experiments were conducted in the same 7300-liter simulation chamber described in the previous section. The temporal profiles of NO₃ and N₂O₅ were measured using CRDS in an excess of each aromatic aldehyde (Zhou et al., 2017). They were simultaneously fit to a reaction scheme (see below) to extract the reaction rate coefficient as described by Zhou et al. (2017). The typical experimental procedure consisted of the following steps: (1) N₂O₅ was introduced with pure air into the chamber, and the temporal
160 | profiles of NO₃ and N₂O₅ concentrations were measured to determine the rate coefficient for loss of NO₃ and N₂O₅ to the walls, reactions with impurities, and dilution; (2) The aromatic aldehyde of interest was introduced while continually measuring the temporal profiles of NO₃ and N₂O₅; and (3) SF₆ was introduced to determine the dilution rate when needed.

165 | A box model was used to integrate Reactions (1-11) to obtain the rate coefficients of NO₃ radical reaction with aromatic aldehydes. The obtained temporal profiles of NO₃ and N₂O₅ concentrations were fit to the observed profiles using a non-linear least squares algorithm.

175 | In the algorithm, the sum of squares the difference between calculated and measured values of both the NO₃ and N₂O₅ were minimized while varying the input parameters. In the absence of the aldehydes, the input parameter was just k_d . The value of k_d obtained was then held constant when subsequently fitting the second set of temporal profiles where the rate coefficient for reactions (1)-(7) was varied. The other input parameters included the measured initial concentration of NO₃ ([NO₃]₀), N₂O₅ ([N₂O₅]₀), and the initial aromatic aldehydes ([aro]₀) as well as the temperature-dependent values of k_8 and k_9 (to define the equilibrium
180 | constant (K_{eq})). We used the equilibrium constant for the reaction: $\text{NO}_3 + \text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_5$ recommended by Burkholder et al. (2015). The NO₂ concentration was calculated through the equilibrium constant and measured concentrations of NO₃ and N₂O₅ throughout the course of the reactions; i.e., $[\text{NO}_2] = [\text{N}_2\text{O}_5] / ([\text{NO}_3] \times K_{eq})$ and used in the fits. Such calculated temporal profiles of NO₃ and N₂O₅ were fit to the measured temporal profiles at various concentrations
185 | of the aldehydes. As shown in Table S3, the concentration of aromatic aldehyde was always

50-1500 times higher than that of NO₃ in the chamber at all times. Thus NO₃ loss was essentially first order in its concentration.

2.2 Chemicals

190 The aromatic aldehydes were purchased from Sigma-Aldrich. The stated purities of these chemicals were: benzaldehyde (≥ 99.5%), O-TA (97%), M-TA (97%), P-TA (≥ 97%), 2,4-DMBA (≥ 90%), 2,5-DMBA (99%)₂ and 3,5-DMBA (97%). Methyl methacrylate was bought from TCI. The chemical purity of benzaldehyde- α -d1 was 99%₂ while its isotopic purity was 98%. All the aldehydes (in liquid form) were further purified by repeated
195 freeze-pump-thaw cycles before use. Substantial concentrations of reactive impurities were not detected in these samples based on the PTR-TOF-MS/FTIR measurements. A mixture of NO₂ and O₃ was flowed into a 1-liter bulb to generate N₂O₅ through Reactions 12 and 8.

200 The N₂O₅ crystals were collected in a cold trap (190 K) and purified by trap-to-trap distillation in a mixture of O₂/O₃. N₂O₅ was stored in a cold trap maintained at 190 K.

3. Results and Discussion

3.1 Rate coefficients determination of NO₃ reaction with a series of aromatic aldehydes

205 In the study, we measured the rates coefficients k_1 - k_7 using a relative method and an absolute method. They are outlined separately below for ease of presentation.

3.1.1 Relative method

Methyl methacrylate, MMA, was used as the reference compound in this work because the
210 rate coefficient at 298 K for its reaction with NO₃ radical has been measured in the same chamber using the same method as here (Zhou et al., 2017) to be $k_{\text{MMA}} = (2.98 \pm 0.35) \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. We acknowledge that there are other recommendations that are slightly higher than the value we used. One can always renormalize the rate coefficient for any specific value. The experimental conditions and associated parameters are shown in Table S2.

215 Figure 1 shows plots of $\{\ln(\frac{[aro]_0}{[aro]_t}) - k_d \times t\}$ against $\{\ln(\frac{[ref]_0}{[ref]_t}) - k_d \times t\}$ for the seven aromatic aldehydes. Each plot is linear with an intercept of zero within the uncertainties. The $k_d \times t$ term is relatively small (3.6-7.6%) compared to the ratio $\{\frac{k_d \times t}{\ln(\frac{[aro]_0}{[aro]_t}) \text{ or } \ln(\frac{[ref]_0}{[ref]_t})}\}$, and slight
variations in its value do not affect the accuracy of the measured rate coefficients. Figure 1 also shows that the measured values of the rate coefficient ratios are reproducible. The ratios of
220 rate coefficients, $\frac{k_{1,7}}{k_{ref}}$, were calculated from these plots using the algorithm of Brauers and

Finlayson-Pitts (1997), which takes into account errors in both the abscissa and ordinate. These errors were estimated from the uncertainty of the concentration calculated from the calibration plots generated before the kinetics runs. The noted errors for $\frac{k_{1,7}}{k_{ref}}$ are twice the standard deviation in the least-squares fits multiplied by a factor to account for the limited number of measurements using the Student *t*-distribution.

