Abstract. The mean altitude of the smoke loading over the southeast Atlantic moves from the boundary layer in July to the free troposphere by October. This study details the month-by-month changes in cloud properties and the large-scale environment as a function of the biomass-burning aerosol loading at Ascension Island (8°S, 14.5°W) from July to October, based on island measurements, satellite retrievals and reanalysis. In July and August, the smoke loading predominantly varies within the boundary layer. During both months, the low-cloud fraction is less and is increasingly cumuliform when more smoke is present, with the exception of a late morning boundary layer deepening that encourages a short-lived cloud development. The meteorology varies little, suggesting aerosol-cloud interactions explain the cloudiness changes. September marks a transition month during which mid-latitude disturbances can intrude into the Atlantic subtropics, constraining the free-tropospheric aerosol closer to the African coast. Stronger boundary layer winds on cleaner days help deepen, dry, and cool much of the marine boundary layer compared to that on days with high smoke loadings, with stratocumulus reducing everywhere but at the northern deck edge. The September free troposphere is better-mixed on smoky days compared to October. Longwave cooling rates generated by a sharp water vapor gradient at the aerosol layer top encourages a small-scale vertical mixing that could help maintain the well-mixed smoky September free troposphere. The October meteorology primarily varies as a function of the strength of the free-tropospheric winds advecting aerosol offshore. The free-tropospheric aerosol loading is less than in September, and the moisture variability is greater. Low-level clouds increase and are more stratiform in October when the smoke loadings are higher. The increased free-tropospheric moisture can help sustain the clouds through reducing evaporative drying during cloud-top entrainment. Enhanced subsidence above the coastal upwelling region increasing cloud droplet number concentrations may further prolong cloud lifetime through microphysical interactions. Reduced subsidence underneath stronger free-tropospheric winds at Ascension supports slightly higher cloud tops during smokier conditions. Overall the monthly changes in the large-scale aerosol and moisture vertical structure act to amplify the seasonal cycle in low-cloud amount and morphology. This is climatically important as cloudiness changes dominate changes in the top-of-atmosphere radiation budget.

1 Introduction

The impact of absorbing aerosol on marine boundary layer clouds is governed by the relative location of the aerosol layer to the cloud layer, with aerosol embedded within the cloud layer giving rise to local aerosol-cloud microphysical and radiative interactions, while aerosol above a cloud layer can only be radiatively active until it is entrained into the cloud (Johnson et al., 2004; Johnson, 2005; Costantino and Bréon, 2013; Yamaguchi et al., 2015; Zhou et al., 2017; Zhang and Zuidema, 2019; Kacarab et al., 2020; Herbert et al., 2020; Che et al., 2021). Many studies focusing on the southeast Atlantic region apply a seasonal-averaging to improve the robust detection of absorbing aerosol impacts (e.g., Wilcox, 2010, 2012; Adebisi and Zuidema, 2018; Mallet et al., 2020). This averages over a noticeable rise in the smoke layer, from mostly within the boundary layer in July (Zuidema et al., 2018), to a mixture of boundary layer and free-tropospheric smoke in August (Zhang and Zuidema, 2019; Redemann et al., 2021; Haywood et al., 2021), to mostly above and distinctly separated from the cloud layer by September and October (Shinozuka et al., 2020; Redemann et al., 2021; Haywood et al., 2021).

Zhang and Zuidema (2019, hereafter ZZ19) characterized the diurnal behavior of the cloudy boundary layer thermodynamic structure as a function of the near-surface smoke loading during August over Ascension Island (8° S, 14.5° W). This was motivated by the observation that the near-surface refractory black carbon (rBC) mass concentrations are largest during August, based on measurements from two years gathered through the Layered Atlantic Smoke Interactions with Clouds (LASIC; Zuidema et al., 2015, 2018) campaign. When more smoke is present within the marine boundary layer (MBL) in August, low clouds are fewer, with lower liquid water paths and lower precipitation frequencies and intensities, compared to clouds occupying a cleaner MBL. The reduction in cloudiness, which often spans multiple days, is consistent with a boundary layer semi-direct effect (Ackerman et al., 2000), wherein the relative humidity is reduced within a warmer boundary layer and less able to sustain cloud. The August analyses also support a novel finding in which the boundary layer is more coupled in the late morning (after sunrise) under smokier conditions, facilitating the cloud vertical development and deepening the boundary layer. Boundary layer decoupling from afternoon to pre-dawn encourages the trapping of sub-cloud moisture that is then ventilated upwards in the morning. The coupling is short-lived and most of the cloudiness reduction occurs in the afternoon.

Here we build on ZZ19 and extend the analyses to the other months with biomass-burning aerosol, straddling July through October. Already known is that the free-tropospheric transport of smoke to the remote part of the southeast Atlantic is related to variability in the strength of the southern African Easterly Jet (AEJ-S; Adebisi and Zuidema, 2016) during primarily September-October, and, that the AEJ-S can also advect water vapor (Adebisi et al., 2015; Deaconu et al., 2019; Pistone et al., 2021). The meteorology governing aerosol transport in July-August is less well-known, although case studies indicate lower-level easterlies bring aerosol in closer contact with the cloud layer then, easing entrainment (Diamond et al., 2018; Zuidema et al., 2018). Also less well-known, is how the cloud properties are influenced solely by meteorology, separate from the aerosol transport, and by the co-varying moisture loading. This affects our understanding of how much synoptics could also be imprinting into possible aerosol-cloud interactions. The unique island-based field measurements combined with specifically-developed satellite datasets, provide more detailed characterizations capable of supporting new insights than was possible prior to 2016.

This study characterizes the sub-seasonal evolution in low-cloud properties and thermodynamic structures as a function of the aerosol loading from July-October of 2016 and 2017. LASIC field measurements are combined with space-based retrievals of aerosol and low-cloud properties that can distinguish the above-cloud aerosol optical depth (Meyer et al., 2015), diurnally-resolved geostationary satellite cloud retrievals, and the newer ERA5 reanalysis (Hersbach et al., 2020). Compositing methods and datasets are introduced in Section 2. Sections 3-6 present an overview of the seasonal cycle and the observed differences by month for high and low smoke loading. Section 7 illustrates how sharp water vapor gradient in the free troposphere can help maintain a well-mixed free troposphere. Section 8 summarizes the key findings.

2 Datasets and compositing approach

Ground-based measurements were collected by the Department of Energy (DOE) Atmospheric Radiation Measurement (ARM) Mobile Facility 1 (AMF1; Miller et al., 2016). Radiosonde measurements of temperature, water vapor mixing ratio (q_v), relative humidity (RH) and wind characterize the thermodynamic and dynamic vertical structure above Ascension Island and St. Helena Island (5° W, 15° S, southeast of Ascension). Cloud-capping inversion base and top heights are derived from the radiosonde potential temperature (θ) and q_v profiles following Yin and Albrecht (2000), with corrections made to profiles that fail the identification algorithm based on visual inspections. An Intensive Observing Period in 2016 deployed 8 radiosondes per day in August-September, and otherwise 4 per day. A Ka-band 35 GHz zenith-pointing cloud radar (KAZR) provides the diurnal cycle of the cloud vertical structure. Microwave radiometers at both the AMF1 site and the airport (~5 km away from the AMF1) provide a measure of the cloud liquid water path (LWP). Surface rain frequencies and intensities were measured by a disdrometer and a tipping bucket rain gauge at the AMF1 site. No radar or disdrometer data are available for October, 2017. The near-surface rBC mass concentrations are derived from a single-particle soot photometer (SP2). A micro-pulse lidar underpins vertically-resolved extinction profiles (Delgado et al., 2018) for the radiative transfer calculations. Surface observers from the United Kingdom's Meteorological Office at Ascension Island, trained to look away from the island, report cloud types following the World Meteorological Organization's (WMO) protocol (WMO, 1974) every 3 hours. These reports inform the frequency of occurrence of cumuliform and stratiform clouds over Ascension. Cumuliform clouds include low-cloud type 1 ($C_L=1$, cumulus with little vertical extent) and $C_L=2$ (cumulus with moderate or strong vertical extent). Stratiform clouds include $C_L=4$ (stratocumulus formed by the spreading out of cumulus), $C_L=5$ (stratocumulus), $C_L=6$ (stratus but not of bad weather), and $C_L=8$ (stratocumulus and cumulus with bases at different levels). Detailed descriptions of LASIC observations, including quality control and post-processing information, can be found in Section 2 of ZZ19.

