Abstract

31 The planetary boundary layer (PBL) ~~height (BLH)~~ governs the vertical transport of
32 mass, momentum and moisture between the surface and the free atmosphere, and thus
33 the determination of its PBL-characterization height (BLH) is recognized as crucial for
34 air quality, weather and climate analysis. Although reanalysis products can provide
35 important insight into the global view of BLH in a seamless way, the *in situ* observed
36 BLH on a global scale remains poorly understood due to the lack of high-resolution (1-
37 s or 2-s) radiosonde measurements. The present study attempts to establish a near-
38 global BLH climatology at synoptic times (0000 and 1200 UTC) and in the daytime
39 using high-resolution radiosonde measurements over 300 radiosonde sites worldwide
40 for the period 2012 to 2019, which is then compared against the BLHs obtained from
41 four reanalysis datasets, including ERA-5, MERRA-2, JRA-55, and NCEP-2. The
42 variations of daytime BLH exhibit large spatial and temporal dependence, and as a
43 result the BLH maxima are generally discerned over the regions such as Western United
44 States and Western China, in which the balloon launch times mostly correspond to the
45 afternoon. The diurnal variations of BLH are revealed with a peak at 1700 Local Solar
46 Time (LST). The most promising reanalysis product is ERA-5, which underestimates
47 BLH by around 130 m as compared to radiosondes released during daytime. In addition,
48 MERRA-2 is a well-established product and has an underestimation of around 160 m.
49 JRA-55 and NCEP-2 might produce considerable additional uncertainties, with a much
50 larger underestimation of up to 400 m. The largest bias in the reanalysis data appears
51 over the Western United States and Western China and it might be attributed to the
52 maximal BLH in the afternoon when the boundary layer PBL has grown up. Statistical
53 analyses further indicate that the biases of reanalysis BLH products are positively
54 associated with orographic complexity, as well as the occurrence of static instability.
55 To our best knowledge, this study presents the first near-global view of high-resolution
56 radiosonde derived boundary layer height BLH and provides a quantitative assessment
57 of the four frequently used reanalysis products.

58 **Keywords.** Radiosonde; boundary layer height; reanalysis; sensible heat flux

59 1. Introduction

60 The planetary boundary layer (PBL) is where most of exchanges of heat, moisture,
61 momentum and mass take place between the free atmosphere and ground surface (Stull,
62 1988; Liang and Liu, 2010). The spatial and temporal variability of PBL ~~and its~~
63 evolution, through a variety of physical processes, has a profound influence on research
64 fields such as air quality (Stull, 1988; Li *et al.*, 2017), ~~boundary layer cloud and fog~~
65 ~~(Liu and Liang, 2010)~~, convective storm (Oliveira *et al.*, 2020) and global warming
66 (Davy and Esau, 2016), among others. It is well known to be influenced by radiative
67 cooling at night and by downward solar radiation reaching the ground surface at
68 daytime, respectively, forming a stable boundary layer (SBL) and convective boundary
69 layer (CBL), with a typical ~~PBL boundary layer~~ depth (BLH) of less than 500 m and 1–
70 3 km (Zhang *et al.*, 2020a), respectively. For climate models, most of the PBL processes
71 occur at sub-grid scales and thus are either underrepresented or not fully represented
72 (von Engel and Teixeira, 2013). Meanwhile, there are many problems in elucidating
73 the PBL processes using numerical model simulations (Martins *et al.*, 2010), even over
74 the relatively homogeneous ocean (Belmonte and Stoffelen, 2019), which is likely due
75 to the scarcity of fine-scale vertical observations of the atmosphere.

76 Over the oceans Belmonte and Stoffelen (2019) performed a climatological
77 comparison between state-of-the-art reanalysis and scatterometer surface winds in the
78 PBL, revealing mean and transient PBL model errors. Houchi *et al.* (2010), based on
79 high-resolution radiosondes, verified the climatological wind profiles and found in
80 particular a factor of 2–3 lower wind shear simulated by the European Centre for
81 Medium-Range Weather Forecasts (ECMWF) model. Wind shear is recognized to be
82 able to significantly modulate turbulent mixing of atmospheric pollutants (Zhang *et al.*,
83 2020b), and thus the inabilities of the model in this regard may have repercussions for
84 air quality prediction.

85 The critical interaction between PBL turbulence and vertical structures of
86 thermodynamic variables, as the heart of PBL physics, makes the determination of BLH

87 a big challenge, due largely to the difficulty for those instruments with coarse vertical
88 resolution in resolving the sharp gradients of temperature and water vapor at the top of
89 the PBL, and estimating PBL-top entrainment and lateral entrainment (Teixeira *et al.*,
90 2021). Thus, this highlights the importance of high-resolution vertical measurements of
91 thermodynamic variables. The temporal and spatial variations in BLH have been
92 extensively assessed in previous studies at a regional or national scale, such as the
93 contiguous United States (Seidel *et al.*, 2012; Zhang *et al.*, 2020a), Europe (Palarz *et*
94 *al.*, 2018), ~~China (Guo *et al.*, 2016; Zhang *et al.*, 2018, Su *et al.*, 2018)~~, Arctic and
95 Antarctic (Zhang *et al.*, 2011), which are mainly implemented by ~~low~~high-resolution
96 radiosonde measurements, reanalysis or both. Fortunately, a few pioneering studies in
97 characterizing BLH have adopted high-resolution measurements at a national scale over
98 China (Guo *et al.* 2016; Zhang *et al.*, 2018, Su *et al.*, 2018) and United States (Seidel
99 *et al.*, 2010). ~~N~~And notable diurnal and seasonal cycles have been revealed (e.g., Guo
100 *et al.*, 2016; Short *et al.*, 2019). Besides the regional results, several attempts have been
101 made to provide global-scale retrievals of BLH using the Global Positioning System
102 radio occultation (GPS RO) and Integrated Global Radiosonde Archive (IGRA) version
103 2 (Seidel *et al.*, 2010; Gu *et al.*, 2020; Ratnam and Basha, 2010), in which seasonal
104 variations and maritime-continental contrasts of BLHs have been achieved. The
105 measurements of GPS RO, at a vertical resolution of 100 m around the PBL top, are
106 typically used to determine BLH by searching for the altitude with a sharp gradient in
107 the refractivity profile (Basha *et al.*, 2018). However, such sharp gradient of refractivity
108 might overestimate BLH compared to other methods that the community usually used,
109 such as the parcel method (Seidel *et al.*, 2010). Compared with high-resolution
110 soundings, IGRA is sparsely sampled in the vertical (about 10-30 layers below 500
111 hPa), which could result in large uncertainties in estimating BLH. Likewise, additional
112 errors could be introduced in reanalysis products for their sparse vertical resolutions
113 (about 6-42 layers below 500 hPa), which are equivalent to or bigger than IGRA. A
114 large spread emerges in the explicit determination of BLH from a variety of instruments,
115 in spite of that the BLH detection based on radiosonde is the most accepted

116 methodology for deriving CBL and SBL (Seidel *et al.*, 2012; de Arruda Moreira *et al.*,
117 2018).

