13 **Abstract**

14 New particle formation (NPF) is a large source of cloud condensation nuclei (CCN) and cloud
15 droplet in the troposphere. In this study, we quantified the contribution of NPF to cloud droplet number
16 concentration (CDNC, or N_d) at typical updraft velocities (V) in clouds using a field campaign data of
17 aerosol number size distribution and chemical composition observed on May 25-June 18, 2017 in
18 urban Beijing. We show that the NPF drives the variations of CCN and cloud droplet and increases N_d
19 by 30-33% at $V=0.3-3\text{ m s}^{-1}$ in urban atmosphere. A markedly reduction in N_d is observed due to water
20 vapor competition with consideration of actual environmental updraft velocity, decreasing by $11.8\pm 5.0\%$
21 at $V=3\text{ m s}^{-1}$ and $19.0\pm 4.5\%$ at $V=0.3\text{ m s}^{-1}$ compared to that from a prescribed supersaturation. The
22 effect of water vapor competition becomes smaller at larger V that can provide more sufficient water

23 vapor. Essentially, water vapor competition led to the reduction in N_d by decreasing the environmental
24 maximum supersaturation (S_{max}) for the activation of aerosol particles. It is shown that S_{max} was
25 decreased by 14.5-11.7% for $V=0.3-3 \text{ m s}^{-1}$. Particularly, the largest suppression of cloud droplet
26 formation due to the water vapor competition is presented at extremely high aerosol particle number
27 concentrations. As a result, although a larger increase of CCN-size particles by NPF event is derived
28 on clean NPF day when pre-existing background aerosol particles are very low, there is no large
29 discrepancy in the enhancement of N_d by NPF between the clean and polluted NPF day. We finally
30 show a considerable impact of the primary sources when evaluating the NPF contribution to cloud
31 droplet based on a case study. Our study highlights the importance of fully consideration of both the
32 environmental meteorological conditions and multiple sources (i.e. secondary and primary) to evaluate
33 the NPF effect on clouds and the associated climate effects in polluted regions.

34 **1 Introduction**

35 In the global climate system, aerosols, cloud condensation nuclei (CCN) and cloud droplets are
36 very important components. Clouds, serving as a bridge connecting aerosols and climate, are the most
37 uncertain factor of climate change (IPCC, 2013; Seinfeld et al., 2016; Cai et al., 2020). The
38 microphysical link between aerosols and clouds as the most important part has received extensive
39 attention. Cloud droplet activation is a key process from aerosol to clouds, and there has been a lot of
40 researchers trying to simulate the microphysical processes by using parametric model (e.g. Boucher
41 and Lohmann., 1995; Abdul-Razzak et al., 1998; Kiehl, 1999; Khvorostyanov and Curry., 1999; Abdul-
42 Razzak and Ghan., 2000; Nenes et al., 2002, 2004; Petters et al., 2007; Ren et al., 2018; Genz et al.,
43 2020).

44 As a main source of aerosols, new particle formation events (NPF) have been observed and

45 occurred frequently in different atmospheric environments in the world (Spracklen et al., 2010; Yue
46 et al., 2011; Peng et al., 2017; Kerminen et al., 2018; Bousiotis et al., 2019; Zimmerman et al., 2020).
47 The contribution of nucleation events to global aerosol number concentrations (or condensation nuclei,
48 CN) cannot be ignored, as NPF contributed 81% of the aerosols in the Marine environment and 64%
49 in the terrestrial environment (Merikanto et al., 2010). When these nucleated particles are mixed within
50 the planetary boundary layer, they may subsequently grow to CCN-relevant sizes, or act as CCN in
51 convective clouds (Fan et al., 2013; Li et al., 2010). In reality, from field studies, these fine particles
52 caused by NPF can subsequently turn into an enhancement in CCN number concentration (N_{CCN}) at
53 cloud-relevant supersaturations (Kalkavouras et al., 2017; Peng et al., 2014; Wu et al., 2015; Ma et al.,
54 2016; Li et al., 2017; Zhang et al., 2019). But researchers have different considerations on the
55 definition of NPF events, as well as the initiation and duration of NPF (Dal Maso et al., 2005; Leino
56 et al., 2016). As a result, the calculation methods about N_{CCN} enhancement during the NPF differ among
57 the studies (Asmi et al., 2011; Kerminen et al., 2012; Peng et al., 2014).

58 Moreover, clouds are not characterized by a constant supersaturation. The cloud droplet number
59 concentration (CDNC, or N_d) depends on the size distribution, chemical properties of aerosol and the
60 cloud updraft velocity, all of which also define the maximum supersaturation (S_{max}) that can be formed
61 in a cloud parcel (Nenes and Seinfeld, 2003). Studies have shown that the CDNC in clouds exhibits a
62 sublinear response to aerosol particle increases (Twomey, 1977; Leaitch et al., 1986; Ghan et al., 1993;
63 Boucher and Lohmann, 1995; Nenes et al., 2001; Ramanathan et al., 2001; Sullivan et al., 2016), as is
64 different from CCN due to the limitation of the water vapor in the actual environment. Using the
65 prescribed supersaturation to calculate CDNC may therefore provide a bias on evaluation the aerosol
66 indirect effect. For example, Kalkavouras et al. (2017, 2019) reported the average 12% enhancement

67 of CDNC during two consecutive NPF episodes in the eastern Mediterranean (Santorini and Finokalia)
68 during summer, and this enhancement was significantly smaller than the enhancement of N_{CCN} (~87%)
69 during the NPF day. Hence, it is critical to fully consider the background meteorological conditions
70 (e.g. using dynamic water vapor under different updraft velocities) to simulate the S_{max} when evaluating
71 the effect of NPF on clouds and the associated climate effects.

72 Relevant studies have been carried out in clean regions, but fewer in polluted urban areas. While
73 field studies have shown that NPF events can occur frequently in polluted urban sites although the
74 high concentration of background particles are not conducive to the generation of new particles (Wu
75 et al., 2011; Peng et al., 2014; Zimmerman et al., 2020), and its characteristics like nucleation, growth
76 rate, final size and environmental effect may be larger than that of relatively clean atmosphere.
77 Wiedensohler et al. (2012) also found, under the high concentration levels of gaseous pollutants and
78 strong oxidation in polluted area, the high concentration of nanoparticles generated by NPF events can
79 rapidly grow to tens or even hundreds of nanometers in a few hours. Zhang et al. (2019) observed the
80 subsequent growth of newly formed particles can last 2-3 days in urban Beijing, producing more CCN-
81 sized particles. Previous studies in polluted regions demonstrated the complex and non-linear
82 relationship between aerosol particles and CCN due to multiple emission sources (Zhang et al., 2014,
83 2016, 2017, 2019; Ren et al., 2018; Fan et al., 2020), highlighting the importance of understanding of
84 the connections between aerosols and CCN or cloud droplet close to the source regions. Particularly,
85 owing to the extremely high CN number concentrations (with order of magnitude as high as 10^4 or
86 even 10^5 cm^{-3}) during NPF events in urban area, the effect of competition for water vapor and reduction
87 in cloud supersaturation is expected to be more exacerbated.