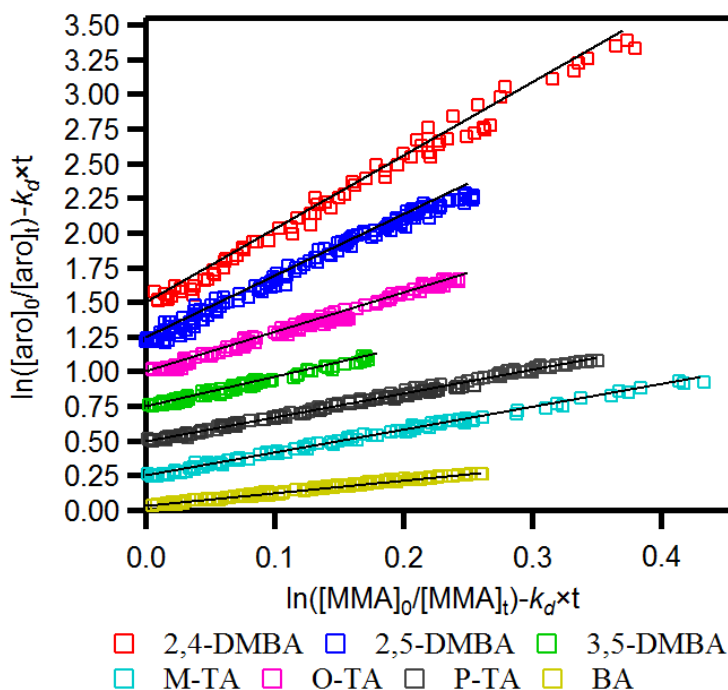

Figure 1. Plots of relative kinetic data obtained from the reaction of aromatic aldehydes (aro) with NO₃ radical using methyl methacrylate (MMA) as the reference. M-TA, P-TA, 3,5-DMBA, O-TA, 2,5-DMBA and 2,4-DMBA were shifted 0.25, 0.5, 0.75, 1.0, 1.25, and 1.5, respectively, for clarity.

The relative rate coefficients of the studied aromatic aldehydes, termed k_{RR} , are shown in Table S2. The estimated uncertainties for k_{RR} were the sum of the precision of our measurements (noted above) and the quoted uncertainties in the rate coefficient for the reference reaction according to the expression:

$$\sigma(k_{RR}) = \frac{k}{k_{ref}} \times k_{ref} \sqrt{\left[\frac{\sigma_{k_{ref}}}{k_{ref}}\right]^2 + \left[\frac{\text{error}}{k_{ref}}\right]^2}$$

3.1.2 Absolute method

The method used to analyze the temporal profiles of NO₃ and N₂O₅ to obtain k_1 - k_7 has been

described by Zhou et al. (2017;2019). Figure 2 shows an example of the temporal profiles of NO_3 and N_2O_5 for Reaction (1) from which the rate coefficient k_1 was derived. Similar analyses yielded k_2 - k_7 (Figure S2-7).

245 Panel (a) of Figure 2 shows the temporal profile of NO_3 and N_2O_5 concentrations plotted on a logarithmic scale. The concentrations decrease exponentially (the lines are linear in the log-space), and the decay rates are lower in the absence of the reactant aldehyde than in its presence. The rate coefficients for the loss of NO_3 and N_2O_5 to the walls and dilution, k_{10} and k_{11} , were determined to be in the ranges $(3.7\text{-}7.1)\times 10^{-3} \text{ s}^{-1}$ and $(3.2\text{-}12.0)\times 10^{-4} \text{ s}^{-1}$, respectively. As Zhou et al. (2017) [explained](#), we cannot merely take the slopes of decay of NO_3 with time
250 to calculate the rate coefficients k_1 - k_7 since NO_3 and N_2O_5 are coupled through their equilibrium. The equilibration is maintained throughout the course of Reactions (1)-(7). To account for this situation, we fit the profiles of both NO_3 and N_2O_5 to a reaction scheme, as described previously.

255 Panels (b) and (c) of Figure 2 show the NO_3 and N_2O_5 temporal profiles on a linear scale in the absence and the presence of the reactant aldehyde. The two panels also show the [fits of the data](#) to the mechanism that included only Reactions (1)-(11). The fits are acceptable but with larger variations at longer reaction times. We have to consider the contributions to NO_3 and N_2O_5 losses due to the reactions of NO_3 with the products of the Reactions (1)-(7). Values of the rate coefficients derived from such fits included all the potential reactions that can
260 contribute to the removal of NO_3 , and they are shown in the SI (Table S4). When the secondary reactions with the products were included, the fits were better at the longer reaction times, and they are shown in [Panel \(d\)](#) of Figure 2. The residuals of the fits are shown at the bottoms of [Panel \(c\)](#) and (d); they clearly show the improvement in the fits and the lack of a trend with reaction time. Larger deviations are to be expected in [Panel \(c\)](#) at longer reaction
265 times as the reaction [products](#) build up. The rate coefficients k_1 - k_7 calculated using the reaction scheme shown in Table S4 are taken to be those measured by the direct method. As expected, the rate coefficients calculated by including the contributions of the secondary reactions were slightly less than those without the secondary reaction contributions (see
Figure S8). The differences were, on average, about 5%.