118 A wide range of reanalysis products, such as those from the fifth generation
119 ECMWF atmospheric reanalysis of the global climate (ERA-5), the National
120 Aeronautics and Space Administration (NASA) Modern-Era Retrospective-analysis for
121 Research and Applications version 2 (MERRA-2), Japanese 55-year Reanalysis (JRA-
122 55), and the NCEP climate forecast system version 2 (NCEP-2), provide a rich
123 ensemble of climate data products (Saha *et al.*, 2014; Hersbach *et al.*, 2020; Kobayashi
124 *et al.*, 2015; Gelaro *et al.*, 2017), but are sensitive to both empirical parameterizations
125 and the diagnostic method chosen, while verification by direct observations of BLH are
126 sparse (Seibert *et al.*, 2000). Some inter-comparisons between instruments or model
127 data, such as radiosonde, CALIOPLIDAR, and ERA-interim reanalysis have been
128 previously conducted, and a rough-good consistency has been yielded in seasonal and
129 spatial variation (e.g., Guo *et al.*, 2016; ~~Korhonen *et al.*, 2017~~; Zhang *et al.*, 2016).
130 However, Basha *et al.* (2018) demonstrate that ERA-interim can underestimate BLH
131 by around 900 m compared to GPS RO. This underestimation may be caused by
132 different kinetic or thermodynamic assumptions use. For instance, ERA-interim is
133 implemented with a bulk Richardson number method (Palm *et al.*, 2005), which is
134 believed to be suitable for all atmospheric conditions (Anderson, 2009). It is worth
135 highlighting that the state-of-art reanalysis could be one of the most promising data
136 sources for obtaining the synoptic or climatological features of BLH.

137 Despite much progress made in developing the BLH products, there are still some
138 unresolved issues in quantifying the variability of BLH from a global perspective.
139 These issues include: the worldwide variation of BLH by high-resolution vertical
140 soundings, the inter-comparisons among reanalysis datasets, and further evaluations
141 with radiosonde observations, especially in the daytime based on the same retrieval
142 algorithm. To this end, this study seeks to address the following scientific questions: (1)
143 a climatological distribution of near-global BLH by using high-resolution radiosonde
144 measurements; (2) inter-comparisons of ERA-5, MERRA-2, JRA-55, and NCEP-2 with

145 additional evaluation with radiosondes; and (3) investigate potential sources for the
146 biases of BLH between observation and reanalysis. The rest of the paper is organized
147 as follows. The descriptions of high-resolution radiosonde data, reanalysis products,
148 and the bulk Richardson number method are given in Section 2. Section 3 presents the
149 spatial distributions of BLH by radiosonde and reanalyses and their inter-comparisons.
150 A brief conclusion and remarks are finally outlined in Section 4.

151 **2. Data descriptions and BLH retrieval method**

152 *2.1 High-resolution radiosonde measurements*

153 ~~In~~ ~~Until~~ ~~January~~ 2018, IGRA provided atmospheric soundings at around 445
154 radiosonde sites across the globe, including pressure, temperature, humidity and wind
155 vector. The number of pressure levels below 500 hPa is around 10-30. By comparison,
156 for high-resolution radiosondes, the sampling rate is 1-s or 2-s, corresponding to a
157 vertical resolution of approximately 5–10 meters throughout the atmosphere. The high-
158 resolution radiosonde measurements used in the present study are obtained from 342
159 sites around the world, which are provided by several organizations, including the
160 China Meteorological Administration (CMA), the National Oceanic and Atmospheric
161 Administration (NOAA) of United States, the German Deutscher Wetterdienst (Climate
162 Data Center), the Centre for Environmental Data Analysis (CEDA) of United Kingdom,
163 the Global Climate Observing System (GCOS) Reference Upper Air Network
164 (GRUAN), and University of Wyoming.

165 The CMA maintains the China Radiosonde Network (CRN), which contains 120
166 operational stations homogeneously distributed across mainland China with a vertical
167 sampling rate of 1 second (5–8 m resolution), since 2011 (Guo *et al.*, 2016; 2019; Zhang
168 *et al.*, 2016; 2018; Su *et al.*, 2020). The NOAA started the Radiosonde Replacement
169 System (RRS) program in 2005, which involved 89 sites with a vertical resolution of 5
170 m (Zhang *et al.*, 2019). The German Deutscher Wetterdienst (Climate Data Center) has
171 been sharing the radiosonde measurements at 14 sites with a sampling rate of 2 seconds

172 since 2010. Moreover, the 10 m resolution soundings at 12 sites was provided by the
173 CEDA, which began to share soundings since 1990, and 8 radiosonde sites were shared
174 by GRUAN with a vertical resolution smaller than 10 m. An additional 93 sites came
175 from the University of Wyoming, which started in 2017⁸, with a sampling rate of 2-s
176 or 1-s. In total, over 678,000 soundings at 342 stations are used here for the period of
177 January 2012 to December 2019 in total of eight years, including 633,000 soundings at
178 the regular release times of 0000 and 1200 UTC and 43,000 more irregular observations
179 during intensive observation period (IOP).

180 Radiosonde measurements are taken twice per day following the World
181 Meteorological Organisation (WMO) protocol for synoptic times at 0000 and 1200
182 UTC (Seibert *et al.*, 2000), except for special field campaign observations at specified
183 stations or time ranges during IOPs. The protocol implies that stations at different
184 longitudes sample the diurnal cycle differently. For instance, stations near 0°E (London)
185 and 180°E (Samoa) sample at midnight and midday, while stations near 90°E
186 (Bangladesh) and 90°W (Chicago) sample at dawn and dusk, with intermediate
187 longitudes at linearly varying intermediate local solar times (LSTs) of day. For
188 wintertime regions near 90°W and 90°E, the release times are insufficient for evaluating
189 the BLH during daytime. Hence, the BLH estimates from regular radiosondes will vary
190 with longitude and season (McGrath-Spangler and Denning, 2012). Generally, the
191 principal PBL mechanism at night is associated with an SBL, which gradually
192 transitions into CBL in the morning (Stull, 1988; Zhang *et al.*, 2018). The transition
193 from SBL to CBL is generally quick and occurs swiftly after sunrise, but the reverse
194 process can be slow in the late evening (Taylor *et al.*, 2014). Despite the dominance of
195 CBL during the daytime, an SBL still occurs, especially in the event of overcast sky
196 (Zhang *et al.*, 2018; 2020) and near strong divergence in moist convective downbursts
197 (King *et al.*, 2017). To illustrate the daytime variation of BLH, we only selected the
198 soundings that are launched 2 hours after sunrise and 2 hours before sunset. The sunrise
199 and sunset times are gauged in a longitude bin size of 15 degrees and based on the
200 latitude of station and the calendar day of the release. [Using this definition, a total of](#)

201 190,013 profiles including soundings launched at both synoptic times and during IOP,
202 spanning January 2012 to December 2019, are used to obtain the BLHs in the daytime
203 ~~As a result, 190,013 profiles which include soundings launched at both synoptic times~~
204 ~~and during IOP, spanning from January 2012 to December 2019, to obtain the BLH in~~
205 ~~the daytime.~~ The spatial distribution of file number for each site is displayed in Figure
206 S1, in which the sites with less than 10 matches are excluded.