88 The current study quantifies the contribution of NPF to CCN and CDNC in the polluted urban

89 atmosphere of Beijing using field measurements of aerosol number size distributions and chemical
90 composition. We aim to investigate the NPF impacts on N_d and S_{max} formed in clouds by applying five
91 updraft velocities. Effect of the background pre-existing particles on the enhancement of CCN and
92 CDNC is also discussed by contrasting the results on typical “clean” NPF day and “polluted” NPF day.
93 Given the influence of strong local primary sources like traffic emissions in urban area, a case study
94 has been done finally to evaluate the interference from evening rush hour.

95 **2 Methodology**

96 **2.1 Experimental site**

97 A field campaign was conducted from May 25, 2017 to June 18, 2017 at the Institute of
98 Atmospheric Physics (IAP), Chinese Academy of Sciences (39.98° N, 116.39° E) for measurements
99 of aerosol physical and chemical properties. The IAP located between the north Third Ring Road and
100 Fourth Ring Road in northern Beijing, which is a typical urban background site, mainly affected by
101 traffic and catering emissions. Beijing is hot in summer with high ambient relative humidity, which is
102 conducive to generate atmospheric convection and reduce the high background aerosol condensation
103 sink. And the radiation in summer is relatively strong, which promotes the generation of nucleated
104 particles. Besides, local sources from traffic and cooking emissions, which may contribute many CCN-
105 size particles, can be important at the site (Sun et al., 2015).

106 **2.2 Measurements of aerosol size distribution and chemical composition**

107 The number size distribution of particles in the size range from 10 to 550 nm (scanned range)
108 were measured with time resolution of 5 minutes by a scanning mobility particle sizer (SMPS; Wang
109 and Flagan, 1990; Collins et al., 2002) , which consists of a differential mobility analyzer (DMA,
110 model 3081L, TSI Inc.) to classify particles with different particle sizes, and a condensation particle

111 counter (CPC, model 3772, TSI Inc.) to detect the size-classified particles. The sampled particles were
112 dried to a relative humidity < 30% before entering the DMA. According to the particle number size
113 distribution (PNSD), we can identify the NPF event by a typical “banana” shape (Kalkavouras et al.,
114 2019) with a sudden increase of nucleated particle number (10-30 nm) and further grow into larger
115 particles over a short time period (usually less than 4 h). While non-NPF events may also have sudden
116 increases of nucleated particles at a short time scale, but they do not show further growth.

117 The non-refractory chemical composition of PM₁ is measured by an Aerosol Chemical Speciation
118 Monitor (ACSM), which consists of an aerodynamic lens to efficiently sample and focus submicron
119 particles into the ACSM (Ng et al. 2011). And the measurements were deployed at ground level and at
120 the 260 m level of the tower (Du et al., 2017), Before sampling into the ACSM, aerosol particles are
121 dried by silica gel desiccant. The ACSM was operated at a time resolution of 15 min. And the non-
122 refractory chemical components that can be measured mainly include organics, sulfate salts (SO₄²⁻),
123 nitrate salts (NO₃⁻), ammonium (NH₄⁺), and chloride (Cl⁻) (Ng et al. 2011). The refractory components
124 mainly include Black carbon (BC), the BC mass concentration was measured using a seven-
125 wavelength aethalometer (AE33, Magee Scientific Corp) .

126 **2.2 Calculation of CCN number concentrations**

127 According to the hygroscopic growth process of particles described by Köhler theory (Köhler et
128 al., 1936), with the growth of particles, their surface water vapor phase equilibrium (supersaturation
129 ratio) will gradually increase. When they grow to a certain size, the required equilibrium
130 supersaturation ratio will not increase, but will decrease. This means the system reaches a critical point,
131 at which the corresponding particle size and supersaturation ratio are called critical diameter (d_c) and
132 critical supersaturation (S_c). Beyond this critical point, particles can condense and grow spontaneously

133 without increasing the S_c . Therefore, if a particle grows to a critical particle size at or above the critical
134 S_c , the particle is activated to form a cloud droplet.

135 In calculation, the corresponding minimum particle size (d_m) can be obtained according to a
136 prescribed environmental supersaturation, and all particles with particle size larger than the d_m can be
137 activated. So CCN number concentrations can be calculated by integrating the PNSD from d_m to the
138 largest particle size measured:

$$139 \quad CCN(d_c) = \int_{d_c}^{\infty} n(d_p) dd_p \approx \sum_{d_m}^{550} \Delta N_i, \quad (1)$$

$$140 \quad d_c = \left(\frac{4A^3}{27\kappa\sigma_w^2} \right)^{1/3}, \quad A = \frac{4M_w\sigma_w}{RT\rho_w}, \quad (2)$$

141 In κ -Köhler formula (5), κ is a hygroscopic parameter which depends on the chemical
142 composition of the particle. In this study, we derived the hygroscopic parameter, κ , by a simple mixing
143 rule on the basis of chemical volume fractions under the assumption of internal mixture (Petters and
144 Kreidenweis, 2007; Gunthe et al., 2009). We used ACSM data to calculate the volume fraction of
145 organic and inorganic, according to the next calculation rule:

$$146 \quad \kappa_{\text{chem}} = \sum_i \varepsilon_i \kappa_i, \quad (3)$$

147 where κ_i and ε_i are the hygroscopic parameter and volume fraction for each individual (dry) component
148 in the mixture, respectively.

149 **2.3 Calculation of cloud droplet number concentrations**

150 The cloud droplet number depends on the S_{max} that can be formed in adiabatic ascending clouds,
151 since this “cloud-relevant” supersaturation is not fixed, it is limited by the competition of water vapor.
152 Nenes and Seinfeld et al (2003, 2004) established a global cloud parametric model based on the
153 “population splitting” concept, which was later improved by Fountoukis and Nenes (2005). The S_{max}
154 was calculated from an equation that expresses the water vapor balance in adiabatic ascending cloud

155 (Nenes and Seinfeld., 2003):

$$156 \quad \frac{ds}{dt} = \alpha V - \gamma \frac{dw}{dt}, \quad (4)$$

157 where α and γ are two coefficients can be calculated by meteorological constants, the first term on
158 the right side of equation (7) expresses the increase of supersaturation due to the adiabatic cooling of
159 the parcel, while the second term expresses the decrease of supersaturation due to the depletion of
160 water vapor by the activated droplets. And the left side express the growth rate of supersaturation,
161 when it is equal to 0, the supersaturation reaches the maximum value.