The MODerate resolution Imaging Spectroradiometer (MODIS) on board the Terra and Aqua satellites supported Collection 6 retrievals of liquid-cloud properties (Platnick et al., 2003) and fine-mode aerosol optical depths at 550 nm (τ_{af} ; Levy et al., 2013) at 1° resolution (Level-3). The fine-mode distinction is chosen to exclude contributions from large non-smoke particles, primarily from sea spray. Above-cloud aerosol optical depth at 550 nm (ACAOD) from the same platforms, at 0.1° resolution, are available from Meyer et al. (2015, hereafter MODIS-Meyer). Cloud droplet number concentrations (N_d) are calculated based on cloud effective radius (r_e) and cloud optical thickness (τ_{cloud}) from the MODIS-Meyer product, following Painemal

and Zuidema (2011). MODIS-Meyer cloud and aerosol retrievals are aggregated to 1° resolution to match the Level-3 MODIS retrievals, if the former can provide an areal coverage of at least 20%. Daily-mean MODIS-based retrievals rely on averages between the Terra and Aqua retrievals weighted by their frequency, subsequently averaged spatially over 2° by 2° , 3° by 3° , and 4° by 4° domains centered on Ascension. Low-cloud fractions across the diurnal cycle are retrieved using the Visible Infrared Solar-Infrared Split Window Technique (VISST; Minnis et al., 2008) from the Spinning Enhanced Visible and Infrared Imager (SEVIRI) on board the geostationary Meteosat10 satellite. These are averaged over a 4° by 4° domain latitudinally centered on Ascension but centered slightly to the island's east (6° - 10° S, 15° - 11° W) to better capture the upwind clouds more typical of the island. All-sky albedos at the top-of-atmosphere (TOA), at Terra and Aqua overpass times, are the ratio of the reflected shortwave fluxes at TOA to the incoming solar radiation measured by the Clouds and the Earth's Radiant Energy Systems (CERES; Wielicki et al., 1996) sensors, drawing on the CERES Single Scanner Footprint (resolution of 20 km) product Edition 4 (Su et al., 2015).

Geopotential height, temperature and wind velocity maps are based on the European Centre for Medium-Range Weather Forecasts (ECMWF) fifth-generation atmospheric reanalysis (ERA5; Hersbach et al., 2020), available every hour and gridded to 0.25° spatial resolution. Back trajectories from Ascension Island at 2000 m, or just above the cloud tops, help indicate the transport of aerosol most likely to entrain into the boundary layer near Ascension. The back trajectories rely on the NOAA Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPPLIT; Draxler and Hess, 1998) model, initialized by the NOAA National Center for Environmental Prediction (NCEP) Global Data Assimilation System (GDAS) at 0.5° spatial resolution and relying on the model vertical velocity. Radiative transfer calculations rely on the Atmospheric and Environmental Research Rapid Radiative Transfer Model for GCMs (RRTMG; Clough et al., 2005), using version 4.84 of the longwave (LW) code and version 3.8 of the shortwave (SW) code.

The basic approach is to construct composites of the more and less smoky conditions for each month, and to analyze the differences in cloud properties with an eye on the accompanying meteorology as well as aerosol. Composites can identify representative conditions more robustly than case studies, and are more forgiving of anomalies as long as the anomalies do not dominate. A difficulty rests with what to call smoky in each month: surface-based measurements may not be indicative of the free-tropospheric aerosol loading and vice versa. Joint histograms of daily ACAOD and rBC mass concentrations over Ascension, by month, indicate that smoke is predominantly present in the boundary layer during July, equally frequent in the boundary layer and free-troposphere in August, and mostly in the free troposphere in September and October (Fig. 1a-d). This is consistent with aircraft *in situ* and lidar assessments, when available (Haywood et al., 2021; Redemann et al., 2021), and with the surface-based lidar assessments, although the latter can be obscured by lower cloud, and, as a point measurement, may not be representative of a larger region. Yet, ACAOD is only available when there is cloud underneath (Meyer et al., 2015), allowing free-tropospheric smoke in clear conditions to go undetected. The ACAOD measure may be most suspect in July, when there is less low cloud compared to other months (ZZ19). To better detect all smoke, the daily-mean clear-sky τ_{af} is also examined. The July joint histogram of τ_{af} and rBC mass concentrations in July confirms the free-troposphere is frequently clean, and that smoky periods primarily consist of high loading of near-surface rBC mass concentrations (Fig. 1e). Later in the season, in September and October, the level of agreement between the joint histograms of rBC-ACAOD and rBC- τ_{af} further

supports the interpretation of a shift in smoke vertical distribution towards the free-troposphere over time (Fig. 1g and h). That
125 said, ACAOD and τ_{af} are not entirely interchangeable, with a correlation of only ~ 0.55 over a 3° by 3° domain-average in
September and October and with ACAOD often exceeding τ_{af} (Fig. 2). Comparisons to aircraft-derived above-cloud aerosol
optical depths reveal a genuine high bias to the satellite ACAOD estimates (Chang et al., 2021), thought to reflect a too-high
single-scattering albedo assumption within the retrieval (Peers et al., 2021).

Elevated smoke layers are rarely present over Ascension in July (Fig. 1a). A few days exist with high ACAOD (above 0.2)
130 with those in 2017 coinciding with high near-surface rBC mass concentrations, but not so in early July 2016; Fig. 3, both
confirmed by lidar observations (not shown). Variations in column τ_{af} track the near-surface rBC variations, except for early
July 2016 (Fig. 3). This suggests that the surface-based rBC values can reasonably indicate when aerosol exists within the
atmospheric column, most of the time, for July. In August, τ_{af} and ACAOD variations are more similar instead, when they
are both available within a 3° by 3° domain. High ACAODs/ τ_{af} s appear to anticipate high near-surface smoke loadings by up
135 to a week (Fig. 3). As an elevated smoke layer is almost always present above Ascension during August (Fig. 1b and visual
inspections of island-based lidar profiles), surface-based rBC variations are deemed to better represent the variability in total
column aerosol loading than ACAOD. Therefore, for August, the composite classifications follow those of ZZ19, which are
based on the near-surface smoke loading. Occasionally, an increase in the free-tropospheric smoke loadings is evident over the
larger (3° by 3°) domain before it is perceived by the island-based rBC measurement, for example during the third week in
140 August, 2016. In September and October, the near-surface smoke loadings are much less than in July-August (Fig. 1), and τ_{af}
and ACAOD vary more similarly instead (Fig. 3). The τ_{af} confirm that those days with missing ACAODs indeed correspond
to days with little free-tropospheric aerosol (e.g., early September 2016, 2nd week of October 2016 and 2017).

We use approximate daily-mean thresholds to establish the more/less smoky composites for each month, relying primarily
on the rBC values for July and August, and τ_{af} (primarily) and ACAOD (secondarily) for September and October. The latter
145 choice is because the τ_{af} values vary more smoothly with time than do the ACAOD values. Although the τ_{af} and ACAOD
values over Ascension mostly rely on 2° by 2° domain-averages, when that information is limited it is supplemented by
averages over larger domains (3° by 3° and 4° by 4°). The bias between the τ_{af} and ACAOD values (Fig. 2) is left as is, with
ACAOD primarily used as a sanity check on τ_{af} . Threshold values account for differences in biomass burning activity between
the months, and are relaxed to whole numbers for ease in interpretation. Visual inspections of spatial maps of ACAOD and
150 τ_{af} ensure the classification into more/less smoky days is representative of a larger region around Ascension. The thresholds
applied are: rBC mass concentrations of 100 and 300 ng m^{-3} , respectively, for low and high smoke loadings in July; similarly,
100 and 500 ng m^{-3} for the smokier month of August. In September, optical depths of 0.15 and 0.26, respectively, indicate
low and high smoke loadings, decreasing to 0.11 and 0.19 for October. These thresholds lead to 14 (25) days are selected for
the high (low) smoke loading composite for July, 13 (13) for August, 19 (16) for September, and 19 (13) for October, from
155 the two years combined. The larger clean composite size in July of 25 days, produces results similar to those for the cleanest
13 days (which would be more balanced with the number of high smoke loading days) but are more robust. The number of
high and low smoke loading days is not necessarily evenly distributed between the two years, for example more smoky days
are identified in October 2016 than in 2017, owing to interannual variabilities in biomass burning activities over the southern

African continent and in the seasonally shifting large-scale circulation pattern (Redemann et al., 2021; Ryoo et al., 2021).
160 Prior work establishes that the variability in aerosol loading is primarily governed by the zonal wind strength in September
and October (Adebisi and Zuidema, 2018). A compositing based on aerosol conditions will also select for the representative
synoptic regime, independent of differences between the two years. Although the classifications can be wrong on occasion,
composites are more statistically robust and can prevent unique time periods from dominating perceptions of the representative
aerosol-cloud interaction behavior. An example is the time period from early July, 2016, classified as “less smoky” despite
165 relatively high satellite-derived optical depths. This classification is not completely correct, but the composite is nevertheless
dominated by those days for which the full atmospheric column is truly clean (e.g., early July 2017) because there are more of
them.

3 July-October overview

The boundary layer cools, shoals, and moistens over Ascension from July to October (Fig. 4), with the free troposphere
170 warming more quickly than the surface, increasing the lower tropospheric stability from July to October (Fig. 4). The boundary
layer is most likely to be decoupled in July, although the mean thermodynamic profiles indicate some decoupling between the
sub-cloud and cloud layer for all four months. The free-tropospheric wind speeds increase from July to October (Fig. 3).
These are primarily easterly winds above 2 km and affect the timing of free-tropospheric smoke arriving above Ascension.
The easterly wind episodes become more frequent beginning in August (Fig. 3). In September, the amount of smoke in the
175 boundary layer reduces abruptly (Haywood et al., 2021, see also). In October, as convection moves southward over the African
continent and biomass-burning activity reduces (Adebisi et al., 2015; Redemann et al., 2021), less smoke is present both below
and above the low clouds, despite continuing strong easterlies, reflecting the southward movement of convection. In September
and October, the “more smoky” periods correlate well with the strength of the 2-4 km easterlies (Fig. 3), reflecting the critical
role of the free-tropospheric zonal jet in transporting biomass-burning smoke over the remote ocean. The August-September
180 transitions in synoptic regimes occur earlier in 2016 than 2017, evident in the time series of the various aerosol measures (Fig.
3), and consistent with larger-scale spatial distributions (Redemann et al., 2021).