207 2.2 ERA-5, MERRA-2, JRA-55 and NCEP-2 reanalysis datasets

208 ERA-5 is the successor of ERA-interim and has undergo a variety of
209 improvements, including more recent parameterization schemes and data assimilation
210 system, better spatial resolution, both horizontally and vertically (137 levels), and
211 improved representation of evaporation balance, cyclones, soil moisture, and global
212 precipitation (Hersbach *et al.*, 2020). The BLH is composited in the ERA-5 product on
213 a 1440×721 grids with 0.25° longitude and 0.25° latitude resolution. It is computed by
214 the bulk Richardson number method, with a temporal resolution of 1 hour.

215 MERRA-2 is the latest atmospheric reanalysis of the modern satellite era
216 produced by NASA's Global Modeling and Assimilation Office (GMAO). It includes
217 aerosol data assimilation, improvements on ozone, and cryospheric processes (Gelaro
218 *et al.*, 2017). In this product, the BLH is packaged and defined by identifying the lowest
219 level at which the heat diffusivity drops below a threshold value (McGrath-Spangler
220 and Denning, 2012). ~~The formula for calculating BLH is as followseomputed as:~~

$$221 \text{BLH(MERRA2_packaged)} = 44308 \times (1 - (P_{PBLtop}/P_{Surface})^{0.1903}) \quad (1)$$

222 where BLH(MERRA2_packaged) is in unit of meter, P_{PBLtop} the BLH (packaged
223 parameter in MERRA-2, in unit Pa), and $P_{Surface}$ the surface pressure (in unit Pa).
224 However, to preclude the uncertainty raised by different methods adopted, the BLH by
225 MERRA-2 is extracted by bulk Richardson number method, by utilizing the parameters
226 of horizontal wind, temperature, geopotential height, relative humidity (RH), and
227 surface pressure as inputs. ~~These input data are~~ ~~the data is~~ provided on a grid of 576×361
228 points with 0.625° longitude and 0.5° latitude resolution and has

229 42 pressure levels (about 16 layers below 500 hPa), with a temporal resolution of 3 h.
230 ~~In this product, the BLH is defined by identifying the lowest level at which the heat~~
231 ~~diffusivity drops below a threshold value (McGrath-Spangler and Denning, 2012).~~

232 ~~However, to preclude the uncertainty raised by different methods adopted, the~~
233 ~~BLH by MERR-2 is extracted by bulk Richardson number method, utilizing the~~
234 ~~parameters of horizontal wind, temperature, geopotential height, relative humidity (RH),~~
235 ~~and surface pressure.~~

236 JRA-55 is the second Japanese global atmospheric reanalysis commissioned by
237 the Japan Meteorological Agency (JMA) (Kobayashi *et al.*, 2015). Data contains 37
238 pressure levels between 1 hPa and 1000 hPa (16 layers below 500 hPa), provided on a
239 grid of 288×145 points, with a horizontal spacing of $1.25^\circ \times 1.25^\circ$ and a temporal
240 resolution of 6 hours. The parameters, including geopotential height, temperature,
241 horizontal wind, surface pressure, and RH, are used to assess BLH as before.

242 NCEP-2 has the coarsest model resolution than ERA-5 (Rinke *et al.*, 2019), with
243 a spatial resolution of 2.5° longitude and 2.5° latitude. The total level is 17 (6 layers
244 below 500 hPa), which is substantially less than MERRA-2, JRA-55 or ERA-5, and the
245 temporal resolution is 6 hours. Similar parameters to JRA-55 are preserved to compute
246 BLH. It is noteworthy that all model times include 0000 and 1200 UTC and hence
247 collocate well with the synoptic radiosonde times.

248 *2.3 Normalized sensible heat flux in the daytime*

249 ~~—The sensible heat flux represents the level of energy that induces CBL growth (Wei~~
250 ~~*et al.*, 2017), whereas the latent heat fluxes characterize the evaporation of moisture~~
251 ~~from the soil to the CBL, which feedbacks on the development of CBL and the~~
252 ~~formation of PBL cloud (Pal and Haeffelin, 2015). For a given amount of heat flux,~~
253 ~~small latent heat fluxes usually mean more energy being available for PBL growth~~
254 ~~(Chen *et al.*, 2016). Moreover, the surface heat flux is closely associated with near-~~
255 ~~surface meteorological variables. For instance, a lower RH usually indicates a larger~~
256 ~~sensible heat flux and lower latent heat flux (Guo *et al.*, 2019; Zhang *et al.*, 2013).~~

Suppose that the heat supplied to the air at the radiosonde balloon launch time is the area shaded under the heat flux curve (Fig.11.12 in Stull 1988), the normalized sensible heat flux in the daytime is defined by

$$\overline{Q_H} \propto \int_{T_{sunrise}}^{T_{launch}} Q_H \rho^{-1} c_p^{-1} dt \quad (1)$$

where $T_{sunrise}$ and T_{launch} are the sunrise time and radiosonde balloon launch time, Q_H the sensible heat flux, ρ the near surface density and c_p equals $1004 \text{ J}^\circ\text{C}^{-1}\text{kg}^{-1}$. The similar principle is applied to the calculation of normalized latent sensible heat flux as well.

2.3.4 Bulk Richardson number method

In the spirits of a like-for-like comparison, the BLHs derived from radiosonde and reanalysis data (MERRA-2, JRA-55, and NCEP-2) are calculated using the bulk Richardson number (BRN), which also serves as the built-in algorithm in ERA-5 for BLH products. The BRN, an algorithm used to reflect how strongly buoyancy is coupled to the vertical momentum (Scotti, 2015), has been widely used for the climatological study of BLH from radiosonde measurements thanks to its applicability and reliability for all PBL regimes (Anderson 2009; Seidel *et al.*, 2012; Guo *et al.*, 2019). It determines the BLH by identifying the level at which the bulk Richardson number, represented by $Ri(z)$, reaches its critical value (Palm *et al.*, 2005) and is formulated as:

$$Ri(z) = \frac{\left(\frac{g}{\theta_{vs}}\right)(\theta_{vz} - \theta_{vs})z_{AG}}{(u_z - u_s)^2 + (v_z - v_s)^2 + (bu_*^2)} \quad (2)$$

where g is the gravitational acceleration, z_{AG} the height above ground level (AGL), θ_v the virtual potential temperature, u_* the surface friction velocity, and u and v the horizontal wind components and b a constant, which is usually set to zero due to the fact that friction velocity is much weaker compared with the horizontal wind (Seidel *et al.*, 2012). The subscripts of z and s denote the parameters at z height above ground and ground level, respectively.