162 Nenes et al.(2001) used a sectional representation of the CCN spectrum (i.e. aerosol
163 supersaturation distribution $n^s(s')$) and total number of particles with critical supersaturation smaller
164 than s , $F^s(S)$, which is given by

$$165 \quad F^s(s) = \int_0^s n^s(s') ds' = \sum_{j=1}^{i-1} N_j + N_i \left(\frac{s - s_{c,i-1}}{s_{c,i} - s_{c,i-1}} \right), \quad (5)$$

167 If the maximum supersaturation (S_{max}) is known, the activated cloud droplet number (N_d) can be
168 calculated from equation (8), as

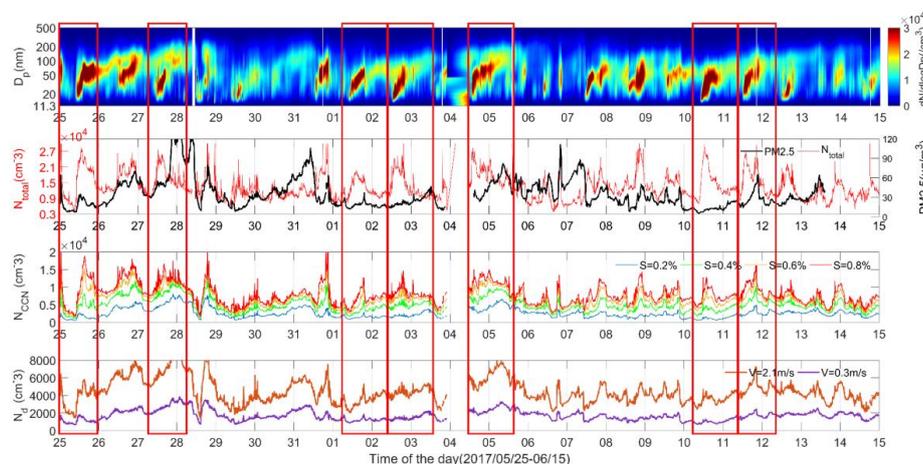

$$169 \quad N_d = F^s(s_{max}), \quad (6)$$

170 In this study, we used the PNSD, chemical components, and empirical values of cloud updraft
171 velocity to determine the S_{max} and N_d during NPF days in urban Beijing. Owing to that calculation of
172 cloud updraft velocity is almost impossible, the typical cloud updraft velocity (ranging from 0.3 to 3
173 m s⁻¹) that can represent the conditions of different clouds types (stratocumulus/cumulus and
174 convective clouds) in summer of north China is applied here according to field observation or empirical
175 data (Morales and Nenes. 2010; Zheng et al., 2015).

176 3 Results and discussion

177 3.1 Time series of observed NPF events and calculated N_{CCN} and N_d

178

179 **Figure 1.** Time series of the (from top to bottom) particle number size distribution (PNSD) (typical
180 NPF events are marked in red box), particle number concentration (N_{total}), particle mass concentration
181 ($PM_{2.5}$), CCN number concentration (N_{CCN}), and cloud droplet number concentration (N_d). Data are
182 from 25 May to 15 June 2017. The different colors for N_{CCN} represent the calculated value under
183 different supersaturations (S) (the S of 0.2%, 0.4%, 0.6%, 0.8% corresponds to the colors in blue, green,
184 yellow, red respectively). And different colors of N_d represent the results at different updraft vertical
185 velocity (V) (the V of 0.3 m s^{-1} , 2.1 m s^{-1} corresponds to the colors in orange and purple respectively).

186

187 As a typical NPF event includes the sudden increase of nucleation particles (10–25 nm), the
188 subsequent growth of the newly formed particle, the duration of the event (more than two hours) and
189 the terminal of the NPF event (Leino et al., 2016), NPF events in total, accounting for about half of the
190 observation time, occurred during the studied periods. Here, we just select 7 NPF events to study as

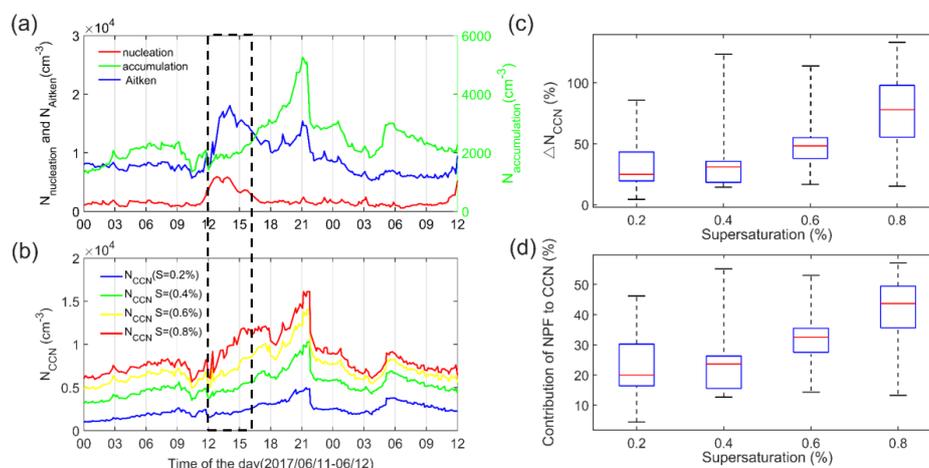

191 marked in red box in Fig. 1.

192 Fig. 1 also presents the time series of N_{CCN} and N_d . The N_{CCN} has a strong response to aerosol
193 increase during the NPF events as expected, and this response always occurs a few hours after the start
194 of NPF, as the growth of nucleation mode particles to sufficient size (Aitken mode or accumulation
195 mode) (Fig. 2). The variation of N_{CCN} seems to be more consistent with that of N_{CN} than N_d . Since the
196 N_{CCN} was calculated based on an assumption that the water vapor in the environment is always
197 sufficient, the increase of N_{CN} which indicates the occurrence of NPF events can bring more CCN as
198 shown in Fig. 1. However, due to the pre-existing aerosol in the background, which may contribute a
199 large amount of CCN, it is necessary to consider a time node (t_{dec}) when NPF begin to impact N_{CCN}
200 and the duration of this effect (Kalkavouras et al., 2019) when we evaluating the CCN enhancement
201 caused by NPF.