Consistent with the strengthening and lowering of the trade-wind temperature inversion from July to October (Fig. 4), the
satellite-derived low-cloud cover increases around Ascension from July to October (Fig. 5a), regardless of the smoke loading.
Stratiform clouds become more common, and cumuliform clouds less so, according to the surface observer reports (Fig. 5b).
185 Ascension is slightly downstream of the main southeast Atlantic stratocumulus region ($10^{\circ}\text{E} - 0^{\circ}\text{E}$, $10^{\circ}\text{S} - 20^{\circ}\text{S}$ as per Klein
and Hartmann, 1993) and the gross aspects of the seasonal cycle in low cloud fraction, properties and meteorology appear
similar (Fuchs et al., 2017; Scott et al., 2020).

The striking feature of Fig. 5 is that when more absorbing aerosol is present over the remote southeast Atlantic, the seasonal
cycle in low-level cloudiness and cloud morphology becomes amplified. The low-cloud fraction reduces in July and August,
190 favoring more cumuliform and less stratiform cloud, whereas in October, the low-cloud cover increases, with stratiform clouds
occurring more frequently, compared to cleaner time periods (Fig. 5). A compositing on smaller domains ($2^{\circ} \times 2^{\circ}$ within the

4° x 4° domain, not shown) does not affect this result. A spatial gradient exists, with more cloud to the southeast and less to the northwest, but the cloud fraction evolutions agree between the domains. The amplitude of the diurnal cycle (Fig. 5a) is mostly unaffected by the smoke loading, except in August, when a more pronounced diurnal amplitude can be related to the afternoon clearing of stratiform clouds under smokier conditions (ZZ19). Overall the modulation of the cloudiness seasonal cycle by the presence (or lack of) smoke is important because the cloudiness changes ultimately dominate the change to the top-of-atmosphere shortwave radiation balance (Fig. 5c). The all-sky albedo decreases or increases, depending to first order on the changes in the cloudiness fraction.

4 July: smoke reduces cloud fraction

For more smoky conditions in July, low-cloud is less frequent throughout the day (Fig. 6a), cloud bases are higher by 50-90 m, and cloud tops are typically lower, by up to 150 m, compared to less smoky conditions. An exception is the morning (6-12 LST), when the cloud top heights and liquid water paths don't vary with the smoke loading (Fig. 6a-b) and precipitation frequencies almost match (Fig. 6c). This is reminiscent of the morning cumulus invigoration documented for August (see Fig. 8b in ZZ19) when more boundary-layer smoke is present. Rain frequency is otherwise reduced throughout the day (Fig. 6c), in smokier July conditions, most pronounced in the afternoon, when cloud LWP is also substantially reduced (Fig. 6b). The low-cloud fraction is reduced over a larger area than just at Ascension when the boundary layer is smokier (Fig. 6d).

When more smoke is present, the entire boundary layer is warmer by ~ 0.3 K (Fig. 6e). The boundary layers are more decoupled, with a more moist sub-cloud layer and a drier cloud layer (Fig. 6e), consistent with the reduction in cloudiness. The cloud-top inversions are weaker (by ~ 1 K), lower (by ~ 200 m), and thinner (by ~ 40 m), compared to less smoky conditions (Fig. 6e and Fig. S1). Given that smokier conditions last for a few days (Fig. 3), the shortwave absorption can warm the sub-cloud layer over multiple days, with the warmer sub-cloud layer persisting through the night (shown for August in ZZ19), supporting a boundary-layer semi-direct effect. An aerosol-cloud microphysical interaction is also apparent in the doubling of the satellite-derived N_d (see values printed on Fig. 6e, left panel). The radiosonde-derived wind speeds indicate slightly weaker free-tropospheric winds when the boundary layer is more smoky, but the atmospheric circulation patterns are not significantly different (not shown). The lack of strong synoptic variations suggests the observed low-cloud variability is mostly driven by the presence of the shortwave-absorbing smoke.

5 September: mid-latitude disturbances reduce stratocumulus cloud and raise boundary layer heights on cleaner days

Previous studies assessing the impact of above-cloud absorbing aerosol on the boundary layer height are not in full agreement. The regional modeling studies of Sakaeda et al. (2011) and Lu et al. (2018) report an increase in cloud-top heights when biomass burning aerosols are present above clouds, attributed to a reduced free-tropospheric subsidence caused by aerosol heating. This can increase the contact with the smoke layer, enhancing entrainment of aerosol into the cloud, increasing N_d .

further increasing the cloud-top height (Lu et al., 2018). In contrast, observational studies report a reduction in the cloud top height (Wilcox, 2010, 2012; Adebisi et al., 2015) which could be because an enhanced lower-tropospheric stability reduces cloud-top entrainment. A climate-scale modeling study (Gordon et al., 2018) also produces a decrease in boundary layer depth under a plume of biomass burning smoke, when the model free-tropospheric conditions are nudged to reanalysis. Most higher-resolution process modeling studies (Johnson et al., 2004; Herbert et al., 2020; Yamaguchi et al., 2015; Zhou et al., 2017) impose a free-tropospheric model velocity, disallowing an aerosol feedback. The change in boundary layer height accompanying free-tropospheric aerosol is important to clarify, because more shallow boundary layer heights tend to be better coupled to the surface (Zuidema et al., 2009), with the surface moisture fluxes better able to sustain higher cloud fractions. On the other hand, if the cloud base remains invariant while the MBL shoals, the clouds should thin.

The radar-derived cloud top height varies little with smoke loading, with a slight increase in the afternoon and after sunset, by up to 60 m, on days with more smoke (Fig. 7a). More clear is that cloud frequencies, particularly in the lower levels, increase with the smoke loading, by up to $\sim 20\%$. This is because the cloud bases lower, by up to 230 m, when more smoke is present (Fig. 7a). The island-based cloud frequency profiles can be limited in interpreting cloud cover over a larger area, due to a systemic island orographic effect and subsampling by the relatively short time series of point measurements, but diurnal cycle composites of SEVIRI-derived low-cloud fraction also indicate an increase in afternoon cloud cover, if weak (Fig. S2). Cloud occurrence increases just above lifting condensation level when more smoke is present, more pronounced in the morning (Fig. 7a), while surface observers only report a subtle shift in low cloud type as a function of smoke loading (Fig. 5b).

A focus on the cleaner conditions provides a useful alternative perspective. When the free troposphere is less aerosol-laden, the boundary layer is less humid (q_v decreases by 1 g kg^{-1} , RH by $\sim 5\%$), the cloud layer is cooler ($\sim 1\text{K}$ at inversion base), with a stronger and slightly higher cloud-top inversion (1.8 K and 70 m) (Fig. 7b and Fig. S3). The changes in the free troposphere are equally dramatic: much weaker winds, less moisture, and more stable thermodynamic structure. Differences between the composite-mean N_d s and rBC mass concentrations are statistically insignificant (numbers printed on Fig. 7b), indicating negligible aerosol-cloud microphysical interactions (as expected, given the small amount of boundary layer aerosol). The 700-hPa atmospheric circulation differs significantly between days with low and high free-tropospheric smoke loadings at Ascension (Fig. 7c and d). On days with more smoke, the AEJ-S extends further westward, and backtrajectories from Ascension near cloud top clearly trace back to continental Africa (Fig. 7c). On days with little smoke, the circulation is anticyclonic about a deeper land-based pressure high, with the aerosol remaining closer to the coast and further south. The above-cloud air at Ascension is more likely to come from the north and west on these days (Fig. 7d).

The primary distinction between the two composite circulations is a disruption of the mid-latitude eastward flow, in which a high-pressure ridge at 700 hPa associated with baroclinic activity from further south counteracts the free-tropospheric zonal jet at 10° S . The subsidence above the cloud top is stronger on the less-smoky days when the boundary layer at Ascension is also higher (Fig. 7a, b, e and g). The increased subsidence also reflects the mid-latitude intrusion: the anomalous westerlies weakening the free-tropospheric winds also create an anomalous convergence, supporting an anomalous subsidence (Fig. 7e). This is most pronounced east of the 700 hPa pressure ridge (right above the region bounded by Ascension and St. Helena), where the flow shifts from cyclonic to anti-cyclonic and the AEJ-S is most weakened (Fig. 7d). At the surface, the mid-latitude

disturbance strengthens the south Atlantic high and shifts it slightly to the southwest (not shown), strengthening the southerlies in the boundary layer, although weakly felt over the Ascension region (Fig. 7g, cyan vectors). Closer to St. Helena, the prevailing southeasterly boundary layer flow is weakened by the anomalous westerlies, corresponding to the upper-level (700 hPa) mid-latitude disturbance. These changes in the regional atmospheric circulation correlate with a pronounced cloudiness reduction within the main southeast Atlantic stratocumulus deck, except at the northern edge of the deck encompassing Ascension (Fig. 7f).