284 It is known that $Ri(z)$ increases with increasing free flow stability (Zilitinkevich
285 and Baklanov, 2002). Below a critical value of 0.25, the flow is dynamically unstable
286 and likely cause turbulent motion. Nevertheless, since turbulence can also occur away
287 from this critical value (Haack *et al.*, 2014), care must be taken in that the critical value
288 might not be well defined, leading to uncertainty in estimating BLH. Meanwhile, the
289 BLH estimates were found not to change very much by differing the input of critical
290 values ($Ri = 0.2; 0.25; 0.3$) (Guo *et al.*, 2016). Therefore, for a given discrete Ri
291 profile, here we identify the BLH as the interpolated height at which the $Ri(z)$ firstly
292 crosses the critical value of 0.25 starting upward from the ground surface. Besides,
293 Based on the result in Seidel et al. (2012), it is well recognized that the vertical
294 resolution of radiosonde measurement has large impact on the BLH estimated. For
295 instance, BLHs are usually lower for a sparser vertical resolution (Seidel et al., 2012).
296 Therefore, factors that can arise cause uncertainty in estimating BLH by using the
297 bulk Richardson method include, (but not limited to,) meteorological parameters, the
298 surface friction, vertical resolution of data and the critical value of Ri .

299 2.45 Collocation procedure and a case study

300 In contrast to the reanalysis data, the longitude, and latitude distributions of high-
301 resolution radiosonde are irregular. A precise comparison between reanalysis data and
302 sounding is required for consistency in time, latitude, and longitude. The matching
303 procedures implemented in this present study go as follows. (1) A latitudinal and
304 longitudinal matching procedure is carried out by finding the geographical grid cell of
305 the reanalysis product that contains the radiosonde station. (2) Time matching for ERA-
306 5 is to find the exact UTC time (hour) of the weather balloon launch. (3) For MERRA-
307 2, NCEP-2, and JRA-55 datasets, the requirement is to limit the time difference with
308 the weather balloon launch time to 1 hour.

309 A case at 0600 UTC 06 Jun 2016, Chongqing (29.6°N, 106.4°E, 541 m) is shown
310 in Figure 1. In this case, BLH obtained by sounding is 1,337 m and is closest to that by
311 ERA-5, which underestimates the height by 72 m. Compared with the radiosonde
312 profile, MERRA-2 can capture the main vertical structures and the magnitude of wind

313 speed (WS), RH, and temperature, but not the fine-scale vertical variations (Figure 1b).
314 It also slightly undervalues the BLH by 125 m. The basic parameters outlined by NCEP-
315 2, for instance, RH (5% larger than sounding), temperature (3°C less than sounding),
316 and wind speed (4.5 m/s larger than sounding), all have notable differences with the
317 sounding (Figure 1c). Eventually, The NCEP-2 derived BLH is considerably
318 underestimated by 729 m. By and large, the profiles from JRA-55 are not as accurate
319 as those from MERRA-2. More specifically, the wind speed at some heights,
320 prominently above 2 km, is underestimated (Figure 1d); the mean RH is 4% less than
321 that from the sounding. As a result, JRA-55 substantially underestimates BLH by 399
322 m. ~~The basic parameters outlined by NCEP-2, for instance, RH (5% larger than~~
323 ~~sounding), temperature (3°C less than sounding), and wind speed (4.5 m/s larger than~~
324 ~~sounding), all have notable differences with the sounding (Figure 1c). The BLH is~~
325 ~~considerably underestimated by 729 m.~~ Based on this case, we can note that the
326 performances of ERA-5 and MERRA-2 are obviously better than those from JRA-55
327 and NCEP-2 in terms of the BLH. ~~T, and that~~ the remarkable underestimation by
328 NCEP-2 can be attributed to the underestimations in near-surface virtual potential
329 temperature (roughly 2.46 K less than sounding) and temperature. By comparison, :
330 The underestimation in RH can be largely responsible for the smaller BLH in by JRA-
331 55 could be attributed to the underestimated RH. large error in the prediction of basic
332 parameters, such as wind, temperature, and RH.

333 2.5 Normalized sensible/latent heat flux in the daytime

334 The sensible heat flux represents the level of energy that induces CBL growth (Wei
335 et al., 2017), whereas the latent heat fluxes characterize the evaporation of moisture
336 from the soil to the CBL, which feedbacks on the development of CBL and the
337 formation of PBL cloud (Pal and Haefelin, 2015). For a given amount of heat flux,
338 small latent heat fluxes usually mean more energy being available for PBL growth
339 (Chen et al., 2016). When less energy is constrained by the moist ground, more energy
340 is available to heat the air. Moreover, the surface heat flux is closely associated with
341 near-surface meteorological variables. For instance, a lower RH usually indicates a

342 larger sensible heat flux and lower latent heat flux (Guo et al., 2019; Zhang et al., 2013).
343 Suppose that the heat supplied to the air at the radiosonde balloon launch time is the
344 area shaded under the heat flux curve (Fig.11.12 in Stull 1988), the normalized sensible
345 heat flux in the daytime is defined by

$$\overline{Q_H} \propto \int_{T_{sunrise}}^{T_{launch}} Q_H \rho^{-1} c_p^{-1} dt \quad (3)$$

347 where $T_{sunrise}$ and T_{launch} are the sunrise time and radiosonde balloon launch
348 time, Q_H the sensible heat flux, ρ the near-surface density and c_p equals 1004
349 $J^\circ C^{-1}kg^{-1}$. The similar principle is applied to the calculation of normalized latent heat
350 flux as well.

351 **3. Results and discussion**

352 *3.1 Overview of BLHs at two synoptic times and over the day*

353 The near-global mean BLHs at 0000 UTC from 2012 to 2019 by four reanalysis
354 products are shown in Figure 2, in which the results obtained from radiosonde are
355 overlaid by colored circles. The stations with sounding covering at least 2 continuous
356 years are kept. The four reanalysis products yield an analogous result with respect to
357 the spatial variation of BLHs, which are positively correlated with the sounding-derived
358 BLH, with correlation coefficients of 0.90, 0.81, 0.47, 0.46; ~~0.81~~ for ERA-5, MERRA-
359 2, NCEP-2, and JRA-55, ~~and MERRA-2~~, respectively. It is evident that the BLHs from
360 NCEP-2 over the continents of Africa, Asia, and South America are 300 m thicker than
361 those of the other three products (Figure 2b). Furthermore, the BLH in Antarctic by
362 ERA-5 is notably 500 -m lower than that by NCEP-2 and MERRA-2 (Figure 2a). Most
363 of the mean BLHs by radiosonde are consistent with the reanalysis products, except
364 that the values from all four reanalysis products over the Pacific Ocean and the
365 contiguous U.S. are underestimated by about 300 m. Moreover, it is worth to note here
366 that the BLHs by JRA-55 are considerably underestimated by around 1 km over these
367 regimes. For 0000 UTC, the regions nearly from the east coast to the west coast of

368 Pacific Ocean (UTC+8 to UTC+12, and UTC-12 to UTC-8) are covered by sunshine,
369 and thus are filled with deeper PBL.