202 Therefore we used the methods of Kalkavouras et al(2019) to calculate the “decoupling time”,
203 t_{dec} , in the selected seven typical NPF days, and we found t_{dec} occur 2-3 hours later after t_{start} in most
204 of NPF days. So we took the period from 12:00 to 16:00 to estimate the change of CCN during NPF
205 events (the end time is taken as 16:00 to avoid the interference of evening traffic emissions). According
206 to the time nodes determined above, we defined the enhancement percentage of CCN number
207 concentration as the ratio of the average increment of CCN during NPF period to the average
208 concentration of pre-NPF events. The enhancements in CCN number from NPF were calculated for
209 0.2%, 0.4%, 0.6%, 0.8% supersaturation, with the average values of 33.9%, 42.3%, 53.4%, and 76.3%,
210 respectively (Table S1 and Figure 2b). As a result, we show that the NPF drives the variance of N_{CCN} ,
211 and 24.4%, 26.1%, 32.4%, 40.3% of environment total CCN are directly originated from NPF at 0.20%,
212 0.4%, 0.6%, 0.8% supersaturation respectively, suggesting large source of CCN from NPF events. And

213 about 60-75% CCN are from the background pre-existing particles in urban Beijing, which is much
214 larger than that derived in remote Finokalia, Crete, Greece by Kalkavouras et al (2019).

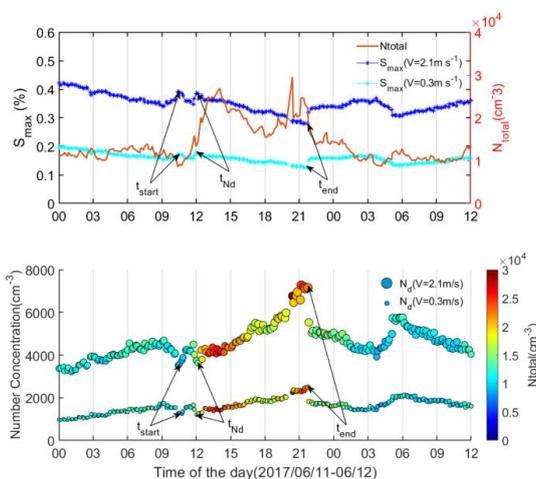

215
216 **Figure 2.** (a) Diurnal evolution of nucleation (10-25 nm, red line), Aitken (25-100 nm, blue line), and
217 accumulation mode (>100 nm, green line) particle number concentration on 11 June 2017, respectively;
218 (b) Diurnal evolution of CCN number concentration under different supersaturations (0.2%-0.8%); (c)
219 Box diagram for the average enhancement of CCN caused by NPF under different supersaturations
220 (0.2%-0.8%) on all NPF days; (d) Box diagram for the average contribution of NPF to CCN under
221 different supersaturations (0.2%-0.8%) on all NPF days.

222 3.2 Impact of NPF on cloud droplet number in Beijing

223 The estimated results of S_{max} and N_d for two selected vertical updraft velocity of $V=0.3 \text{ m s}^{-1}$ and
224 $V=2.1 \text{ m s}^{-1}$ on 11 June 2017 are shown in Fig. 3a and Fig. 3b. Generally, the S_{max} was calculated to be
225 under 0.4% and 0.2% for $V=2.1 \text{ m s}^{-1}$ and $V=0.3 \text{ m s}^{-1}$ respectively, and the corresponding critical
226 particle sizes (d_c) are 70 nm and 110 nm. It means that most activated drops are from accumulation-
227 mode particles and larger particles in Aitken-mode. The large contribution of the Aitken-mode particles
228 lead to large amount of cloud droplets in urban Beijing, especially for high updraft velocity. Basically,

229 the number concentration of cloud droplets is above 1000 cm^{-3} , which is of a much larger magnitude
230 compared with that in the clean areas (Morales et al., 2014; Sullivan et al., 2016; Kalkavouras et al.,
231 2019).

232
233 **Figure 3. (a)** Diurnal evolution of the maximum supersaturation (S_{max}) in the cloud for updraft
234 velocities of 2.1 m s^{-1} and 0.3 m s^{-1} , and the total aerosol particle number concentrations in cm^{-3} (N_{total} ,
235 right axis); **(b)** Diurnal evolution of calculated cloud droplet number concentrations (N_d) (left axis) for
236 updraft velocities of 2.1 m s^{-1} and 0.3 m s^{-1} .

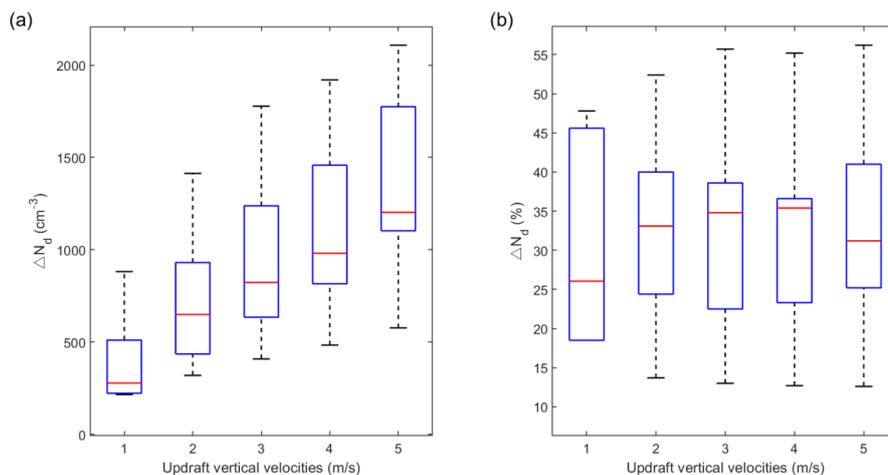

237 In the cloud, the change in the quantity of particles can be directly reflected by the change in S_{max} ,
238 as shown in Fig. 3. The rise of environmental supersaturation means that the water vapor in the air
239 mass is sufficient, that suggests the water vapor produced by the adiabatic rise of clouds is more than
240 the water vapor consumed by the condensation of particles. When the production equals to the
241 consumption of water vapor, the water vapor in air mass reaches a balance, and the environmental
242 supersaturation stops increasing. With the further growth of the CCN to form droplets, more water
243 vapor will be consumed, this equilibrium will be broken and the environmental supersaturation will
244 begin to decrease. This moment indicates the cloud droplets in air mass begin to “feel” the particles

245 generated from NPF, for example, the N_d rapidly increased from ~ 4000 to nearly 8000 cm^{-3} over 9
246 hour period starting at 12:00 am (Fig. 3b). This moment at 12:00 a.m will be defined as t_{Nd} , and the
247 time lag between t_{start} and t_{Nd} was about 2-3 hour, which is shortened by two thirds compared to that
248 reported by Kalkavouras et al., (2019). This case in 11 June was not an individual case, and similar
249 patterns are also shown on other NPF days during the campaign (Fig. S4-S9).