270

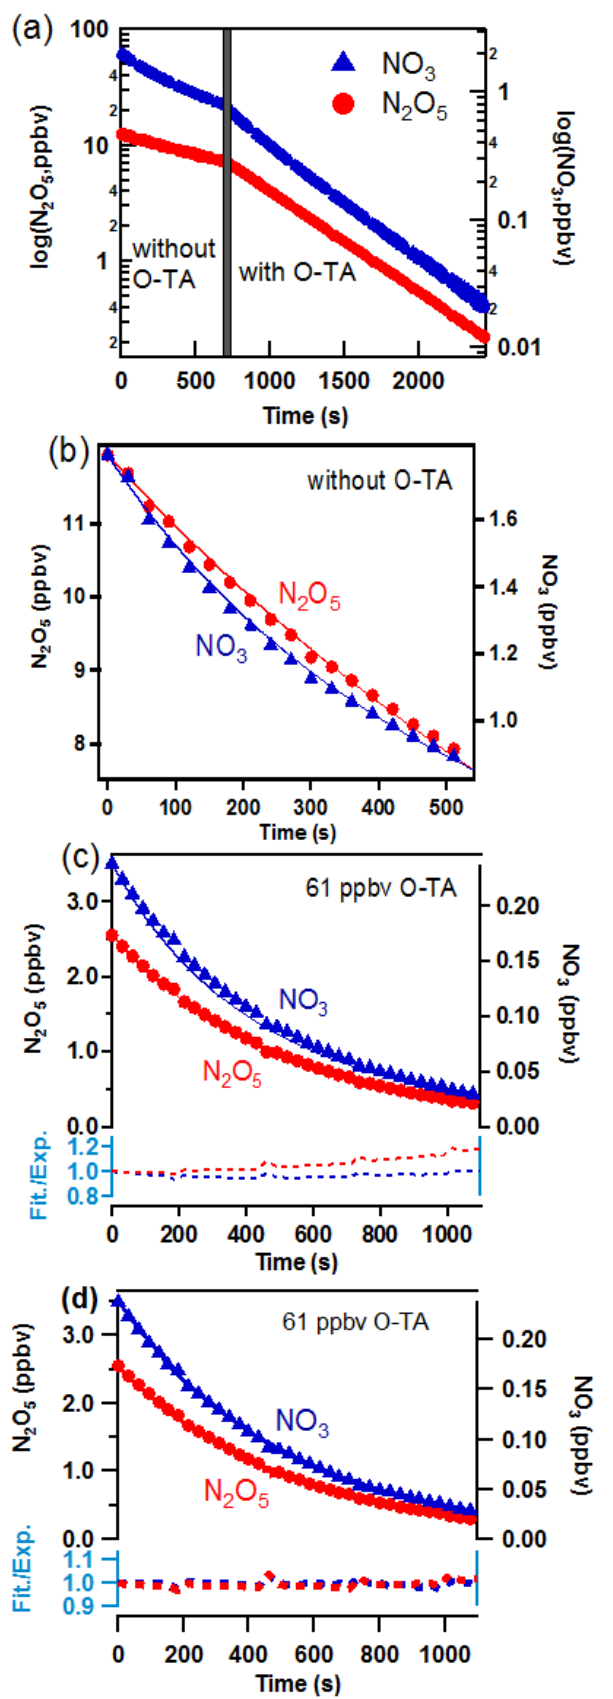

Figure 2 Observed (points) and simulated (lines) profiles of N_2O_5 (left axis) and NO_3 (right axis) as a function of time. Mixing ratios of o-tolualdehyde are shown in each Panel. Panel (a): the temporal profiles on a log scale. Panel (b): Temporal profiles on a linear scale and the fits

275 | to the data as discussed in the text [to determine the wall loss of N₂O₅ and NO₃ during the experiment](#). Panel (c): Fits of simulations not including the subsequent secondary reactions of NO₃ with the products of the initial reaction. The dash lines at the bottom show the ratio of simulated lines to measured data points (Fit./Exp.) for NO₃ (blue) and N₂O₅ (red). Panel (d): Fits of simulations including the subsequent secondary reactions of NO₃ with the initial
280 | reaction products (shown in Table S4). The dash lines at the bottom show the ratio of simulated lines to measured data points (Fit./Exp.) for NO₃ (blue) and N₂O₅ (red). The improvements in the fits are clear in [Panel](#) (d).

The results of our measured values for k_{1-7} are summarized in Table S3. The quoted
285 | errors of the rate coefficient from each experiment are at the 95% confidence level based on the precision of the fits; they were typically less than 7%. The weighted averages of results from multiple experiments were calculated, and then the influence of the small number of measurements [was](#) accounted for by using a Student *t*-distribution table. We added the estimated systematic uncertainties to the precision in quadrature, assuming that they are
290 | uncorrelated. Contributions to estimated systematic errors included: (1) The systematic errors of -8/+11% and -9/+12%, respectively, in the measurements of NO₃ and N₂O₅ (Zhou et al., 2019); (2) The uncertainty of around 10% in the rate coefficients used in the reaction schemes shown in Table S4; and (3) The estimated uncertainty of 7% in the concentration of aromatic aldehydes. This includes the uncertainties in the calibration and spectral analysis. All the
295 | noted uncertainties are at the 95% confidence level, assuming a Gaussian error distribution.

It is important to note that we need the absolute concentrations of NO₃ and N₂O₅ even though the reaction was first order in NO₃ due to the strong coupling between the concentrations of NO₃ and N₂O₅ via an equilibrium. The presence of the aldehydes would influence the temporal profiles of both N₂O₅ and NO₃. Here we are attributing the entire
300 | change to the reaction of NO₃ with the aldehydes. The validity of this assumption is shown by the measured rate coefficients being independent of the ratio of [NO₃]/[N₂O₅]. This ratio was changed simply by changing [NO₂] that shifts the equilibrium concentrations of NO₃ and N₂O₅.

305 | **3.1.3 Comparison of Rate coefficients obtained from absolute and relative methods**

The rate coefficients for the reactions of NO₃ with [seven](#) different aromatic aldehydes, k_1-k_7 , measured using the absolute and relative methods are summarized in Table 1. The rate coefficient values from the two methods are in good agreement with each other. The differences are less than 10%, except for k_1 , which differs by 18%.

310 | As shown in Table [2](#), the final rate coefficients of 7 aromatic aldehydes reaction with NO₃ radical were derived from the weighted average of the absolute and the relative rate

methods, using the equation discussed above (Eq. S2 and Eq. S3).

Table 1. Rate coefficients k_1 - k_7 measured in the study using two different methods.