St. Helena Island is located approximately 2 days upwind within the boundary layer flow, with Lagrangian forward trajectories from St. Helena placing boundary layer air near if slightly west of Ascension (Fig. 7 within Zuidema et al., 2015). A height cross-section between Ascension Island and St. Helena Island (16° S, 6° W; gray dashed line on Fig. 7e), indicates a consistent increase in the 700-800 hPa subsidence on days with less free-tropospheric smoke loadings (Fig. 7g). As such, the radiosondes at St. Helena can provide insight into the 24-48 hour adjustment of clouds to their large-scale environmental conditions (Klein et al., 1995; Mauger and Norris, 2010; Eastman et al., 2016) for the clouds characterized at Ascension.

A 2 day lead is incorporated into the St. Helena comparisons between low/high smoke days in Figure 8. Two days prior to the less smoky days at Ascension, the boundary layer heights are much higher at St. Helena, by 320 m compared to more smoky days, with a weaker temperature and moisture cloud-top inversion gradient (1.6 K and 1.6 g kg^{-1} ; Fig. 8a and Fig. S4). This indicates that the cloud tops at Ascension are higher, despite stronger subsidence, because the boundary layer is deeper upstream. The potential temperature, q_v and RH vertical structure differences as a function of smoke loading are qualitatively similar to those at Ascension (Fig. 8a). The boundary layer is deeper and less humid near the surface (Fig. 8a), and the lower-tropospheric stability is substantially reduced, on days with less smoke overhead. The boundary layer southerlies extend up to 2 km (Fig. 8a) before reversing in response to the deeper land-based heat low. Spatial climatologies indicate the radiosonde composites are representing a larger pattern (Figs. 8b-e). Important for the boundary layer cloud characteristics, the strengthened surface Atlantic high encourages advection of air off the Southern Ocean by near-surface winds (Fig. 8d, black contours and gray vectors). A pronounced decrease in lower-tropospheric stability near and south of St. Helena (Fig. 8d, colored contours) is in full agreement with the radiosonde profiles sampled over St. Helena (Fig. 8a) for low smoke loading days. This can be explained by anomalous negative horizontal temperature advections at 800 hPa (Fig. 8e, colored contours), as a result of anomalous southerly flows (gray vectors) corresponding to negative geopotential height anomalies at 800 hPa (black contours). The MODIS-derived low-level cloudiness is substantially reduced and disrupted west of the prime meridian (Fig. 8c, colored contours), compared to days dominated by free-tropospheric flow off of the continent (Fig. 8b).

September is a transition month when the continent is warming up but the ocean is still cool and the mid-latitude westerlies are positioned further north, similar to the southeast Pacific (Painemal and Zuidema, 2010). These Atlantic mid-latitude disturbances, also discussed within Baró Pérez et al. (2021), are most frequent in September within our study, and are consistent with the climatologies of Fuchs et al. (2017); Gaetani et al. (2021). Other examples are documented in Diamond et al. (2018); Adebisi and Zuidema (2018) and Abel et al. (2020). Pennypacker et al. (2020) also document that ultra-clean days at Ascension are most common during September, although only attribute these partially to a Southern Ocean origin.

6 October: increased cloud cover on smokier days

In October, the temperature gradient between the continental heat low in southern Africa and equatorial convection continues to encourage stronger free-tropospheric easterlies (Tyson et al., 1996; Nicholson and Grist, 2003; Adebisi and Zuidema, 2016), capable of transporting biomass burning smoke far westward at altitudes reaching up to 5-6 km. This encourages smoke to predominantly stay in the free-troposphere over the southeast Atlantic (Fig. 1 and 3). Nevertheless, reduced burning and increased moist convection on the African continent reduces aerosol transport but increases moisture transport, compared to September.

At Ascension, the radar-derived cloud frequency profiles (October 2016 only) emphasize a more persistent stratiform cloud structure, through the linear increase in cloud frequency with height, lasting throughout the diurnal cycle and invariant of the smoke loading (Fig. 9a). Cloud occurs more frequently when it is less smoky (Fig. 9a, confirmed through a Student's t-test), consistent with the satellite-derived low-cloud fraction covering a larger area (Fig. 5a), except in the afternoon (12-18 LST). There is some indication that the cloud layer rises under smokier conditions, with higher cloud bases by up to 90 m in the late morning, a reduced sub-cloud relative humidity (Fig. 9c), and higher cloud tops by up to 70 m in the afternoon (Fig. 9a). Surface observations indicate more stratiform clouds under smokier conditions (Fig. 5b), but cloud liquid water paths are also less and rain is less frequent (Fig. 9b). Combined, these observations suggest smokier conditions correspond with thinner stratiform cloud layers near the trade-wind inversion. Figure 9c indicates slightly warmer and drier sub-cloud layers in smokier conditions. The moisture and wind profiles clearly differ, with more moisture overhead between 1.5-3.5 km and stronger winds from the surface to 4km on days with more free-tropospheric smoke. The increase in free-tropospheric moisture immediately above the cloud tops reduces the gradients of RH and q_v across the inversion, by $\sim 2 \text{ g kg}^{-1}$ (Fig. 9c and Fig. S5). This should help sustain the stratiform cloud layer through suppressing evaporative drying by cloud-top entrainment. Fig. 9d indicates a broad, zonally-oriented band of elevated τ_{af} , also seen in ACAOD (not shown). The satellite-derived low-cloud fraction is enhanced west of 5° W by up to 0.35 (including at Ascension), and slightly reduced to the south, east of 0° E by at most 0.1 (Fig. 9e), indicating a more zonally-oriented, westward extending cloud deck, when more smoke is present overhead.

An anomalous anti-cyclonic October circulation at 700 hPa offshore of continental Africa indicates a strengthening of the dominating large-scale circulation on the days when the smoke loading is elevated over Ascension (Fig. 9f), consistent with the measured stronger winds. The free-tropospheric subsidence is reduced underneath the strengthened easterlies centered on 10° S , consistent with a secondary circulation (Adebisi and Zuidema, 2016) and explaining the slight increase in cloud top heights at Ascension on smokier days. Also notable in Fig. 9f is the enhancement in the subsidence just off of the coast of Namibia ($17^\circ \text{ S} - 28^\circ \text{ S}$) to the southwest of the strengthened anticyclonic high, correlating with a local increase in N_d on days with more smoke (Fig. 9g). A broad expanse of increased N_d , stretching from near the Namibian coast to beyond Ascension, is evident. At Ascension, the composite-mean MODIS-Meyer derived N_d and surface-based rBC almost double between the high versus low smoke conditions (printed on Fig. 9c). Christensen et al. (2020) select days with enhanced clear-sky τ_a to the south of the main stratocumulus deck, and find an increase in cloud fraction/lifetime far downwind within Lagrangian trajectories, consistent with the increased low-cloud fraction to the west in Fig. 9e. This, along with the rain suppression occurring on smokier days

and little change in the lower tropospheric stability (Fig. 9b and c), supports the idea that an aerosol lifetime effect (Albrecht, 1989) is active, consistent with Christensen et al. (2020). To this we can add that the increase in free-tropospheric moisture also helps maintain the cloud against entrainment-driven cloud thinning. The elevated N_d on more smoky days can also contribute to the significant brightening of the cloudy scene near Ascension in October, despite the reduction in cloud liquid water path
330 (all told, a net ~ 0.05 increase in TOA all-sky albedo; Fig. 5c).

We lack an explanation for the smaller reduction in cloud fraction to the south of the main stratocumulus deck. The contrasting decrease in N_d over a narrow region confined within $\sim 2^\circ$ along the coast of Namibia on more smoky days (Fig. 9g) correlates with anomalous near-surface northerly winds (gray vectors on Fig. 9g). This circulation pattern advects moist, warm air along the coast of Namibia, encouraging an inland fog (Andersen et al., 2020). Perhaps this produces enough precipitation
335 to reduce N_d near-shore, although that remains a speculation.

7 September: longwave cooling by water vapor maintains a well-mixed free-troposphere

The September thermodynamic profile is better-mixed, to a higher altitude, over the southeast Atlantic (Fig. 7a and Fig. 8a) when more absorbing aerosol is present, and in comparison to October. Individual profiles often indicate clear collocations between the elevated humid layer and the aerosol layer (see examples in ZZ19 supplement, Adebiyi et al., 2015; Deaconu et al.,
340 2019; Pistone et al., 2021). The aerosol/humidity layer may already be well-mixed when leaving the African continent; here we show that longwave cooling at the top of the humidity layers can help maintain their vertical structure through encouraging downward small-scale mixing. The individual free-tropospheric humidity layers typically include a stability cap at the top, ensuring a sharp gradient to the water vapor mixing ratio, with q_v reductions to near 0 g kg^{-1} above the aerosol layer reflecting the large-scale subsidence. The extremely dry overlying atmosphere provides a strong exposure of the underlying water vapor to
345 outer space, creating a longwave radiative cooling profile that is maximized at the top of the moisture layer and helps maintain a stability cap (Mapes and Zuidema, 1996). A negative buoyancy, generated at the top of these layers, can aid downward mixing. Although the longwave cooling from the additional water vapor transported within the aerosol layers is typically small compared to that from the aerosol shortwave absorption (Marquardt Collow et al., 2020), the vertical structure of the radiative heating is also altered, with most of the longwave cooling occurring above the maximum in the shortwave heating from aerosol.
350 It is this displacement that helps maintain a better-mixed aerosol/humidity layer.