370 Comparable results at 1200 UTC are presented in Figure S2. Africa, the Middle
371 East, and the west of India and China, corresponding to local noon and afternoon, have
372 maximal BLHs of around 1.8 km. Moreover, it is noteworthy that the values from
373 NCEP-2 and JRA-55 over these areas are visibly lower than those from ERA-5 and
374 MERRA-2, particularly over Africa and the Middle East, whereas these low values can
375 barely be validated with soundings due to their sparse distribution. Over these areas,
376 the BLHs are underestimated by reanalysis by about 200 m relative to the sounding
377 results. Notably, BLHs from NCEP-2 over the continents of Africa are 1 km lower than
378 those from ERA-5 and MERRA-2. According to the results at 0000 and 1200 UTC, the
379 comparisons between reanalysis products and soundings demonstrate that the BLHs are
380 well resolved in the nighttime but are underestimated at daytime by reanalysis datasets.

381 For the near-global variation of BLH at a certain synoptic time, daytime and
382 nighttime appear on the map simultaneously, but as a function of longitude, which is
383 displayed in Figure 2. Thus, the variations at a fixed synoptic time on the map create a
384 picture of the diurnal BLH variation. Given the dominance of CBL in the daytime,
385 investigating the BLHs in the daytime is thus favorable for unravelling the underlying
386 causes for the discrepancies existed in the BLHs from both radiosonde and reanalysis.
387 Therefore, the following results show the variations of daytime BLH only, unless
388 otherwise noted.=

389 ~~3.2 Variations over the day and comparisons with reanalysis products~~

390 The climatological mean variations in the daytime BLH from the soundings and
391 four reanalysis products are drawn in Figure 3. The period spans from January 2012 to
392 December 2019 for most of the stations provided by China, the U.S., Germany, and the
393 U.K. As implied by the results from soundings (Figure 3e), the deepest PBL is observed
394 over the Tibetan Plateau (TP) and the northwest of China, the south of Africa, and the
395 west of U.S, with values as high as 1.7 km. The possible reason for this phenomenon is

396 that the weather balloons over these regions are basically launched in the early
397 afternoon of boreal summer (June–July–August) when the maximal BLH is usually
398 observed (Collaud Coen *et al.*, 2014; Guo *et al.*, 2016). The BLHs over the Pacific
399 Ocean are noticeably large, with values of 1.3 km. The longitudinal variation of BLH
400 is evident, likely due to LST variations of the soundings. Additionally, BLHs in the
401 middle and low latitudes are larger than high latitudes, which is consistent with the
402 findings in Gu *et al.* (2020).

403 By and large, the climatological results of BLH by radiosonde and four model
404 products are comparable, indicating that both capture the spatial diurnal and seasonal
405 variations implied by the sounding LST times sampled. Among the model products,
406 ERA-5 shows the best prediction of BLH contrasted with radiosonde, with a correlation
407 coefficient of 0.88 (Figure 3a). Furthermore, the results from MERRA-2 are positively
408 correlated with those from the soundings, with a correlation coefficient of 0.66 (Figure
409 3b). The performances of JRA-55 and NCEP-2 are significantly poorer than those of
410 ERA-5 and MERRA-2, with correlation coefficients of 0.4 and 0.41, respectively
411 (Figure 3c, d). The values of BLH over the west of U.S and the west of China are
412 seriously underestimated by NCEP-2 and JRA-55 by around 800 m. Thus, we note that
413 ERA-5 and MERRA-2 are more robust in deriving the BLH, purely based on the
414 climatological distribution of BLHs.

415 Figure 4 illustrates the diurnal variations in BLH at 0000 and 1200 UTC and
416 during daytime. A notable diurnal variation can be noticed, with a minimum of 343 m
417 at 0400 LST and a maximum of 1224 m at 17 LST (Figure 4a). The magnitude in BLH
418 during daytime are essentially larger than that at 0000 and 1200 UTC and has a maximal
419 value of 1926 m at 1700 LST (Figure 4b). It follows that most of soundings (about 78%)
420 some soundings that are released at 0000 and 1200 UTC are excluded by the collocation
421 procedure designed for collecting samples in the daytime. Note that the result during
422 daytime will not significant change with/without IOP data. –

3.2 Correlations with near-surface meteorological variables and surface heat flux

The PBL is the lowest part of the troposphere and evolves diurnally due to near-surface thermodynamic variables through turbulent exchanges of momentum, heat, and moisture (Pithan *et al.*, 2015). Thus, the surface meteorological variables depend on the underlying land surface and its coupling with the PBL, and they could act as a good proxy for BLH under some specific circumstances (Zhang *et al.*, 2013; Zhang *et al.*, 2018). An analysis of the correlation between the BLHs by radiosondes and near-surface meteorological variables is presented in Figure 5. The variables include near-surface air temperature at 2 m AGL (T_{2m}), pressure (Ps), RH, and WS, which are extracted from the first level in sounding. The first level is assumed to be associated with the near-surface variables (Serreze *et al.*, 1992; Wang and Wang 2016). We note that BLH, T_{2m} , RH and WS all have substantial diurnal and seasonal variability as partly expressed in Eq. (2).

Moderate positive (negative) correlation coefficients can be noticed between BLH and T_{2m} (RH), with mean values of 0.39/-0.51 (Figure 5a, c), implying that both T_{2m} and RH could be an adequate indicator for the temporal variation of BLH. Moreover, the correlations between BLH and WS are also positively notable, with a mean value of 0.24 (Figure 5d). By contrast, the correlation between Ps and BLH is negatively significant above most of the regions (Figure 5b).

The correlation analyses between BLH and normalized heat fluxes, which are assessed by ERA5 reanalysis products, are displayed in Figure 6. It is notable that positive/negative correlation coefficients usually exist in normalized sensible/latent heat flux, with a global mean of 0.29 and -0.31. This correlation is not high because BLH also depends on the radiative heating/cooling and the temperature profile in different stations (Yang *et al.*, 2004).

For the climatological variation of BLH, the near surface variables such as T_{2m} , RH and WS, and the normalized sensible/latent heat flux could be a good indicator.

450 Conversely, the development of BLH could also limit the magnitude of RH (McGrath-
451 Spangler, 2016).

452
453 3.32 Variations over the day and eComparisons with reanalysis products

454
455 The radiosonde stations are mainly dispersed over the U.S, China,
456 ~~Austria~~Australia, Europe, the Pacific Ocean, and the polar region, and only a few
457 stations contribute over the rest of the world. The polar region contains a station with a
458 ~~latitude longitude~~-larger/lower than 67.7°N/°W. Therefore, six regions are specifically
459 examined in terms of the bias between radiosonde and model product.