3.1.4 Comparison with the literature for NO₃ radical kinetic with aromatic aldehydes

Table 2 summarizes the rate coefficients measured in this work with data from the literature for the reactions of the NO₃ radical with aromatic aldehyde, BA, O-TA, M-TA, P-TA, 2,4-DMBA, 2,5-DMBA, and 3,5-DMBA. As shown in Table 2, the rate coefficient for BA has been reported by five studies. Three of them (Atkinson et al., 1984; Carter et al., 1981; Clifford et al., 2005) used the relative method with different reference compounds. Atkinson et al. (1991) corrected the values from their earlier report, and they are used for the comparison. Bossmeyer et al. (2006) measured both NO₃ and BA using differential optical absorption spectroscopy (DOAS) in their chamber. They measured the loss of BA in a known (measured continuously) NO₃ concentration and fitted BA's measured temporal profile to obtain k_1 . Calvert et al. (2011) recommended k_7 to be $4.0 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ with a 30% uncertainty based on these studies. However, our value from absolute and relative methods using methyl methacrylate as reference reaction (its rate coefficient has been determined using absolute method in our previous study (Zhou et al., 2017)) is in good agreement with Atkinson (1991) and Bossmeyer et al. (2006). Hence, we suggest that the weighted average based on these three studies, $2.6 \pm 0.3 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at $298 \pm 2 \text{ K}$, is a reliable value. The rate coefficients for ortho/meta/para-tolualdehyde have only been studied by Clifford et al. (2005), who reported them to be (9.8 ± 0.4) , (9.5 ± 0.4) and $(9.5 \pm 0.7) \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, respectively. In this work, k_1 - k_7 were determined relative to MMA as the reference as well as using an absolute method to be: $(8.5 \pm 1.0 \text{ \& } 9.1 \pm 1.2)$, $(5.1 \pm 0.6 \text{ \& } 4.7 \pm 0.6)$ and $(5.0 \pm 0.6 \text{ \& } 4.8 \pm 0.6) \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, respectively. This work agrees best with the value of Clifford *et al.* (2005) for ortho-tolualdehyde, but those of k_3 and k_4 are smaller than those of Clifford et al. (2005). The reasons for these discrepancies are unclear, but the excellent agreement (<7% difference) between the two techniques presented here gives us confidence in our determinations. This work provides the first experimental determinations of the rate coefficients for NO₃ reactions with 2,4-DMBA, 2,5-DMBA, and 3,5-DMBA, where the two complementary methods agree well. The recommended rate coefficients of the weighted average of relative method and absolute method are shown in Table 2.

355

3.2 Mechanisms of the reactions

3.2.1 Products investigation from the reaction of benzaldehyde with NO_3

The stable products formed in Reaction (1) were investigated at 298 ± 2 K and 760 Torr in the same 7300-liter simulation chamber. Benzaldehyde, $0.9\text{--}1.4 \times 10^{13}$ molecule cm^{-3} (as shown in Table S5), was introduced into the chamber, and its removal was measured for 2 hours to obtain the wall loss rate coefficient. Then, roughly $1.1 \times 10^{12}\text{--}1.5 \times 10^{14}$ molecule cm^{-3} of N_2O_5 was introduced. Stable products formed in the chamber were identified and quantified (when possible) using the PTR-TOF-MS and FTIR.

Two stable products, $\text{C}_6\text{H}_5\text{C}(\text{O})\text{O}_2\text{NO}_2$ (benzaldehyde-PAN; BAPAN) and $\text{C}_6\text{H}_5\text{ONO}_2$, were detected and measured. The former was detected using both PTR-TOF-MS (m/z 184.024 and its fragment m/z 105.034) and FTIR ($965\text{--}1005$ cm^{-1} centered at 989 cm^{-1}) and the latter using only PTR-TOF-MS. Since we do not have a sample of BAPAN, we could not quantify the yield of this product using PTR-TOF-MS. However, Caralp *et al.* (1999) have reported the IR band strengths for BAPAN. Using their reported band strength, we could quantify BAPAN to be $80 \pm 10\%$ of the benzaldehyde that was removed via reaction, where the quoted uncertainty is the precision in the fit at the 2σ level. When we account for the uncertainties in the absorption cross sections of BAPAN reported by Caralp *et al.* (1999) ($\sim 20\%$) and the uncertainties in the concentration of initial benzaldehyde concentration ($\sim 10\%$), and add the precision of the measurements, we conclude that the yield of BAPAN is $80 \pm 22\%$. We assume that the uncertainties are uncorrelated and hence added them in quadrature. The obtained BAPAN amounts are shown in Figure 3 as the function of benzaldehyde consumption; the details are shown in Table S6 in the SI. We could not quantify $\text{C}_6\text{H}_5\text{ONO}_2$ because of the lack of a standard. Assuming that the ion-molecule reaction rate coefficients for proton transfer to BAPAN and $\text{C}_6\text{H}_5\text{ONO}_2$ are similar, we estimate that the yield of $\text{C}_6\text{H}_5\text{ONO}_2$ is smaller than that of BAPAN. These two products are expected if the reaction proceeds via H atom abstraction, most of the peroxy radical reacts with NO_2 (Platz *et al.*, 1998) as denoted by the reaction scheme A:

(A)

A fraction of the peroxy radicals reacts with itself (or other peroxy radicals) to make the phenoxy radicals, which ultimately leads to a nitrate, according to the mechanism B:

390 Unfortunately, we could not reduce the concentration of NO_2 sufficiently to suppress pathway B completely. A small fraction of the $\text{C}_6\text{H}_5\text{C}(\text{O})\text{O}_2$ would also react with NO_3 but would still yield the $\text{C}_6\text{H}_5\text{C}(\text{O})\text{O}$ radicals. Also, any reactions of phenyl radical with NO_2 can be neglected because of the large abundance of O_2 that will quickly convert it to $\text{C}_6\text{H}_5\text{O}_2$ radical. Numerical modeling of the reaction sequence shown in the SI (Table S4) suggests that the

395 yield of BAPAN is more than 95% under our experimental conditions. Based on these results, we suggest the yield of BAPAN in our reaction system to be essentially 1 and that we detect the nitrate because of the high sensitivity for its detection in our PTR-TOF-MS.