250 When evaluating the impact of NPF on cloud drops, we define this impact continues until N_d
251 begin to decrease meanwhile the S_{max} begins to increase, and we set this time node as t_{end} (the t_{end} here
252 should be distinguished from the time node when NPF events end). Then the enhancements of cloud
253 droplets by NPF are defined as the difference of N_d (ΔN_d) before t_{Nd} (during t_{start} and t_{Nd}) and after t_{Nd}
254 (during t_{Nd} and t_{end}). The average enhancements under different updraft velocities are exhibited in Fig.
255 4a and Fig. 4b. The results show that the mean enhancements in N_d by NPF are 398, 734, 951, 1107,
256 1328 cm^{-3} at updraft velocities of 0.3, 0.9, 1.5, 2.1, and 3 m s^{-1} respectively, corresponding to elevated
257 percentages of 30%, 33%, 33%, 33%, 32%. It suggests that the higher cloud updraft velocity not only
258 generates more cloud droplets, but also induces larger enhancements in N_d . While the percentages of
259 the enhancement remain the same from low to high updraft velocity since this value depends both on
260 the increased quantity of cloud droplets and the concentration of pre-exist cloud droplets.

261 Furthermore, we estimate the changes of N_{CN} and κ to the variance of N_d under different updraft
262 velocities (V) using Eqs. S1, S2 and S3. The results demonstrate changes in N_{CN} contributed 68% in
263 average to the variance of N_d and this contribution increased with the increase of V , and the remaining
264 32% is attributed to the changes in κ (Table S3). Our calculation indicates the importance of NPF
265 events to variations of N_d by elevating the total N_{CN} in polluted urban area.

266

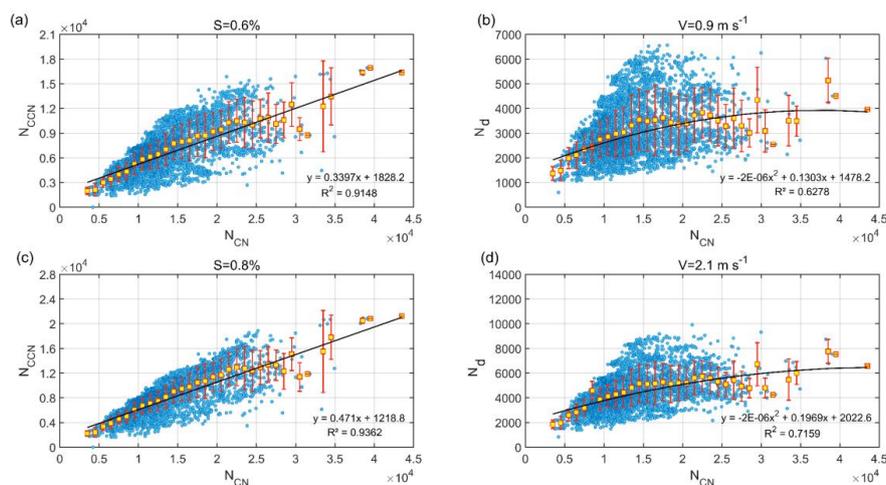

267 Figure 4. (a) Box diagram for the average enhancement of cloud droplets number concentration (N_d)
268 by NPF events under different updraft vertical velocities; and (b) Box diagram for the corresponding
269 enhanced percentages of N_d by NPF events.

270 3.3 The effect of water vapor competition on evaluating N_d

271 Fig. 5 shows the scatter plots of correlations between N_{CN} and N_{CCN} at different supersaturations
272 and the correlations between N_{CN} and N_d under different updraft vertical velocities. The N_{CCN} and N_{CN}
273 were obviously linear correlated, but the correlation between N_d and N_{CN} was non-linear. When
274 showing as the average values with error bars, we find most N_d increase as N_{CN} increase when N_{CN} is
275 below 15000, then N_d began to decrease as N_{CN} continue to increase. This has been presented in
276 previous studies (Nenes et al., 2001; Ramanathan et al., 2001; Sullivan et al., 2016), and was thought
277 caused by the water vapor competition. Although the larger updraft velocities generate more water
278 vapor and can form more N_d , the water vapor competition still occurred when background aerosol
279 particles increased to a certain number. This fully suggests the difference between the fixed
280 supersaturation S used in the calculation of N_{CCN} and the actual supersaturation S_{max} in the air mass
281 used in the calculation of cloud droplets. Because in the actual environment, it is often unable to

282 provide enough water vapor. For example, the S_{max} is lower than 0.5% at the maximum cloud updraft
283 velocity of 3 m s^{-1} according to the calculation in this study. Therefore, although NPF events may
284 strongly increase CCN numbers, the formed cloud droplet numbers are eventually limited by water
285 vapor availability which depends on the supersaturation (S_{max}) that can develop in the cloud. The latter
286 is related to the cloud formation dynamics and the aerosol levels associated with the background in the
287 region.

288
289 **Figure 5.** (a), (c) Correlation between aerosol number concentration (N_{CN}) and mean N_{CCN} at
290 supersaturation of 0.6% and 0.8% respectively. (b), (d) Correlation between aerosol number
291 concentration (N_{CN}) and mean cloud droplet number concentration (N_d) at updraft vertical velocity of
292 0.9 m s^{-1} and 2.1 m s^{-1} respectively.