An example is made of a characteristic profile over Ascension from September 2nd, 2017, in which well-mixed aerosol extinction (derived from the micro-pulse lidar according to Delgado et al., 2018, constrained to an aerosol optical depth of 0.35) and humidity vertical structures are clearly well collocated (Fig. 10). Instantaneous radiative transfer calculations are based on a noon solar zenith angle, a spectrally-dependent single scattering albedo (SSA) of 0.8 at 529 nm based on Zuidema
355 et al. (2018), and an asymmetry parameter of 0.67 loosely based on Cochrane et al. (2021). The spectral dependence of SSA relies on an absorption angstrom exponent of 1 and a mean angstrom exponent of 1.9 (Zuidema et al., 2018), with no humidity dependence. A cloud layer consists of cloud water content calculated from the radiosonde profiles using the adiabatic assumption, with cloud optical properties calculated assuming a cloud droplet number concentration of 40 cm^{-3} following

Painemal and Zuidema (2011). These yield a sharply-defined longwave cooling profile, maximized at $\sim -28 \text{ K day}^{-1}$ over a
360 50 m distance at the top of the free-tropospheric aerosol/moisture layer (Fig. 10). The noon-time shortwave heating produced
by the smoke is larger, with a maximum of $\sim 34 \text{ K day}^{-1}$ over a 50 m layer. A key feature is that the maximum shortwave
heating occurs lower in the atmosphere than does the maximum longwave cooling (Fig. 10, insert). As a result, a net cooling
($\sim -5 \text{ K day}^{-1} 50 \text{ m}^{-1}$) pervades the top 100 m of the layer, even during the time of day when the shortwave warming is
strongest. The net heating profile encourages a small-scale downward vertical mixing that can allow aerosol to move vertically
365 more freely, regardless of time of day. Although such mixing is not deep, based on a simple diabatic heating/static stability
calculation, it does help explain why the free-troposphere is often stratified into individually well-mixed layer (Redemann
et al., 2021; Pistone et al., 2021). In October, more of the convection over land is moist (Ryoo et al., 2021), which will produce
more complex thermodynamic profiles from, e.g., microphysical melting and downdrafts. This may also help explain why the
thermodynamic profiles are less well-mixed in October, also evident in Pistone et al. (2021), and do not reach as high (because
370 surface land heating is reduced).

8 Concluding remarks

This study characterizes the sub-seasonal evolution of marine boundary layer clouds over the remote southeast Atlantic, from
July to October during 2016 and 2017, as a function of the aerosol loading and its vertical distribution. We extend the work
of ZZ19, which focused on August only, and distinguish this from previous studies that apply a longer-time-scale averaging
375 over the biomass-burning season (e.g., Wilcox, 2010, 2012; Costantino and Bréon, 2013; Adebisi and Zuidema, 2018; Dea-
conu et al., 2019). The monthly time scale is emphasized primarily because of the dramatic rise in altitude of the aerosol
mass centroid from July to October over the southeast Atlantic. Smoke episodes arriving at Ascension Island mainly occupy
the boundary layer in July, with the boundary layer smoke loading reaching a maximum in August. Smoke within the free
troposphere becomes more frequent in September and that within the boundary layer reduces dramatically. In October, the
380 free-tropospheric zonal winds reaching Ascension remain strong but transport more moisture than aerosol. This synoptic evo-
lution occurs approximately 2 weeks later in 2017 compared to 2016 (Figs. 1-3). This aerosol-meteorological co-evolution
affects which aerosol-cloud interactions are likely to dominate, since changes in meteorology potentially dominating the cloud
response. Key findings are:

1. When smoke is present, the seasonal evolution in low cloud amount is amplified. The low cloud amount first reduces in
385 July-August, but then increases and becomes more stratiform in October. The cloudiness changes dominate the top-of-
atmosphere all-sky albedo changes associated with the smoke (Fig. 5), although the cloudiness changes are not neces-
sarily attributable to the aerosol.
2. In July, the cloud cover, LWP and rain occurrence are reduced when more smoke is present, particularly in the afternoon.
The thermodynamic and wind vertical structures are similar regardless of the smoke loading, suggesting the variability in
390 the cloud response is primarily driven by the aerosol rather than synoptics (Fig. 6). A morning increase in LWP, even un-

der smokier conditions, is similar to a recoupling of the cloud layer to the sub-cloud layer detailed more comprehensively for August in ZZ19.

3. In September, the days with less free-tropospheric smoke over Ascension are distinguished by mid-latitude synoptic intrusions into the subtropics. An upper-level pressure ridge constrains the circulation around the land-based heat low to the coastal region, reducing the westward extent of the free-tropospheric zonal winds at 10°S that normally disperse the aerosol (Fig. 7). A stronger surface anticyclone over the Atlantic strengthens boundary layer southerlies more likely to advect cleaner Southern Ocean air. The lower tropospheric stability is reduced, despite stronger synoptically-aided subsidence, helping to raise the boundary layer top, particularly noticeable at St. Helena Island (Fig. 8). This provides an alternative explanation to why the observed cloud top heights are lower on the smokier days, despite weakened subsidence.
4. In October, the free-tropospheric zonal winds are stronger when more aerosol is present over Ascension. The same winds enhance the humidity above the cloud top, reducing entrainment-driven evaporative drying. This helps support the increased occurrence of stratiform clouds and satellite-derived low-cloud fraction. Cloud tops are slightly higher at Ascension when the smoke loading is higher, consistent with reduced subsidence from the secondary circulation induced by the strong zonal winds (Fig. 9). A possible aerosol indirect effect is indicated, in that the N_d double when more smoke is present overhead. Enhanced subsidence off of the coast of Namibia may provide another pathway for aerosol to enter the boundary layer and ultimately reach Ascension. The additional aerosol may help prolong the cloud lifetime and enhancing their brightness (Fig. 5c; Christensen et al., 2020). These two effects (an additional moisture source and an aerosol cloud lifetime effect) help explain why the low-cloud fraction is higher, despite a lower liquid water path, compared to the southeast Pacific stratocumulus deck during this time of year (Zuidema et al., 2016).
5. The September free-tropospheric thermodynamic profile is better-mixed than in October. The sharp gradient in water vapor mixing ratio at the top of a September free-tropospheric aerosol layer generates a net cooling at the layer-top, even at solar noon, that is offset vertically from the larger shortwave warming occurring below through aerosol absorption. The negative buoyancy can facilitate a downward vertical mixing and vertical dispersion of the free-tropospheric aerosol, over small distances (Fig. 10). A greater prevalence of moist convection over land in October, for which microphysical and dynamical processes produce more complex thermodynamic vertical structures, may help explain why the thermodynamic profiles are less well-mixed in October (Fig. 9c; Ryoo et al. (2021)).

Previous studies applying a seasonal averaging successfully isolate a cloud thickening when more aerosol is present in the free troposphere, but typically overlook a cloud reduction when more smoke is present in the boundary layer. It may have required recent field measurements to better appreciate that the boundary layer can also be smoky. The cloudiness changes are most dramatic over the main stratocumulus region in September (Fig. 7f), in part because of substantial cloud clearings during the less smoky time periods (e.g., Abel et al., 2020). Fig. 5c also indicates that over the July to October time frame, the all-sky albedo changes in October are the most dramatic near Ascension, consistent with higher cloud fractions and potentially

an aerosol-induced cloud brightening effect (Christensen et al., 2020). Thus, this study also suggests that seasonally-averaged
425 changes in the regional radiation budget induced by biomass burning aerosols might be dominated by the contribution from
September-October, when the low-cloud fraction is large and more easily varied, which then helps explain why the boundary
layer semi-direct effect has been difficult to isolate in previous studies over the southeast Atlantic.

Data availability. The LASIC ground-based datasets are publicly available from the ARM Climate Research Facility (<https://www.arm.gov/research/campaigns/amf2016lasic>). The HYSPLIT model is publicly available from the NOAA Air Resources Laboratory (<https://www.arl.noaa.gov/hysplit/>). The UK Met Office SYNOP hourly weather reports are publicly available from the CEDA archive of the Met Office
430 Integrated Data Archive System (MIDAS, <http://catalogue.ceda.ac.uk/uuid/77910bcec71c820d4c92f40d3ed3f249>). The RRTMG code is publicly available from the AER website (<http://rtweb.aer.com/>). The MODIS Level-3 datasets are publicly available from NASA's Level-3 and Atmosphere Archive & Distribution System Distributed Active Archive Center (<https://ladsweb.modaps.eosdis.nasa.gov/>). The SEVIRI retrievals and CERES SSF data are publicly available from NASA's Langley Research Center (<https://satcorps.larc.nasa.gov/>). The fifth-
435 generation ECMWF (ERA5) atmospheric reanalyses of the global climate data are available through the Copernicus Climate Change Service (C3S, <https://cds.climate.copernicus.eu/>). The above-cloud aerosol optical depth (ACAOD) dataset is available upon request.