Figure 3. A plot of benzaldehyde PAN ($\text{C}_6\text{H}_5\text{C}(\text{O})\text{O}_2\text{NO}_2$; BAPAN) concentrations measured by FTIR as a function of depletion of benzaldehyde. The slope of the plot gives the yield of the BAPAN in the NO_x -rich environment to be roughly $80 \pm 20\%$. Note: the different colors/markers presented the repeated experiments with different initial NO_2 concentrations as: red filled circles: $[\text{NO}_2]_0 = 1.4\text{-}2.9 \times 10^{12}$ molecule cm^{-3} , blue triangle: $[\text{NO}_2]_0 = \sim 2.7 \times 10^{13}$ molecule cm^{-3} , green square: $[\text{NO}_2]_0 = \sim 1.4 \times 10^{14}$ molecule cm^{-3} , red open diamond: $[\text{NO}_2]_0 = \sim 3.3 \times 10^{14}$ molecule cm^{-3} , filled red circles.

405

3.2.1 Kinetic Isotope Effect in the reaction

To further examine the mechanism of NO₃ reactions with the aromatic aldehydes, we measured the rate coefficient for the reaction of NO₃ radical with benzaldehyde- α -d1 (C₆H₅CDO):

As shown in Figure 4, k_{13} is half that of k_1 , i.e., k_1/k_{13} is 1.92. A factor of 2 decrease in the rate coefficient going from benzaldehyde to benzaldehyde- α -d1 is consistent with a primary kinetic isotope effect (KIE), suggesting that abstraction of the aldehydic H atom occurs in the rate-limiting step of this reaction pathway (See calculated KIE below).

Figure 4. The plot of the logarithm (base e) of the ratio of initial benzaldehyde-D1 concentration to those at other reaction times against the logarithm (base e) of the ratio of the initial benzaldehyde concentration relative to those at different times. Both benzaldehyde and benzaldehyde-D1 were competing for the same pool of NO₃ radicals. The slope of the plot is 0.53±0.01. The red and blue circles present two experiments with different concentrations of NO₃ radicals.

3.2.2 Reaction pathway

Linear free energy relationships comparing the reactivities of OH and NO₃ with a series of organic compounds are shown in the SI (Figure S9). Such correlations have been demonstrated in the past by Clifford et al. (2005). We have added our measured values of k_1 - k_7 to the plot. This plot suggests that the linear free energy relationship is consistent with NO₃

430 radicals adding to the seven aromatic aldehydes studied here. Even the reaction of OH
radicals with aliphatic aldehydes is known to proceed by forming a pre-reaction complex.

Figure 5 shows the rate coefficients for the reaction of the NO₃ radical with the seven
aldehydes studied here (also presented in Table 2), along with those with benzene and toluene
($<3 \times 10^{-17}$ and $<6.6 \times 10^{-17}$ cm³ molecule⁻¹ s⁻¹) (Calvert et al., 2011). Benzene and toluene do
435 not react with NO₃ to measurable extents; such reactions may be expected if they were
proceeding via electrophilic addition. Since it is not sufficiently reactive to abstract an H atom
from either the ring or the methyl group, the rate coefficient is very slow, if not zero.
Therefore, the observed reaction rate coefficients suggest that the reaction proceeds via an
H-atom abstraction from the -CHO group (Clifford et al., 2005; Wayne et al., 1991). The rate
440 coefficient for the reaction of NO₃ with benzaldehyde, $(2.6 \pm 0.3) \times 10^{-15}$ cm³ molecule⁻¹ s⁻¹, is
similar to that with acetaldehyde $(2.7 \pm 0.5) \times 10^{-15}$ cm³ molecule⁻¹ s⁻¹, as shown in Figure 5. The
mechanism for the reaction of NO₃ with acetaldehyde is believed to be H-atom abstraction
from the -CHO group after the formation of a pre-reaction complex.