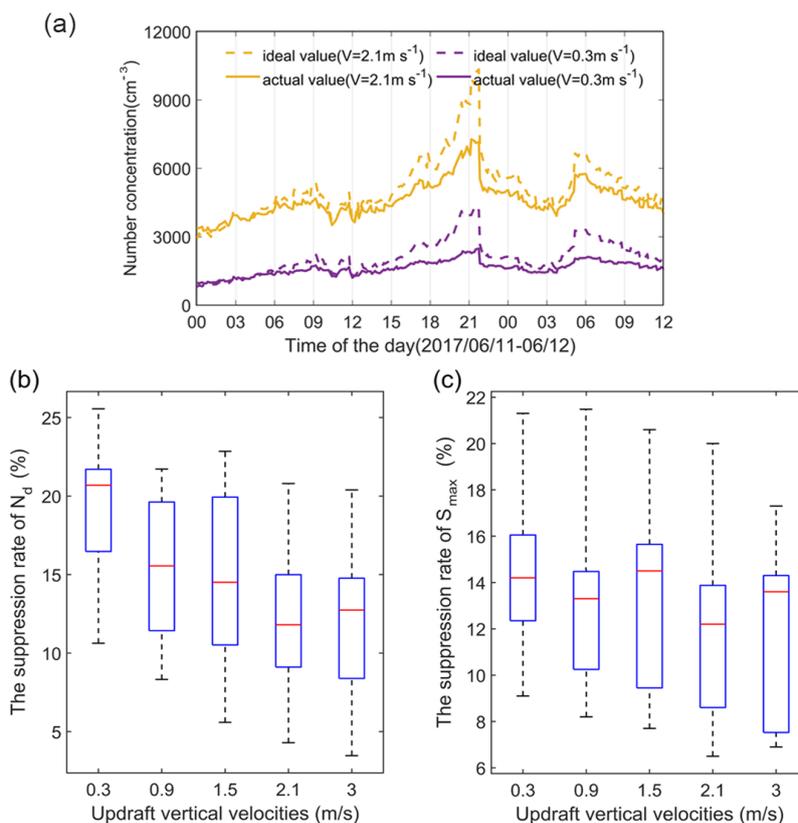

293 To evaluate the effect of water vapor competition on N_d , by taking the case on 11 June as an
294 example, we calculate and show the diurnal variation of N_d with and without the water vapor depletion
295 in Fig. 6a. For the test, if assuming no water vapor depletion, the S_{max} would not decrease after t_{Nd}
296 (12:00), so the ideal number of cloud drops was equal to the estimated N_{CCN} for the supersaturation of

297 S_{max} at the time of t_{Nd} . The effect of water vapor competition under different cloud updraft velocities
298 is assessed by comparing actual derived N_d with the ideal value from a fixed supersaturation (S_{max}) as
299 shown in Fig. 6. The results from other NPF events were also summarized in Table S4 and Table S5.
300 Obviously, the N_d is largely reduced due to the water vapor competition at both the low and high
301 updraft velocity, suggesting significant suppression of cloud droplet formation, with average
302 suppression percentages of $19.0 \pm 4.5\%$, $15.7 \pm 4.7\%$, $14.8 \pm 5.6\%$, $12.3 \pm 4.9\%$, $11.8 \pm 5.0\%$ for N_d at
303 updraft velocity of 0.3, 0.9, 1.5, 2.1 and 3 m s^{-1} on all NPF days. It was consistent with the results of
304 Kalkavouras et al., 2017, they found this competition effects suppress N_d by 20% for $V = 0.3 \text{ m s}^{-1}$ and
305 12.3 % for $V = 0.6 \text{ m s}^{-1}$. The declined percentages with increase of the updraft velocity suggests that
306 the effect becomes smaller at larger V that can provide more sufficient water vapor. In addition, after
307 the t_{Nd} , S_{max} was negatively correlated with N_d for both updraft velocities due to the increasing
308 competition for water vapor from the growing number of droplets (Fig. 3a). Essentially, water vapor
309 competition led to the reduction in N_d by decreasing the required S_{max} for the CN activation. It is shown
310 that S_{max} was decreased by $14.5 \pm 3.5\%$, $13.3 \pm 4.0\%$, $13.4 \pm 4.2\%$, $12.0 \pm 4.1\%$, $11.7 \pm 3.9\%$ for $V=0.3$,
311 0.9, 1.5, 2.1 and 3 m s^{-1} respectively.

312 **3.4 The variations of CCN and cloud droplet on typical "clean" and "polluted" NPF day: a case** 313 **study**

314 Generally, the lower $\text{PM}_{2.5}$ means low background condensation sink (CS) which is conducive for
315 nucleation particles condense and coagulate (Wu et al., 2011; Yue et al., 2011; Wiedensohler et al.,
316 2012). Different from the remote clean area, some of the NPF events in urban Beijing during the
317 campaign occurred with background pollutions (with daily mass concentrations of $\text{PM}_{2.5}$ of $\sim 40 \mu\text{g m}^{-3}$)
318 or are impacted by local primary emissions. This kind of NPF event has different characteristics

319

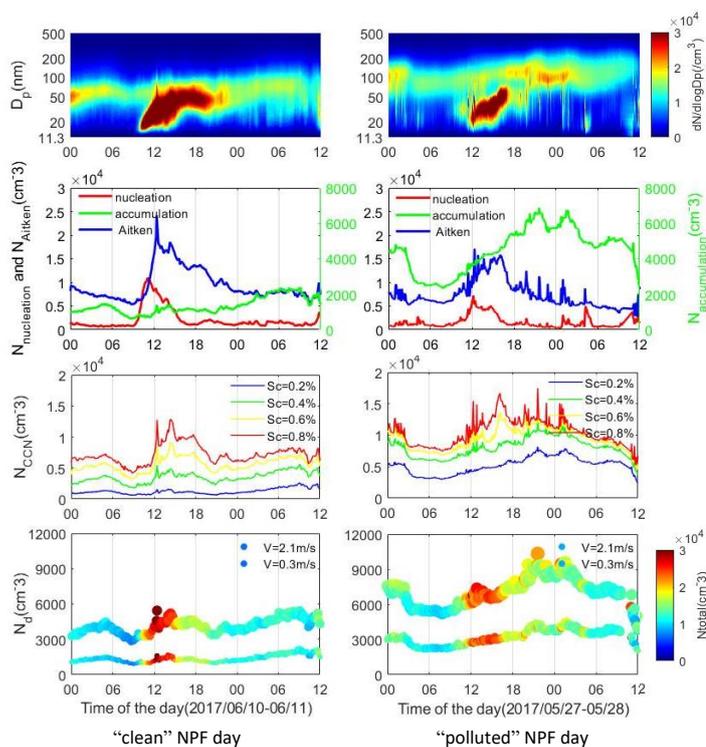

320 **Figure 6. (a)** The diurnal variation of N_d with or without considering water vapor competition at
321 updraft speeds of 2.1 m s⁻¹ and 0.3 m s⁻¹ on 11 June 2017; **(b)** Box diagram for the suppression rate
322 of N_d under different updraft vertical velocities from all selected NPF cases; **(c)** Box diagram for the
323 suppression rate of S_{max} under different updraft vertical velocities from all selected NPF cases.