Author contributions. JZ and PZ conceived this study. JZ analyzed the results, and PZ contributed to their interpretation. JZ wrote the manuscript with edits from PZ.

Competing interests. The authors declare that they have no conflict of interest.

440 *Acknowledgements.* This research is supported by the U.S. Department of Energy, Office of Science (grants DE-SC0018272 and DE-SC0021250). We are indebted to the LASIC scientists, instrument mentors, and logistics staff who made this analysis possible through their efforts in deploying and maintaining the instruments, and processing and calibrating the campaign datasets. We thank Kerry Meyer for providing the MODIS-derived above-cloud aerosol optical depth (ACAOD) product. We thank Michael Jensen and another anonymous reviewer for their constructive comments and suggestions that helped us improve the original manuscript and Franck Eckhardt for his editor-
445 ship.

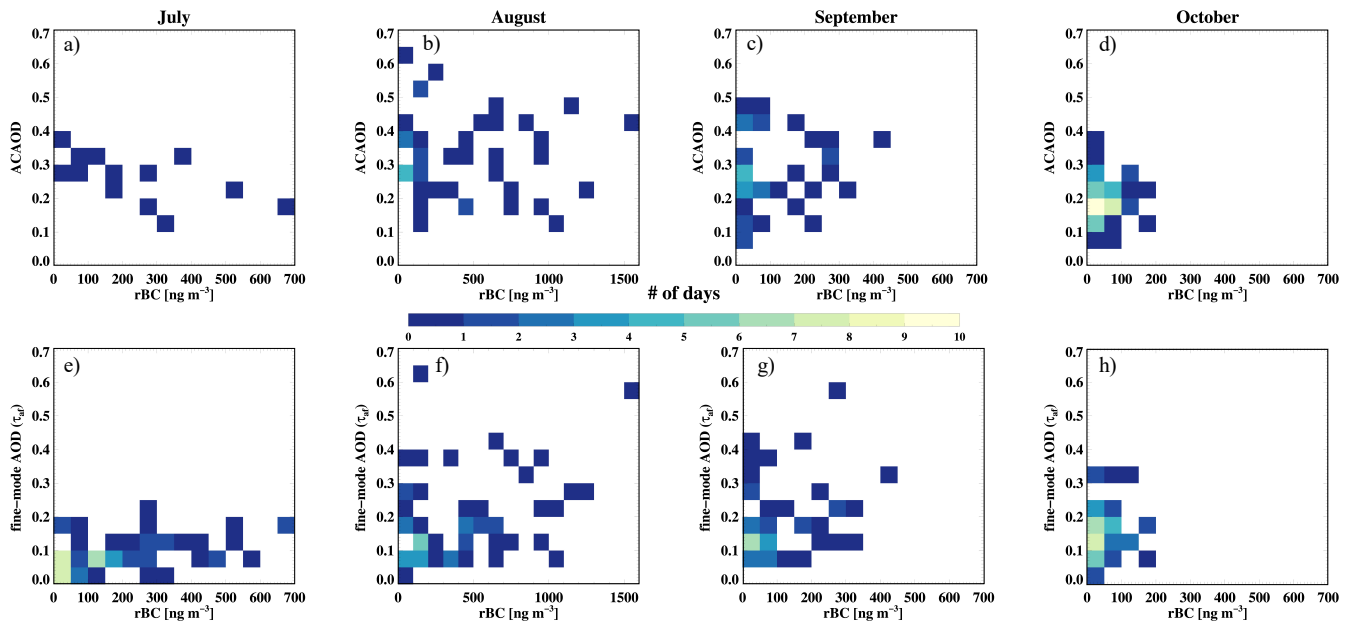

Figure 1. Joint histogram of **a)-d)** MODIS-Meyer above-cloud aerosol optical depth (ACAOD; Meyer et al., 2015) and near-surface rBC mass concentrations and joint histogram of **e)-h)** MODIS-retrieved fine-mode AOD (τ_{af}) and rBC mass concentrations, for July through October, by month, 2016 and 2017 combined. Note the x-axis range is larger for August than the other months.

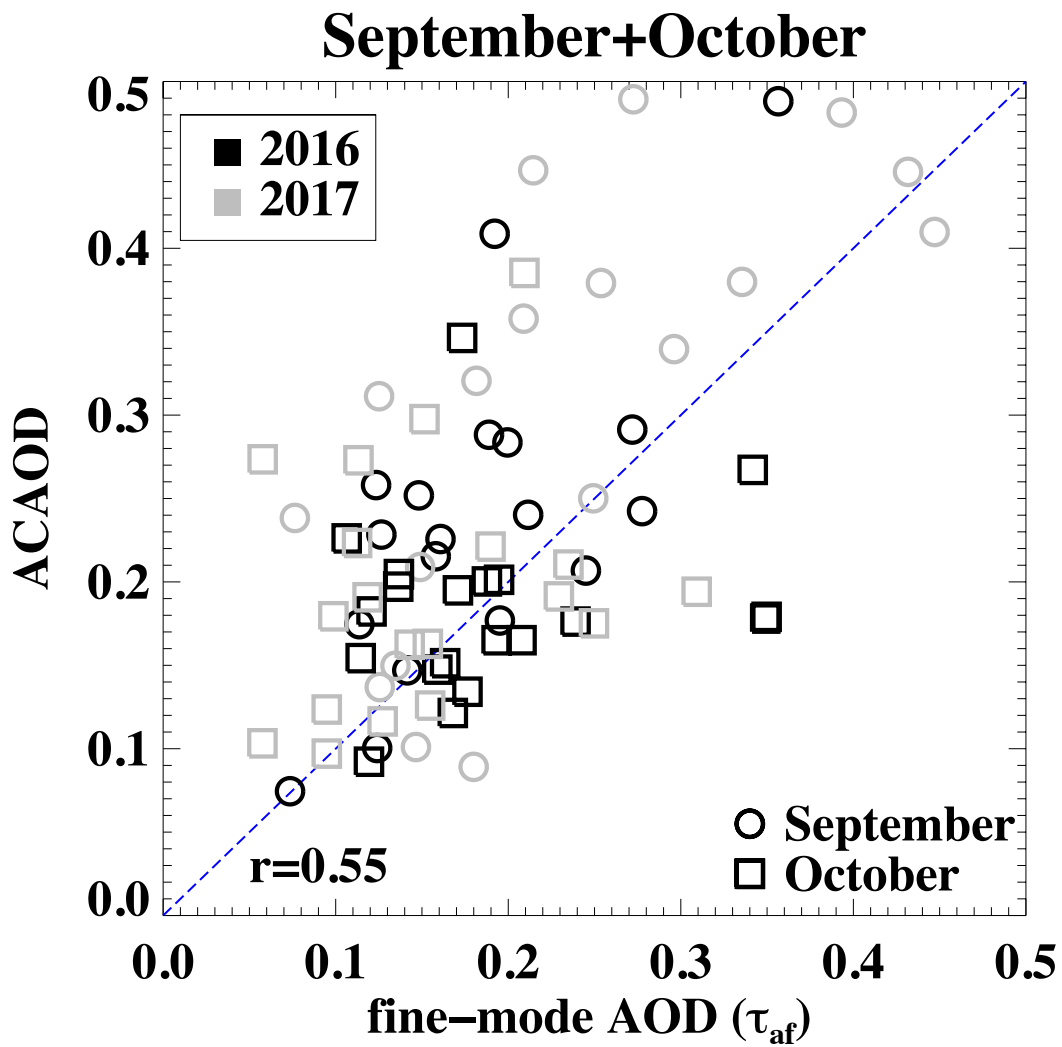

Figure 2. MODIS-Meyer ACAOD versus MODIS fine-mode AOD (τ_{af}), for September and October, using 3° by 3° domain-averages.