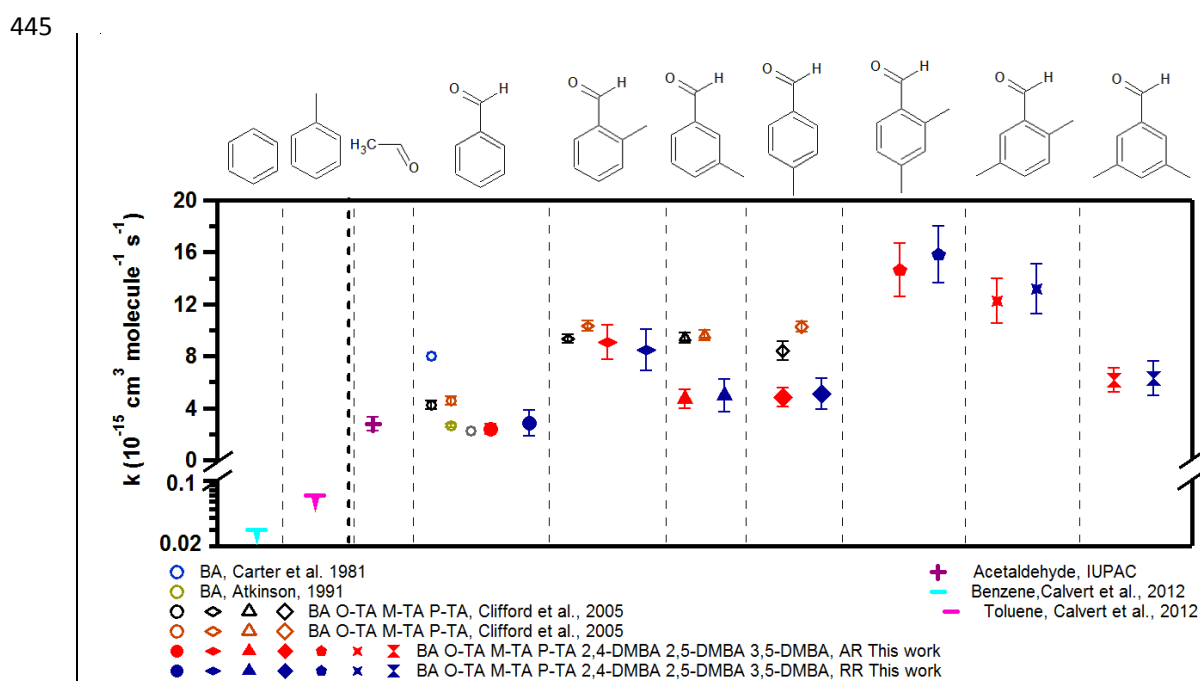

Figure 5 The measured rate coefficients for the reactions of NO₃ radical with the seven
aldehydes studied here. The results of previously reported rate coefficients are also shown
(values are presented in Table 2). The rate coefficient for acetaldehyde of
450 $k_{(\text{CH}_3\text{CHO})} = (2.7 \pm 0.5) \times 10^{-15}$ cm³ molecule⁻¹ s⁻¹ is from IUPAC recommendations. The rate
coefficients for benzene, $k_{(\text{benzene})} < 3 \times 10^{-17}$ cm³ molecule⁻¹ s⁻¹, and for toluene,
 $k_{(\text{toluene})} \leq 6.6 \times 10^{-17}$ cm³ molecule⁻¹ s⁻¹ are from Calvert et al., 2011. 88.4 90.2

As shown in Figure 5 ([also presented in Table 2](#)), this work finds a higher rate coefficient for the reactions of NO₃ with ortho/meta/para-tolualdehydes than that with benzaldehyde. This enhanced reactivity with ring substitution by electron-donating groups suggests an electrophilic role for NO₃ in the reaction. Clifford et al. (2005) noted that the direct influence of the electron-donation to the ring by the CH₃ group is effectively canceled out by the electron-withdrawing effect of the -CHO group as an explanation for their measured rate coefficients being the same for all the tolualdehydes. The trends we observe for [substituting](#) methyl groups in the tolualdehydes and the demethylated aldehydes could suggest electrophilic addition. Of course, the initial addition has to lead to the abstraction of the aldehydic H atom, as shown by the products and the kinetic isotope effect. Alternatively, the reactivity trend could simply be due to the C-H bond energy changes in the aldehydic group upon methyl substitution.

The C-H bond dissociation enthalpies (BDEs) of benzaldehyde and the three tolualdehydes have been obtained from Active Thermochemical Tables (ATcT). As opposed to traditional sequential thermochemistry, ATcT obtains enthalpies of formation by constructing, statistically analyzing, and solving a global thermochemical network (TN), which is formed by including experimental and theoretical determinations pertinent to the chemical species that are included in the network, as explained in more details elsewhere (Ruscic et al., 2004; Ruscic et al., 2005).

The results presented here are based on the most current ATcT TN (ver. 1.122x), obtained by further expanding prior (Bross et al., 2019; Zaleski et al., 2021) versions (1.122r and 1.122v) by including species of interest [in](#) the present study, as well as other ongoing [investigations](#). The current TN incorporates ~2,350 species, interconnected by ~29,000 experimental and theoretical determinations.

Typically, the insertion of a new chemical species in the TN begins by linking the new species to the already existing species via a provisional skeleton of theoretical isodesmic reactions computed using a standard set of mid-level composite calculations carried in-house, and currently consisting of W1 (Martin and de Oliveira, 1999; Parthiban and Martin, 2001), CBS-APNO (Ochterski et al., 1996), G4 (Curtiss et al., 2007), G3X (Curtiss et al., 2000), and CBS-QB3 (Montgomery et al., 1999, 2000). This is subsequently complemented by experimental and theoretical determinations from the literature and, when possible, additional state-of-the-art high-level composite calculations that can deliver sub-kJ mol⁻¹ accuracies. As the number and accuracy of additional determinations [grow](#), the dependence of the final result on the determinations spanning the initial skeleton diminishes and ultimately vanishes.

However, while the enthalpies of formation of gas-phase benzaldehyde and the three tolualdehydes are linked in the TN to their condensed phases, for which there are some thermochemically-relevant experimental data in the literature, the reported BDEs rely heavily on

the results of mid-level composite methods, given the paucity of literature on experimental or theoretical data involving the benzoyl and toluyl radicals and the prohibitively high cost of state-of-the-art high-level composite calculations for this size of species. Analogously, our attempts to expand the TN with dimethyl benzaldehydes and their related radicals were frustrated
495 | by a virtual absence of experimental and worthwhile theoretical data in the literature, combined with the high cost of theoretical calculations even using mid-level composite methods.

The ATcT BDEs of the aldehydic C-H in benzaldehyde and the three tolualdehydes are given at 298.15 K and 0 K in Table [S6](#), together with the corresponding enthalpies of formation of the parents and the related radicals. While only the 298.15 K BDEs are discussed
500 | below, the corresponding 0 K BDEs (a.k.a. D_0 values) are also given in the same table and are, as expected, approximately 6.3 kJ mol^{-1} (or $\sim 2.5 \text{ RT}$) lower. The ATcT uncertainties provided in Table [S6](#) correspond to 95% confidence intervals, following the standard in thermochemistry (Ruscic, 2014; Ruscic and Bross, 2019), and were obtained by using the full ATcT covariance matrix. Consequently, when the enthalpy of formation of the radical is
505 | highly correlated to that of the parent, as happens to be true in benzaldehyde and tolualdehydes, the uncertainty of the resulting BDE is perceptibly lower than the uncertainty that would be obtained by manually propagating the uncertainties of the individual enthalpies of formation in quadrature, since the latter summation assumes zero covariances.