460 The BLH differences between ~~ERA5~~radiosonde and ~~radiosonde ERA-5~~ are shown
461 in Figure ~~75~~, in which we specify the differences over the six above-mentioned regions.
462 As observed in Figure ~~75e~~, the BLH over most of the stations is underestimated to a
463 slight extent, with a near-global mean of ~~131.96~~130.44 m. As expected, the most
464 underestimated regions cover the west of U.S, and southern China (Figure ~~75e~~), with a
465 difference of around 200 m. In addition, it is worth mentioning that the BLHs over the
466 Pacific Ocean are overestimated in four seasons, with a bias of around 400 m (Figure
467 ~~75h~~). Among the six classified regions, BLHs in Europe, East Asia, and polar are
468 reliably determined by ERA-5, with an average bias of around ~~50~~50 m (Figure ~~75b, c,~~
469 i). The bias seems to exhibit a seasonal dependence, and it is around 62 m larger in the
470 warm seasons ~~compared to and smaller in the~~ cool seasons in both hemispheres.
471 Regardless of the small bias, the newest model product, ERA-5, properly estimates the
472 BLH, especially above the regions of Europe, the eastern U.S, East Asia, and polar.

473 Similarly, the BLHs by MERRA-2 are underestimated, with a near-global mean
474 bias of ~~166.35~~159.72 m (Figure ~~86~~), which is slightly larger than that of ERA-5
475 (~~130.44~~131.96 m). This could indicate that the MERRA-2-derived BLH is more

476 dispersed than ERA-5. The spatial distribution of bias value is broadly identical to that
477 of ERA-5, except that the BLHs over Europe, ~~Austria~~Australia, and polar region are
478 well estimated by MERRA-2, due to much smaller mean biases at 42.7840 m,
479 ~~52.9839.70~~ m, and ~~66.2052.27~~ m, respectively (Figure 86b, g, i).

480 In addition, the packaged BLH in MERRA-2 is also evaluated with radiosonde.
481 BLH is as high as 3 km over the TP region at 0600 UTC (Figure S3), corresponding to
482 an overestimation of 0.8 km over this region (Figure S4). Over the rest regions, BLH is
483 slightly or moderately overestimated by around 50 m. However, The BLH difference
484 among various methods could reach up to a kilometer or even more (Seidel *et al.*, 2010),
485 which is probably owing to the variety of kinetic or thermodynamic theories applied in
486 different algorithms.

487
488 By comparison, the mean bias produced by JRA-55 is larger than those from ERA-
489 5 and MERRA-2, with a mean value of 3512.459 m, as shown in Figure 97. The BLHs
490 above most stations are underestimated by JRA-55, particularly for the sites over
491 western China and western U.S, and the Pacific Ocean, with an underestimation of
492 about 800 m. The most underestimated stations cluster at the latitude range of 40–45°N,
493 with a mean difference of around 1 km (Figure 97f). Although the ensemble-near-global
494 mean of bias is significantly larger than ERA-5 and MERRA-2, the estimations over
495 Europe and the pPolar regions seem to be more in line with the observations acceptable,
496 with mean values of 174.997.0 m and 93.849.2 m, respectively (Figure 97b, i).

497 The mean bias by NCEP-2 is larger than that by JRA-55, with a mean value of
498 420.867 m, as illustrated by Figure 108. The distribution results are similar to JRA-55,
499 except for Europe and ~~Australiaia~~, where the bias is about twice that of JRA-55.

500 In general, the comparison analysis of the daytime BLH results between soundings
501 and four reanalysis datasets indicates that ERA-5 reanalysis produces the BLH that is
502 closest to the high-resolution soundings. Interestingly, MERRA-2 can provide a good
503 spatial distribution of BLH. JRA-55 and NCEP-2 can only give a good prediction over

504 some regions, most of which tends to produce a much larger BLH estimates compared
505 to those from ERA-5 and MERRA-2.

506 *3.3 Correlations with near surface meteorological variables and surface heat flux*

507 The PBL is the lowest part of the troposphere and evolves diurnally due to near-
508 surface thermodynamic variables through turbulent exchanges of momentum, heat, and
509 moisture (Pithan *et al.*, 2015). Thus, the surface meteorological variables depend on the
510 underlying land surface and its coupling with the PBL, and they could act as a good
511 proxy for BLH under some specific circumstances (Zhang *et al.*, 2013; Zhang *et al.*,
512 2018). An analysis of the correlation between the BLHs by radiosondes and near-
513 surface meteorological variables is presented in Figure 9. The variables include near-
514 surface air temperature at 2 m AGL (T_{2m}), pressure (P_s), RH, and WD, which are
515 extracted from the first level in sounding. The first level is assumed to be associated
516 with the near surface variables (Serreze *et al.*, 1992; Wang and Wang 2016). We note
517 that BLH, T_{2m} , RH and WD all have substantial diurnal and seasonal variability as
518 partly expressed in Eq. (2).

519 Relatively high positive (negative) correlation coefficients can be noticed between
520 BLH and T_{2m} (RH), with mean values of 0.39/ 0.51 (Figure 9a, c), implying that both
521 T_{2m} and RH could be an adequate indicator for the temporal variation of BLH.
522 Moreover, the correlations between BLH and WD are also positively notable, with a
523 mean value of 0.24 (Figure 9d). By contrast, the correlation between P_s and BLH can
524 be ignored above most of the regions (Figure 9b).

525 The correlation analyses between BLH and normalized heat fluxes, which are
526 assessed by EAR 5 reanalysis products, are displayed in Figure 10. It is notable that
527 positive/negative correlation coefficients usually exist in normalized sensible/latent
528 heat flux, with a global mean of 0.29 and -0.31. This correlation is not high because
529 BLH also depends on the radiative heating/cooling and the temperature profile in
530 different stations (Yang *et al.*, 2004).

531 ~~For the climatological variation of BLH, the near surface variables such as T_{2m} ,~~
532 ~~RH and WS, and the normalized sensible/latent heat flux could be a good indicator.~~
533 ~~Conversely, the development of BLH could also limit the magnitude of RH (McGrath-~~
534 ~~Spangler, 2016).~~

535 3.4 Potential sources for the bias between reanalysis products and radiosonde ~~and~~ 536 reanalysis products

537 The possible sources for the difference between radiosonde and reanalysis could
538 be rather complicated. From the spatial pattern of BLH discrepancy results between
539 radiosonde and reanalysis (Figures 75–108), we can notice that the regions with large
540 differences tend to be observed over regions with high elevation, such as the TP in
541 China and Rocky mountain in the U.S. These regions generally have much more
542 complex orography. Coincidentally, the soundings over the above-mentioned two regions
543 are all obtained from afternoon, in which the PBL develops to the maximum (Figure 4).
544 As expected, highest biases generally are accompanied with peak BLHs, which has also
545 been confirmed in our previous studies (cf. Figure 2c in Li *et al.*, 2017). Therefore, the
546 biases depend on the LST when the weather balloon is launched, which at least could
547 not be ruled out.

548 In addition, the large differences primarily appear in the low and middle latitudes,
549 where thermal convection frequently occurs. Therefore, it is reasonable to infer that
550 static stability could exert an influence on the comparison results. Then, we will analyze
551 the probable influences from terrain and static stability on BLH differences.