324

325 from that in clean conditions, as the sudden increase of nucleation particles less than 25 nm is often
326 accompanied by an increase of large particles at the beginning of NPF. Here, they are named as
327 “Polluted” and “Clean” NPF event respectively. Two days, on 27 May and 11 June, representing the
328 typical “polluted” and “clean” NPF events respectively, are selected for contrasting the effect of the

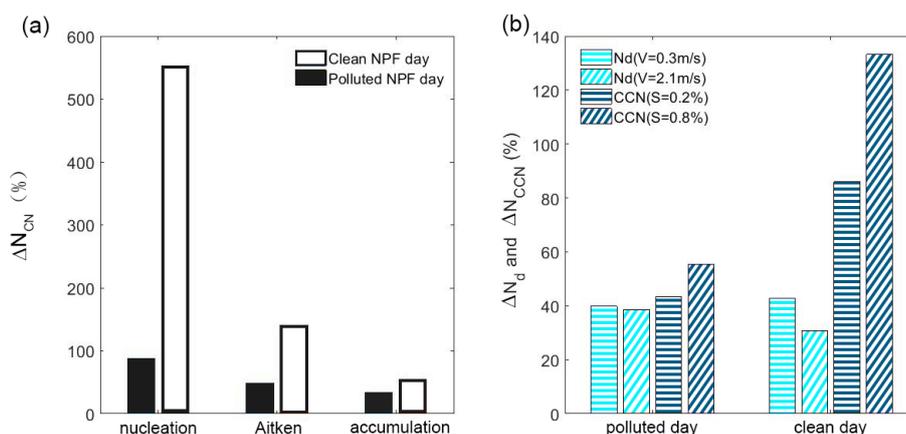

329 two kinds of NPF on CCN and CDNC. As shown in Fig. 7, there is a higher pre-existing background
 330 of accumulated mode particles across the day on “polluted” NPF day of 27 May than that on “clean”
 331 NPF day of 11 June. On “clean” NPF day, much more nucleation and Aitken mode particles, with N_{CN}
 332 enhancement of 7-fold higher than that on “polluted” day (Fig. 8a), were generated and NPF events
 333 developed stronger in the initial stage. The beginning of NPF events (t_{Start}) on polluted case (11:00
 334 a.m.) was about 2 hours later than that on clean case (~9:00 a.m).

335
 336 **Figure 7.** Comparison of two different typical NPF events, “clean” NPF day with cleaner background which
 337 $PM_{2.5}=14$ ($\mu\text{g}/\text{m}^3$) and “polluted” NPF day with $PM_{2.5}=73$ ($\mu\text{g}/\text{m}^3$). Two typical NPF days (10 June and 27 May 2017)
 338 are selected to compare the diurnal evolution trend of particles; CCN number concentration and the diurnal variation
 339 of CCN; cloud droplet number concentration and its evolution pattern under two different NPF types.

340 For the both cases, the N_{CCN} are increased with the evolution of the NPF events (Fig. 7). But the
341 magnitude of the enhancements at the two cases are quite different. The average CCN number
342 concentration during NPF events under polluted day was twice than that of clean day due to that there
343 were a large number of pre-exist CCN-size aerosol particles on polluted NPF days. While, a larger
344 enhancement of N_{CCN} is derived on clean NPF day, showing 80-120% and 40-57% contribution of NPF
345 to N_{CCN} on clean and polluted days respectively. This result is reasonable and consistent with the
346 conclusion of Kalkavouras et al., 2019. However, the enhancement of N_d by NPF on polluted day was
347 almost the same as that on clean day, with an overall enhancement of 30-40% under updraft velocity
348 of 0.3 and 2.1 m s^{-1} . This suggests that it is critical to fully consider the background meteorological
349 conditions (e.g. using dynamic water vapor under different updraft velocities) to simulate the cloud
350 droplet when evaluating the effect of NPF on clouds and the associated climate effects.

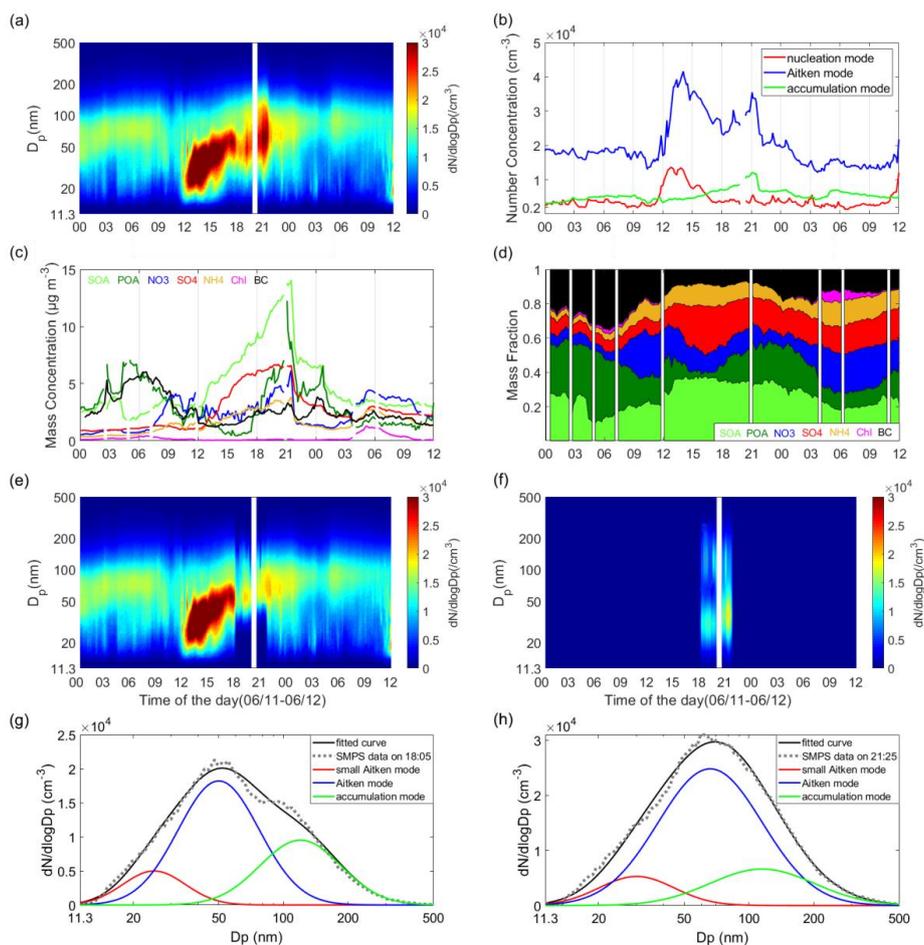

351
352 **Figure 8.** Comparison of two different typical NPF events, (a) Change of N_{CCN} which is influenced by
353 NPF, (b) Chang of N_d and N_{CCN} , which are estimated before and after NPF, dividing the increment by
354 the previous amount and get the this proportion.