The ATcT BDE of the aldehydic C-H in benzaldehyde is $\text{BDE}_{298}(\text{C}_6\text{H}_5\text{C}(\text{O})\text{-H}) = 380.10 \pm 0.84 \text{ kJ mol}^{-1}$. This is noticeably higher (by $6.77 \pm 0.84 \text{ kJ mol}^{-1}$) than the corresponding
510 | BDE of the prototypical aldehyde – acetaldehyde – for which the current version of the ATcT TN produces $\text{BDE}_{298}(\text{CH}_3\text{C}(\text{O})\text{-H}) = 373.37 \pm 0.29 \text{ kJ mol}^{-1}$ (essentially unchanged from the web-accessible value in the earlier ATcT TN ver. 1.122p (Ruscic and Bross, 2020)).

Of particular relevance here is the fact that the aldehydic C-H BDEs in meta- and para-tolualdehyde, $\text{BDE}_{298}(\text{m-CH}_3\text{C}_6\text{H}_4\text{C}(\text{O})\text{-H}) = 379.93 \pm 1.13 \text{ kJ mol}^{-1}$ and
515 | $\text{BDE}_{298}(\text{p-CH}_3\text{C}_6\text{H}_4\text{C}(\text{O})\text{-H}) = 379.85 \pm 1.13 \text{ kJ mol}^{-1}$, are indistinguishable (within the uncertainty) from each other and when compared to the BDE in benzaldehyde. However, in ortho-tolualdehyde, the corresponding BDE is consistently lower essentially by 4.2 kJ mol^{-1} , $\text{BDE}_{298}(\text{o-CH}_3\text{C}_6\text{H}_4\text{C}(\text{O})\text{-H}) = 376.09 \pm 1.13 \text{ kJ mol}^{-1}$, lower by $3.85 \pm 1.00 \text{ kJ mol}^{-1}$ than that
520 | of meta-tolualdehyde, $3.76 \pm 1.00 \text{ kJ mol}^{-1}$ than that in para-tolualdehyde, and $4.01 \pm 0.92 \text{ kJ mol}^{-1}$ than that in benzaldehyde. Therefore, the likely origin of the reactivity differences is simply due to the bond enthalpies in the abstraction of aldehydic H atoms.

Based on the discussion above, it appears that the preponderance of the evidence is
525 | consistent with the abstraction of the aldehydic H atom. However, could such an abstraction reaction start via the addition of NO_3 to the ring followed by abstraction? To examine this possibility, we carried out quantum mechanical calculations of the reaction pathways in

Reaction (1). Stationary points on the potential energy surface (PES) were optimized with the BH&HLYP density functional and 6-311G(d,p) basis set in Gaussian 16 (Becke, 1993; Frisch et al., 2016), except for the NO₃ radical, for which the MP2-D3h geometry was used. This level of theory and empirical treatment of NO₃ follows Boyd's computational studies with smaller aldehydes, XCHO (X = H, F, Cl, Me) (Mora-Diez and Boyd, 2002). Single point energies were evaluated at the DLPNO-CCSD(T)/cc-pVTZ level of theory with tight SCF convergence and TightPNO cutoffs in Orca (Neese, 2012; Riplinger and Neese, 2013; Riplinger et al., 2013). Relative energetics with this basis set are essentially converged, since the effect of using cc-pVQZ on the activation barrier is less than 1 kJ mol⁻¹. The calculated PES is shown in Figure 6. Computed enthalpic and Gibbs energy changes include unscaled vibrational zero-point energies and translational, rotational, and vibrational contributions at 298.15 K (Luchini et al., 2020).

540

Figure 6. Pathways for the reaction between BA and NO₃ calculated using DLPNO-CCSD(T)/cc-pVTZ//BH&HLYP/6-311G(d,p). Enthalpic and Gibbs energy values are in kJ/mol. Key distances in Å.

545

The computed reaction pathways show that the NO₃ radical can form a dearomatized σ -adduct (Figure 6, LHS). The most stable of these adducts (by more than 10 kJ mol⁻¹) occurs at the *para*-position. While this complexation is exothermic, it is endergonic by 17.0 kJ mol⁻¹ due to unfavorable entropic effects, implying this is a readily reversible process. H-atom transfer first forms a pre-reaction complex with the aldehydic group. This complex can undergo H-atom abstraction to yield the stable products observed in our experiments. Application of the Bigeleisen-Meyer equation to this H-atom transfer transition structure (TS) results in a computationally predicted primary KIE of 2.16 (2.17 with Bell's 1D-tunneling

550

correction) (Bigeleisen and Mayer, 1947; Paton, 2016; Rzepa, 2015). This value is almost
555 identical to the measure KIE of 1.92.

Based on this evidence, we suggest that the reactions of NO₃ with aromatic aldehydes
lead to the abstraction of the aldehydic H-atom. The cleavage of the aldehydic C-H bond in
this step is consistent with the observation that a weaker BDE value is correlated with a larger
reaction rate of Reaction (1). CBS-QB3 calculations (SI) imply 2,4-DMBA and 2,5-DMBA,
560 like O-TA, have weaker aldehydic C-H bonds than the other aromatic aldehydes that lack an
ortho-substituent. Since the geometry of the formyl radical is more linear than the aldehyde
(the C-C-O angle increases by around 4 ° upon H-atom abstraction), steric strain relief is likely
a contributing factor to the C-H bond weakening by an ortho-methyl substituent. Additionally,
charge transfer of 0.22e from BA to NO₃ occurs in the computed H-atom transfer TS,
565 consistent with the observation that additional electron-donating substituents, such as methyl
groups, promote Reaction (1). To sum up, the combination of the changes in the C-H bond
energies and the changes in the variations in the initial addition to form a pre-reaction
complex contributed to the observed reactivity trend.