552 We evaluate the influence from the orographic complexity around the sounding
553 station and calculate the standard derivation (STD) of elevation within $1^{\circ} \times 1^{\circ}$ grid, with
554 the help of 30 arc second digital elevation model (DEM) dataset. Terrain is complex
555 over the western China and western US where most of soundings are released inat
556 afternoon and large BLH biases are usually found. Therefore, for all soundings that are
557 launched during the time period ~~at the time interval~~ spanning from 1300 LST to 1800
558 LST we analyze the relationship between BLH biases and the standard derivation of

559 ~~the DEM (Figure 11). The analysis of the correlation between the bias of the BLH and~~
560 ~~the standard derivation of the DEM is shown in Figure 11.~~ It follows that the influence
561 from the orography appears instrumental, given the correlation coefficient varying from
562 ~~-0.84 to -0.84~~ ~~0.31 to -0.95~~ ~~-0.95~~ ~~0.81~~. Furthermore, the errors or uncertainties in
563 ERA-5 are less easily impacted by the orographic complexity given a much flatter fitted
564 line due to the relatively lower correlation coefficient of 0.84 ~~-0.84~~ ~~0.31~~ (Figure 11a).
565 The relationship between BLH biases and DEM spread when only soundings that are
566 released at 1300 LST

567 Based on the correlation between orographic complexity (manifested by the STD
568 of the DEM) and the bias of a reanalysis relative to radiosonde measurements, it is
569 likely that the performances of MERRA-2, JRA-55, and NCEP-2 might be restricted
570 by the complex underlying terrains. One of the reasons could be because global
571 reanalysis with coarse resolution that cannot resolve the sub-grid processes due to
572 topography. However, ERA-5 appears to be less dependent on terrain. In other words,
573 the models used in ERA-5 show sufficient capability and excellent performance in
574 reproducing the atmospheres, particularly in the PBL over complex terrains.

575 Lower tropospheric stability (LTS) is an indicator to describe the thermodynamic
576 state of the lower atmosphere and is defined by the differences in potential temperature
577 at 700 hPa and 1000 hPa (Guo *et al.*, 2016). Typically, the smaller the LTS, the more
578 unstable the low troposphere. The mean LTS over each station is defined by the
579 ensemble mean by four reanalysis datasets, and its spatial distribution is depicted in
580 Figure 12. The lower troposphere over the western United States and western China is
581 more unstable compared to the rest of the world, with LTS of around 6K (Figure 11a),
582 which is likely associated with afternoon launch time of weather balloons. According
583 to the correlation between the bias of BLH and the mean LTS, it is clear that the
584 underestimation in BLH by JRA-55 and NCEP-2 products are negatively correlated
585 with LTS, with correlation coefficients of -0.32 and -0.36 (Figure 12b).

586 Besides the LTS, the role of lifted index could be another influential factor. The
587 lifted index is a predictor of latent instability (Galway, 1956), and it is defined as the

588 temperature difference between the environment temperature and an air parcel lifted
589 adiabatically at 500 hPa. The index is computed by the air temperature, RH, and
590 pressure profiles from radiosondes. We calculate the percentage of negative lifted index
591 above each station, which represents the occurrence rate of latent instability that exists
592 in the daytime (Figure 12c). The stations with high probability of strong instability,
593 denoted by $P(\text{lifted index} < 0)$, are predominantly dispersed over the west U.S, the
594 west and south of China, and the Pacific Ocean, reaching a percentage as high as around
595 70%. These stations are regularly overlapped with great biases in the reanalysis
596 products as shown in Figures ~~7-5-108~~. According to the analysis, it is clear that all four
597 reanalysis products are positively associated with $P(\text{lifted index} < 0)$, with
598 correlation coefficients ranging from ~~-0.34-0.34~~ to ~~-0.47-0.47~~ (Figure 12d). The positive
599 (negative) correlation coefficients in lifted index suggests that the underestimation by
600 reanalysis might be associated with the instability activity in the lower troposphere that
601 has not been adequately represented or simulated by the models used in reanalyses. In
602 light of the surface heating during the day and the growth of the PBL due to air ascent,
603 it is also inferred that afternoon BLHs suffer the greatest errors if this is caused by
604 inadequate air mixing within the free troposphere in models.

605 **4. Conclusions and summary**

606 A climatology of near-global BLH from high-resolution radiosonde measurements
607 has been yielded for the daytime BLH. The high-resolution radiosonde data has a much
608 finer spatial resolution of 5 m or 10 m, compared to that by IGRA, and can establish a
609 finer and more precise structure of the PBL. In addition, direct comparisons among four
610 well-established reanalysis model products have been conducted. The present study
611 adopts over 300 sounding stations with high-resolution, spanning from 2012 to 2019,
612 to investigate the climatological variation of near-global BLH in the daytime and
613 evaluates four model products at the radiosonde sampling.

614 Notable spatial variation can be observed in the climatological mean of BLH at
615 0000 and 1200 UTC. In the afternoon, the regions over the Western United States and
616 Western China have the largest BLHs with values as high as 1.7 km, whereas 0000 and
617 1200 UTC compare generally to earlier times of day (LST) in the rest of the world with
618 hence lower BLH. In addition, BLHs in the middle and low latitudes are larger than
619 those in high latitudes. The T_{2m} and RH, and the normalized sensible/latent heat flux
620 are a good predictor for the spatio-temporal evolution of BLH. The most important
621 result is we found that all the four reanalysis products generally underestimate the
622 daytime BLH, with a near-global mean varying from around 1320 m to 420 m. The
623 largest bias in reanalysis appears over the Western United States and Western China,
624 where the boundary layers grow vigorously in the afternoon. ERA-5 and MERRA-2
625 definitely have better performance than JRA-55 and NCEP-2 in terms of the magnitude
626 of BLH and a higher correlation coefficient with the soundings. The newest version of
627 reanalysis, ERA-5, has the smallest bias and the highest positive correlation relative to
628 radiosondes. The underestimation by NCEP-2 and JRA-55 is robust over some regions,
629 for instance, western China and western U.S, with differences even exceeding 800 m.
630 However, all products can obtain a precise estimate over some regions, for instance,
631 Europe, the eastern U.S, and polar, probably due to morning LST soundings and smaller
632 daytime PBL development. The BLH over the Pacific Ocean is underestimated in all
633 seasons and by all products. The underestimation tends to have a seasonal dependence,
634 i.e., the warm season has a larger underestimation. However, BLH is moderately
635 overestimated by the packaged BLH parameter in MERRA-2, possibly due to different
636 BLH-deriving methods used.

637 We investigated two possible sources contributing to the biases, including
638 topography and static stability. The analysis shows that the DEM spread does have a
639 positive-negative correlation with the bias, suggesting that the reanalysis data cannot
640 provide a reliable simulation result under complex terrain conditions. In addition,
641 reanalysis BLH errors tends to be negativepositively correlated with the occurrence rate

642 of unstable air, suggesting that the reanalyses do not accurately determine BLH when
643 the lower troposphere is unstable.