355 **3.5 The impact of primary emissions during evening rush hour on the calculation of NPF**
356 **contribution to N_d : a case study**

357 During the campaign, very high number concentrations of Aitken particles were frequently
358 observed during evening rush hour (as shown in Fig. 9a and 9b) when primary emissions related to
359 automobile exhaust or cooking activities near the site dominate the PNSD. This is also shown in the
360 diurnal variations of particles chemical composition, with a large increase of primary organic aerosols
361 (POA) and BC both in the mass concentration and fraction (Fig. 9c and 9d). The PNSD showed a
362 major peak in the Aitken mode at ~ 50 nm during the rush hour time and minor peaks in Aitken (~ 30
363 nm) and accumulation (~ 100 - 120 nm) mode, which have been demonstrated related to vehicle
364 emissions (Brines, M et al., 2015). Those primarily emitted particles can serve as CCN and thereby
365 impact the evaluation of NPF contribution to cloud droplet. Therefore, taking the day of June 11 as an
366 example, such effect from primary emissions during evening rush hour is investigated. On the day,
367 after one hour of the eruption of newly formed particles at $\sim 12:00$ a.m, the N_d began to rise rapidly,
368 and this moment was t_{Nd} , the increase of N_d continued from 12:00 until to 21:30 at night (as shown in
369 Fig. 3a and 3b). At 18:00, the primary emissions also begin to impact the N_d . A sudden decrease and
370 dilution in the PNSD is due to a precipitation event at 21:30. From 18:00-21:30, the cloud droplets
371 were from both NPF source and the primary emissions.

372
373 **Figure 9.** (a) Diurnal evolution of the aerosol size distribution; (b) Diurnal evolution of nucleation
374 (red line), Aitken (blue line), and accumulation mode particle number concentration (green line),
375 respectively; (c) Diurnal evolution of the aerosol chemical composition include (BC, NH₄, NO₃, POA,
376 SOA, SO₄, Chl); (d) Mass fraction of aerosol composition; (e) Diurnal evolution of particle number
377 size distributions without considering primary emission; (f) Diurnal evolution of particle number size
378 distributions only considering primary emission during 18:05-21:25; (g) and (h) fitted results of the
379 particle number size distributions at 18:05 and 21:25 respectively

380

381 **Table 1.** Impact of primary emissions on evaluating the contribution of NPF to N_d increment

V , m s ⁻¹	D_c , nm	ΔN_{d_NPF} , cm ⁻³ , %	ΔN_{d_PE} ^a , cm ⁻³ , %	ΔN_{d_total} , cm ⁻³		
0.3	140	241	86.4%	38	13.6%	279
0.9	107	555	82.6%	117	17.4%	672
1.5	93	613	75.8%	196	24.2%	809
2.1	84	675	69.6%	295	30.4%	970
3	75	862	70.9%	354	29.1%	1216

382 ^aPE, primary emission

383

384 It is expected that the newly formed particles continued to grow until 21:30, we estimate the size
385 mode of the newly formed particles after 18:00. In this case, a value of 3.2 ± 0.5 nm h⁻¹, which is the
386 growth rate of the newly formed particles during 12:00-18:00, is applied for the estimation. The
387 calculation results show that the new particles can grow to ~50 nm at 18:05 and ~60 nm at 21:25. So
388 we can get the PNSD of NPF and primary emissions respectively (Fig. 9e and 9f) by fitting the three
389 modes assuming a normal distribution. Fig. 9g and Fig. 9h show the fitted results of the three modes
390 of the PNSD at 18:05 and 21:25 respectively. Then the increment of N_d from NPF are obtained from
391 the PNSD of NPF. In addition, the chemical composition of newly formed particles during evening
392 rush hour is assumed same to that at 18:00 to calculate the κ and the critical diameter. Finally, the
393 increment of N_d from primary emissions are obtained by subtracting the increment of N_d by NPF from
394 the total increment of N_d . When calculating the enhancement of N_d by NPF, the N_d before t_{Nd} (during
395 09:00-12:00), taking as a background, was directly subtracted from the total N_d by NPF after t_{Nd} (during

396 12:00-21:30). The calculated results are summarized in Table 1. The average contribution of primary
397 emission to N_d is 13.6%, 17.4%, 24.2%, 30.4% and 29.1% cm^{-3} for updraft velocities of 0.3, 0.9, 1.5,
398 2.1 and 3 m s^{-1} respectively. The proportion of contribution from NPF and primary emission to N_d
399 increment change with the variation of updraft vertical velocity (V). The higher proportion of
400 contribution from primary emission is obtained at higher V , which may be determined by the different
401 characteristics between atmospheric particles emitted from the evening traffic sources and generated
402 from NPF events. Our result shows considerable impact of those primary sources when evaluating the
403 NPF contribution to cloud droplet, highlighting the importance of considering the influence from
404 multiple (i.e. secondary and primary) sources on clouds in the polluted atmosphere.

405 **4 Conclusions**

406 In this study, we quantified the contribution of NPF to cloud droplet number concentration
407 (CDNC, or N_d) at typical updraft velocities in clouds using field measurements of aerosol number size
408 distributions and chemical composition in urban Beijing. We show that the NPF drives the variations
409 of CCN and cloud droplet. About 25%-40% CCN are from NPF events in polluted atmosphere. And
410 the N_d is increased about 30%-33% by NPF at $V=0.3\text{-}3 \text{ m s}^{-1}$ accordingly. The markedly reduction in
411 N_d is observed due to water vapor competition with consideration of actual environmental updraft
412 velocity, with decrease rates of $11.8\%\pm 5.0\%$ at $V=3 \text{ m s}^{-1}$ and $19.0\%\pm 4.5\%$ at $V=0.3 \text{ m s}^{-1}$ by comparing
413 with that from a prescribed supersaturation. The effect of water vapor competition becomes smaller at
414 larger V that can provide more sufficient water vapor. Essentially, water vapor competition led to the
415 reduction in N_d by decreasing the environmental S_{max} for the activation of aerosol particles. It is shown
416 that S_{max} was decreased by $14.5 \pm 3.5\%$ to $11.7 \pm 3.9\%$ for $V=0.3\text{-}3 \text{ m s}^{-1}$. Our results suggest
417 significant suppression of cloud droplet formation due to the water vapor competition particularly at

418 extremely high aerosol particle number concentrations. As a result, although a larger increase of CCN-
419 size particles by NPF event is derived on clean NPF day when pre-existing background aerosol
420 particles are very low, no large discrepancy in the enhancement of N_d by NPF between the clean and
421 polluted NPF day. Finally, we show a considerable impact of the primary sources when evaluating the
422 NPF contribution to cloud droplet from a case study. Our study highlights the importance of fully
423 consideration of both the environmental meteorological conditions and multiple sources (i.e. secondary
424 and primary) to evaluate the effect of NPF on clouds and the associated climate effects. For example,
425 Merikanto et al. 2010 used model to simulate the variance of CDNC from the year of 1850 to 2000,
426 and showed that NPF made a nearly equal contribution (16-13.5%) to global CDNC in all those years,
427 leading to ~50% enhancement in the year from 1850 to 2000 change in cloud albedo. There are still
428 large uncertainties about how to accurately quantitatively assess the response of these climate effects to
429 NPF. This study is carried out in polluted area, which is a supplement to the related cloud microphysical
430 progress research and provides a new perspective for the follow-up research.