There are potential future experiments that could shed light on the proposed reaction
570 pathway. They include: (1) measurement of the temperature dependence of the reaction rate
coefficient; (2) investigating the influence of various isotopic substitutions (e.g., OD reaction
studies); (3) studying further substitution of the aromatic ring, for example, with fluorine; and
(4) directly detecting the radical formed in the reaction. Further quantum calculations may
also be useful.

575

4. Atmospheric Implications

Once emitted from biomass burning and incomplete fuel burning to the atmosphere, the
studied aromatic aldehydes would be removed through photolysis and reactions with reactive
species such as OH, NO₃ and chlorine atoms. The atmospheric lifetimes of the aromatic
580 aldehydes studied in this work have been calculated with respect to the NO₃ radical reactions
using the rate coefficients, k_{aro} , obtained from this work at ambient temperature and pressure,
in combination with estimated ambient tropospheric NO₃ concentrations, $[\text{NO}_3] = 5 \times 10^8$
molecules cm⁻³, (Atkinson, 1991) following the equation: $\tau_{\text{NO}_3} = 1/(k_{\text{VOC}} \times [\text{NO}_3])$. It has been
pointed out (Brown and Stutz, 2012) that the NO₃ radical concentration is highly variable, as
585 pointed out by and we use this value to illustrate the relative loss rates. The calculated
lifetimes are shown in Table 3, and they are meant only to compare the loss rates roughly.
Actual lifetime needs to be calculated for the location and its condition; it can vary by orders
of magnitude from those noted in the table. Based on our measurements, we expect that the
aromatic aldehydes' atmospheric lifetimes with respect to NO₃ are 37-218 hours (for the

590 | assumed NO₃ concentrations). Table 3 also presents the lifetime of these seven aromatic
aldehydes with respect to OH radicals of 1×10^6 molecules cm⁻³ (again a rough value
characteristic of the mid-tropospheric tropical regions) and Cl atoms (Wingenter et al., 1996)
of 1×10^4 atoms cm⁻³, and the rate coefficients taken from Calvert et al. (2011). It is clear that
595 | photolysis dominates, and OH radicals contribute more than Cl atoms to oxidation the
aromatic aldehyde in the atmosphere during the daytime. Though NO₃ reactions contributed
much less on a diurnally averaged basis, they are the only pathways for the degradation of
these aldehydes at night. The NO₃ reactions can contribute significantly to removing the
aromatic aldehydes at night in a polluted area with high NO_x. They also can form products
such PAN-type compounds to a larger extent than in the daytime degradation.

600

Table 3. Summary of rate coefficients and estimated atmospheric lifetimes of benzaldehyde (BA), o-tolualdehyde (O-TA), m-tolualdehyde (M-TA), p-tolualdehyde (P-TA), 2,4-dimethylbenzaldehyde (2,4-DMBA), 2,5-dimethylbenzaldehyde (2,5-DMBA), and 3,5-dimethylbenzaldehyde (3,5-DMBA) with respect to their reactions with OH, NO₃, and Cl at 298 ± 2 K and atmospheric pressure ^aFor comparison, the rough photolysis lifetimes are also noted for roughly 40N during summer.

| | Rate coefficients (cm ³ molecule ⁻¹ s ⁻¹) | | | Lifetime (hours) | | | |
|--------------|---|----------------------------------|----------------------------|--------------------|----------------------|--------------------|--------------------|
| | k_{OH}^{b} | $k_{\text{NO}_3}^{\text{c}}$ | k_{Cl}^{b} | τ_{OH} | τ_{NO_3} | τ_{Cl} | τ_{hv} |
| BA | 1.26 × 10 ⁻¹¹ | 2.6 × 10 ⁻¹⁵ | 9.90 × 10 ⁻¹¹ | <u>2.2-22</u> | <u>217</u> | 281 | <u>~2</u> |
| O-TA | 1.89 × 10 ⁻¹¹ | 8. <u>7</u> × 10 ⁻¹⁵ | 1.86 × 10 ⁻¹⁰ | <u>1.5-15</u> | <u>64</u> | 149 | <u>~2</u> |
| M-TA | 1.68 × 10 ⁻¹¹ | 4. <u>9</u> × 10 ⁻¹⁵ | 1.71 × 10 ⁻¹⁰ | <u>1.7-17</u> | <u>114</u> | 162 | <u>~2</u> |
| P-TA | 1.68 × 10 ⁻¹¹ | 4.9 × 10 ⁻¹⁵ | 1.41 × 10 ⁻¹⁰ | <u>1.7-17</u> | <u>113</u> | 197 | <u>~2</u> |
| 2,4-DMB A | 3.12 × 10 ⁻¹¹ | 1.51 × 10 ⁻¹⁴ | 8.70 × 10 ⁻¹¹ | <u>0.9-9</u> | <u>37</u> | 319 | <u><2</u> |
| 2,5-DMB A | 3.15 × 10 ⁻¹¹ | 1. <u>28</u> × 10 ⁻¹⁴ | 9.30 × 10 ⁻¹¹ | <u>0.9-9</u> | 43 | 299 | <u><2</u> |
| 3,5-DMB A | 2.78 × 10 ⁻¹¹ | 6.2 × 10 ⁻¹⁵ | 9.30 × 10 ⁻¹¹ | <u>1-10</u> | <u>89</u> | 299 | <u><2</u> |

^a We show a range of lifetimes by assuming [OH] = 1-10 × 10⁶ molecules cm⁻³, [NO₃] = 5 × 10⁸ molecules cm⁻³ (Atkinson et al., 1991), and [Cl] = 1 × 10⁴ (Wingenter et al., 1996). ^b The rate coefficients for the OH and Cl atom reactions are from Calvert et al. (2011). ^c recommended values in Table 2.

This work also found that the aromatic PAN-type compound, for example, was the main product formed from the reaction of aromatic aldehydes with NO₃ radical. The formation of such compounds enables the transport and release of NO_x to the remote troposphere, leading to the production of O₃. Such a situation may occur in wildland fire plumes.

Data availability