644 Although this study suffers from the inhomogeneous distribution of the radiosonde
645 sites, the climatological BLHs at the near-global scale can help us understand the
646 variation characteristics of BLH in different regions and for different LST. For the first
647 time, we present near-global BLH estimates from high-resolution radiosondes, and
648 further conduct a comprehensive comparison of BLH products for four widely used
649 reanalysis datasets using the BLHs derived from the soundings. The findings provide
650 insights into the limitations of reanalysis data and, more importantly, are expected to
651 greatly benefit future research works related to applications of different kinds of
652 reanalysis data in the future.

655 This study is jointly supported by the National Key Research and Development
656 Program of the Ministry of Science and Technology of China under grant
657 2017YFC1501401, the National Natural Science Foundation of China under grant
658 41771399, 41531070 and 41874177, and S&T Development Fund of CAMS
659 (2021KJ008). The authors would like to acknowledge the National Meteorological
660 Information Centre (NMIC) of CMA, NOAA, German Deutscher Wetterdienst
661 (Climate Data Center), U.K Centre for Environmental Data Analysis (CEDA), GRUAN,
662 and the University of Wyoming (<http://data.cma.cn/en>,
663 <ftp://ftp.ncdc.noaa.gov/pub/data/ua/data/1-sec/>, <https://cdc.dwd.de/portal/>,
664 <https://catalogue.ceda.ac.uk/>, [ftp://ftp.ncdc.noaa.gov/pub/data/gruan/processing/level2/
665 RS92-GDP/version-002/](ftp://ftp.ncdc.noaa.gov/pub/data/gruan/processing/level2/RS92-GDP/version-002/), <http://weather.uwyo.edu>) for providing the high-resolution
666 sounding data. We would like to thank the ECWMF for ERA-5 data
667 ([https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-
668 levels?tab=form](https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels?tab=form)), GMAO for MERRA-2

669 (<https://disc.gsfc.nasa.gov/datasets?keywords=MERRA-2&page=1>), NCAR and Japan
670 Meteorological Agency for JRA-55 (<https://climatedataguide.ucar.edu/climate->
671 [data/jra-55](https://climatedataguide.ucar.edu/climate-data/jra-55)), NOAA for NCEP-2
672 (<https://psl.noaa.gov/data/gridded/data.ncep.reanalysis2.html>). NASA for 30 arc
673 second digital elevation height (DEM) data (<https://search.earthdata.nasa.gov/>).

Figure 3. Spatial distributions of the mean BLHs determined at the near-global high-resolution radiosonde observational network locations during the daytime for the period 2012 to 2019, which is extracted from ERA-5 (a), MERRA-2 (b), JRA-55 (c), NCEP-2 (d), and radiosonde measurements (e), respectively. Similar to Figure 2, the scatter plot illustrates the correlations between reanalysis-derived and sonde-determined BLHs in the daytime.

909

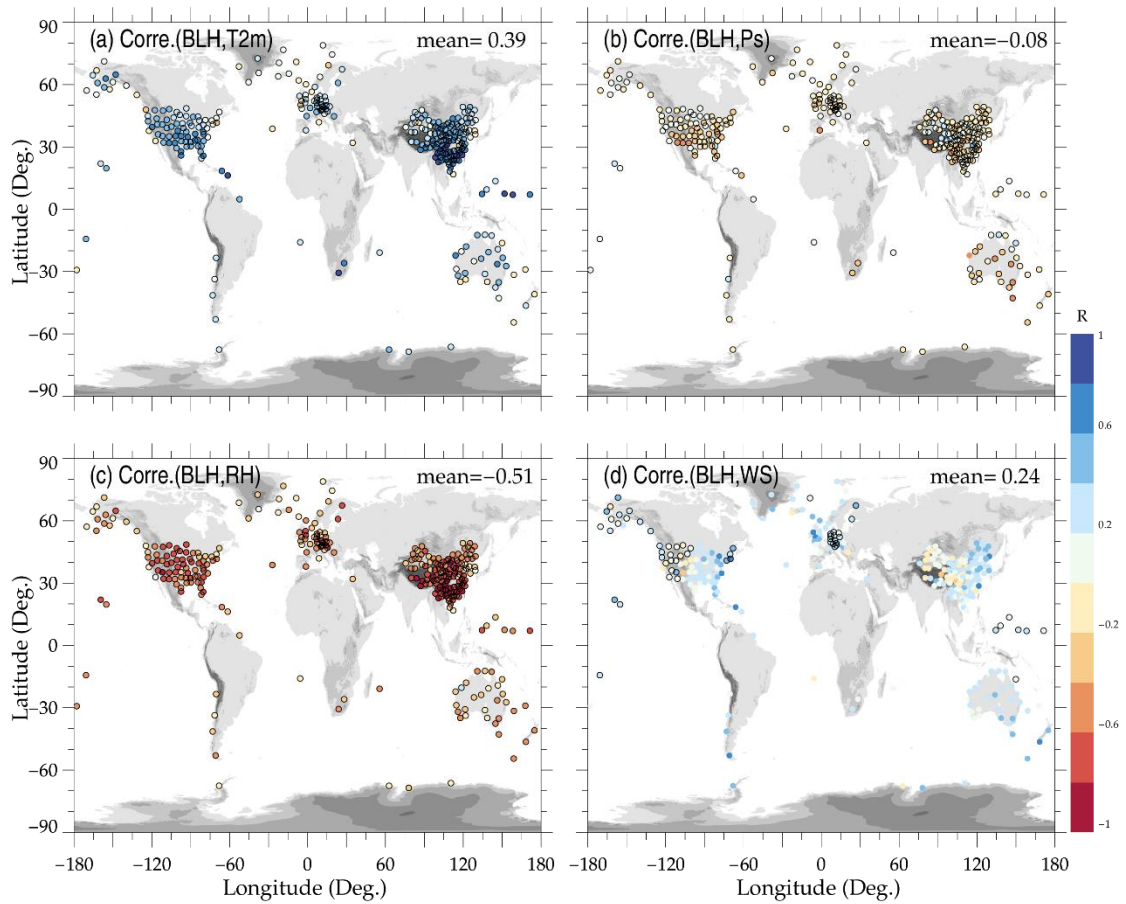

910

911

912 **Figure 4.** Box and whisker plots of diurnal variation (in LST, 24 hours) of BLH
 913 determined by all soundings operationally launched at 0000 and 1200 UTC (a) and by
 914 the soundings launched at both synoptic times and intensive observation times that are
 915 limited to the daytime alone (b). Solid green line and dotted blue line highlight the
 916 number of sonde station and total sounding for each hour of day, respectively.

917

918

919 **Figure 59.** Correlations between the radiosonde-derived BLHs and near-surface air
 920 temperature at 2m AGL (T_{2m} ; a), near-surface pressure (P_s ; b), near-surface RH (c),
 921 and near-surface wind speed (WS; d). Dots outlined in black denote that the correlation
 922 coefficient values are statistically significant ($p < 0.05$), and the mean correlations are
 923 texted in the upper right corner of each panel.