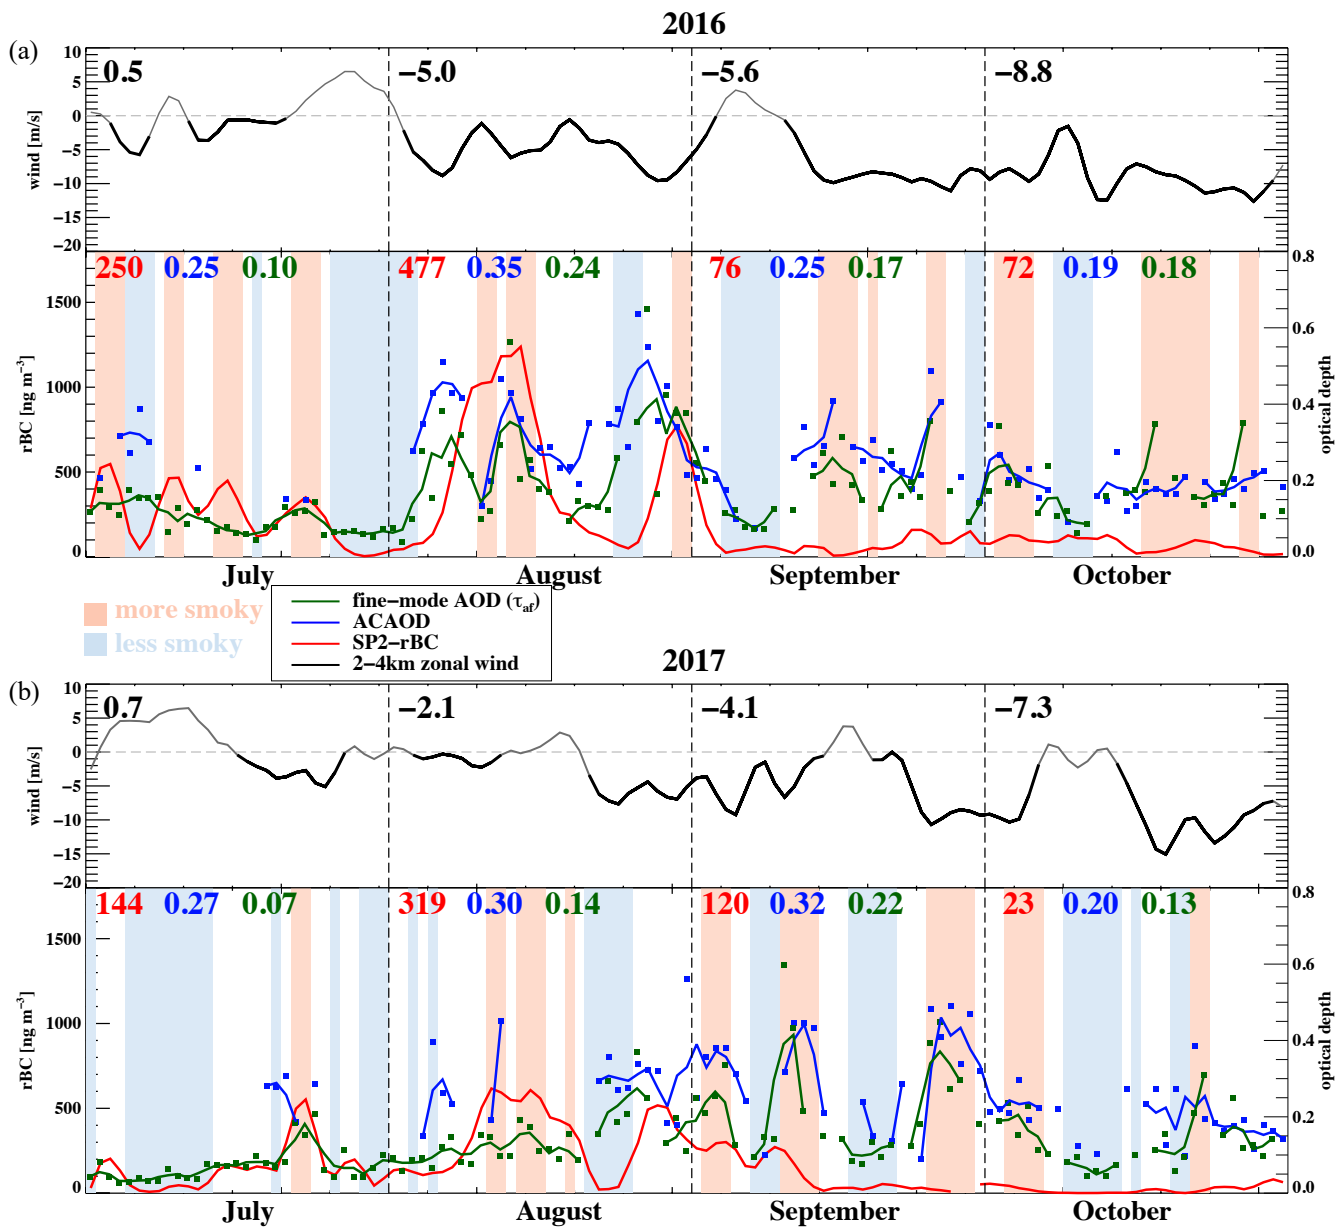

Figure 3. Time-series of daily rBC mass concentrations (red), ACAOD (blue), τ_{af} (dark green), and 2-4 km mean zonal winds (gray/black) from July through October for (a) 2016 and (b) 2017. A 3-day running mean is applied to all, easterlies lasting at least 5 days are highlighted with a thicker black line, and monthly mean values are indicated. More/less smoky composites are indicated by light-red/light-blue shadings in the background.

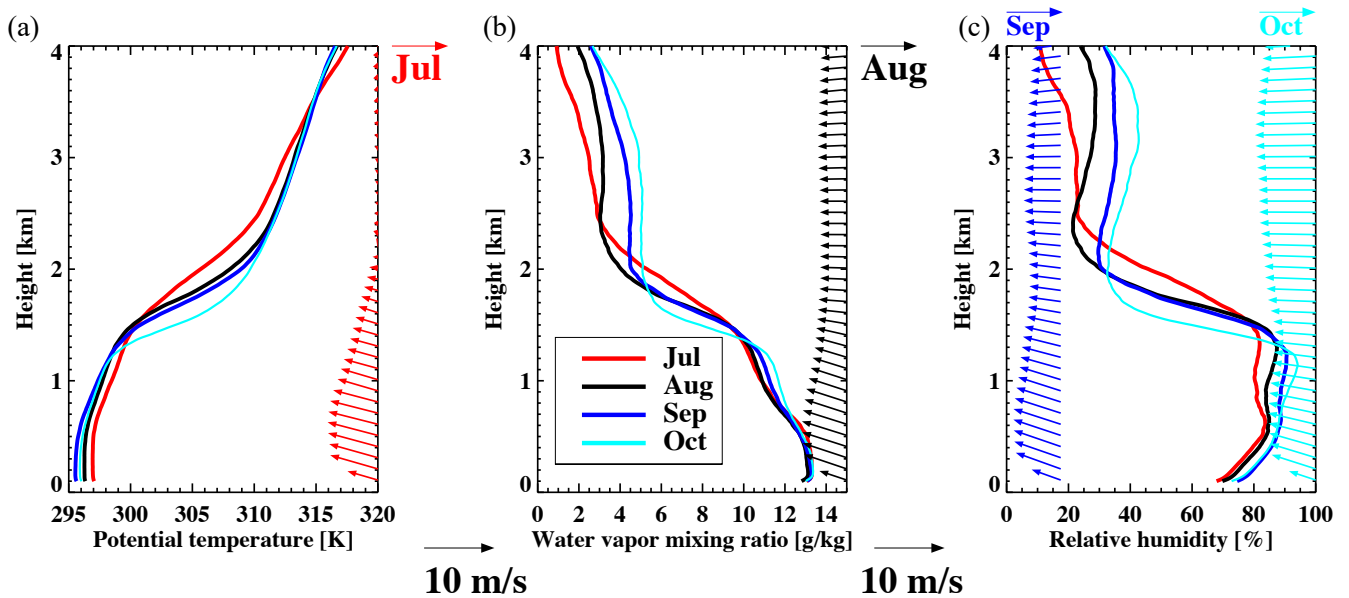

Figure 4. Monthly-mean radiosonde profiles (0-4 km above sea level) of **a)** potential temperature, **b)** water vapor mixing ratio, **c)** relative humidity, and winds (colored vectors), by month, for 2016 and 2017 combined.

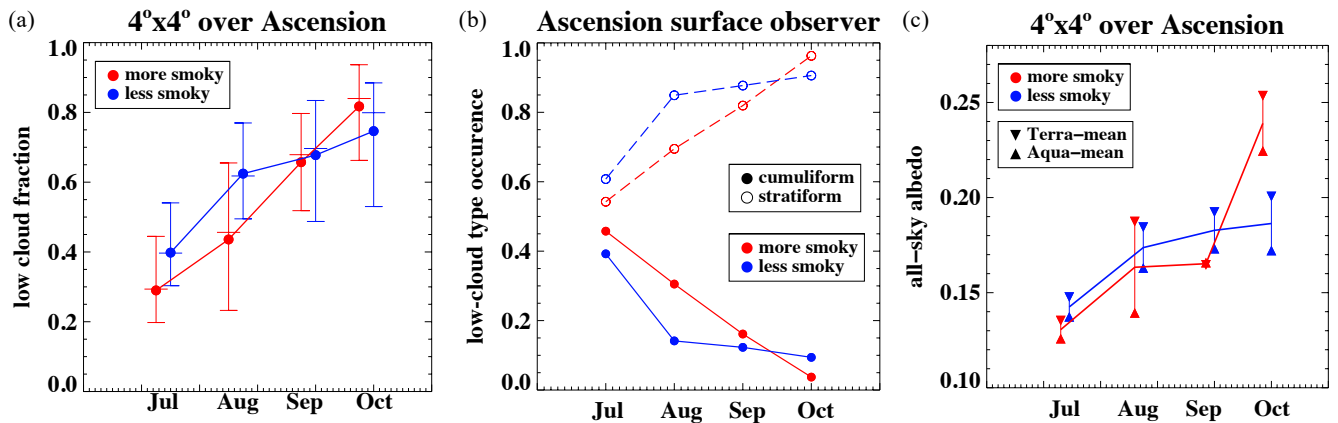

Figure 5. **a)** SEVIRI-derived diurnally-averaged areal-mean ($4^{\circ} \times 4^{\circ}$) low-cloud fraction, with the diurnal range and median values also indicated, **b)** surface-observed cloud type frequency of occurrence (stratiform and cumuliform; empty and filled circles, respectively), and **c)** all-sky areal-mean CERES albedo for both Terra and Aqua. All are composited by high and low smoke (red and blue) loadings, as a function of month.

July

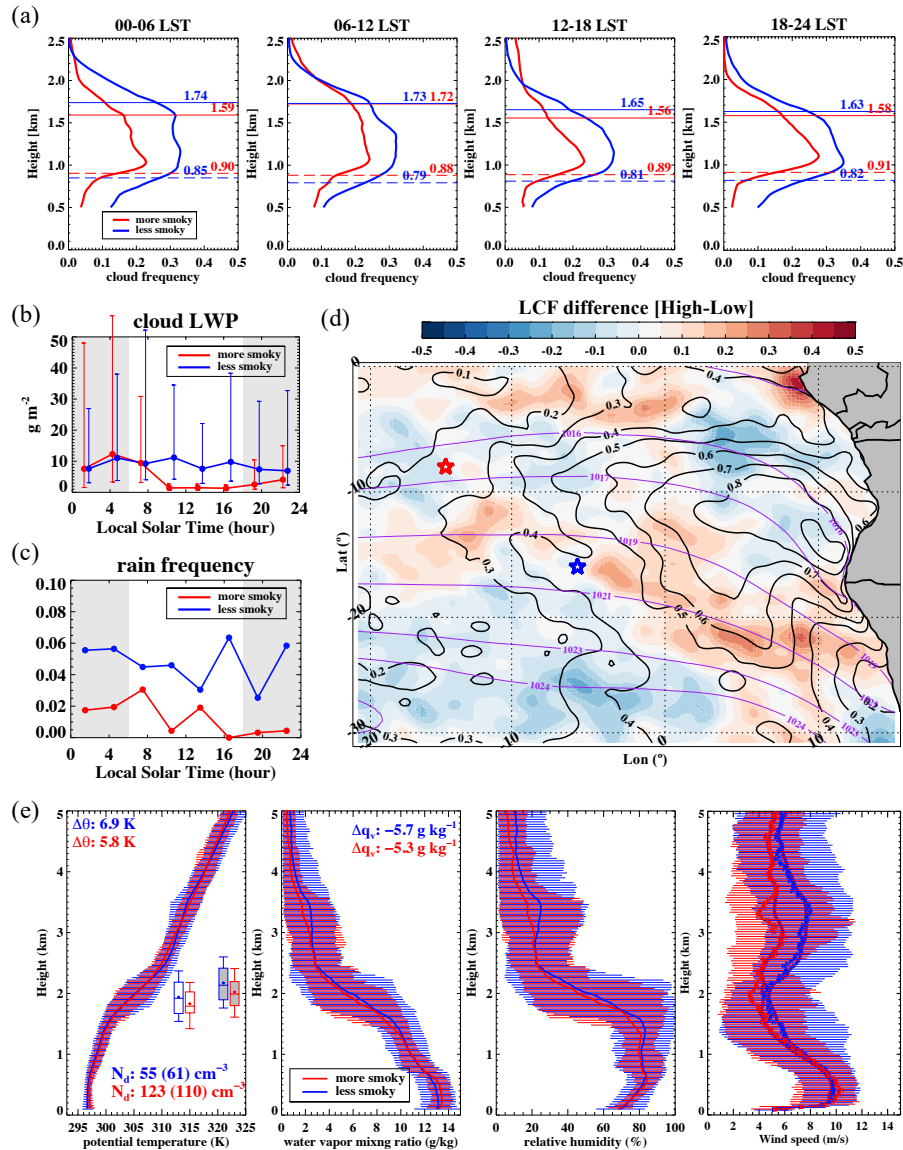

Figure 6. **a)** Diurnal cycle in the mean cloud frequencies derived using the Ka-band zenith pointing cloud radar (KAZR) reflectivities > -35 dBZ at their vertical resolution of 30 m. Composite-mean KAZR-derived (cloud frequency > 0.05) cloud top heights (solid line) and cloud base heights (long dash) are overlaid. **b)** Diurnal cycle of liquid water paths at the airport for July 2017, shown as medians (filled circles) and interquartile ranges (vertical bars). **c)** Disdrometer-derived rain frequencies, at the AMF1 site, shown as 3-hour aggregations of one-minute samples with rain rates exceeding 0 mm/hr. **d)** Difference in MODIS daily liquid cloud fraction (LCF; filled-contours, high smoke minus low smoke), overlaid with July-mean sea level pressure (hPa, purple) and LCF (black). Ascension Island and St. Helena Island locations indicated with red and blue stars respectively. **e)** Radiosonde profiles (0-5 km above sea level) of potential temperature (θ), water vapor mixing ratio (q_v), relative humidity, and wind speed, horizontal bars indicate 10th and 90th percentile values. Composite-mean (median) MODIS-Meyer cloud droplet number concentrations (N_d ; 2° by 2° means centered over Ascension), as well as statistics of inversion base height (unfilled box-whiskers), inversion top height (filled box-whiskers), mean changes in θ and q_v across inversion, are included in the left-two panels. **a-c)** and **e)** are composited by high smoke (red) and low smoke (blue) conditions. 2016 and 2017 data are combined unless specified otherwise.

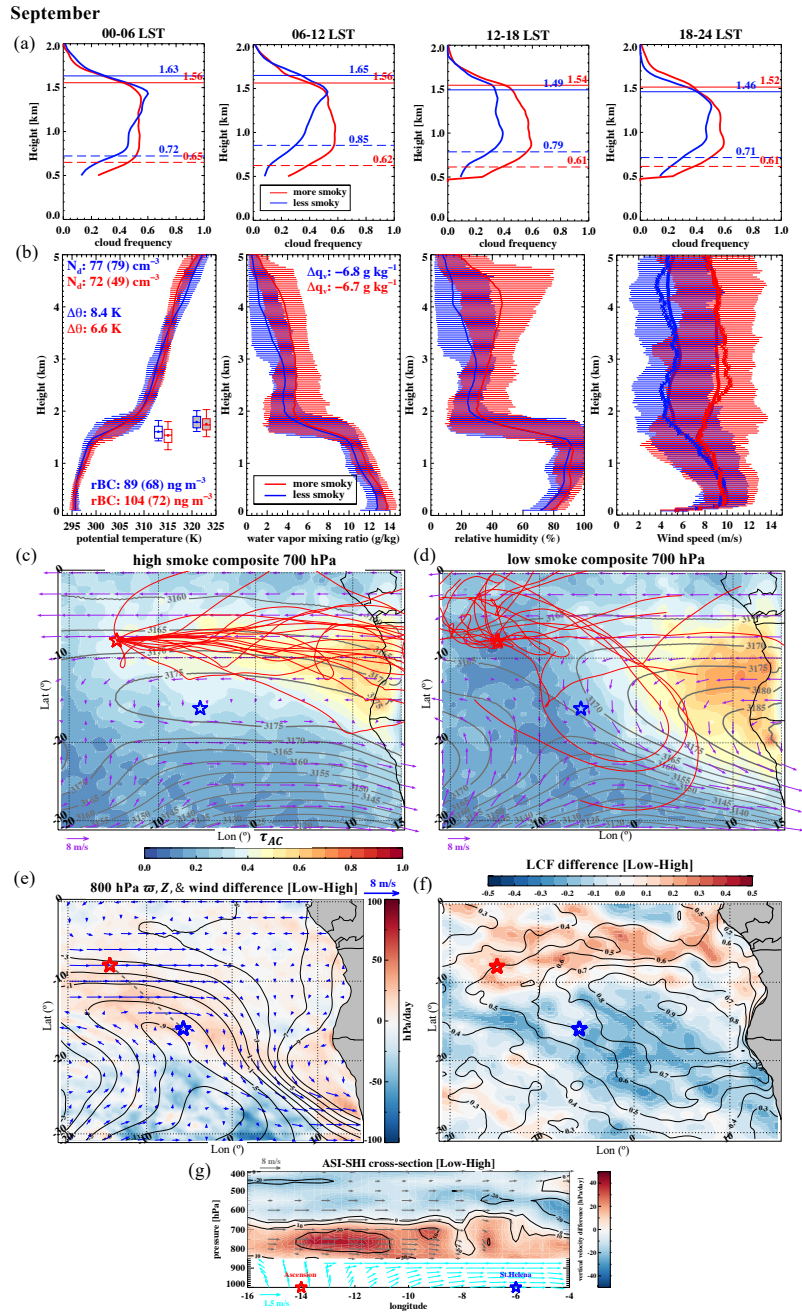

Figure 7. **a)** and **b)** as in Fig. 6a and 6e, but for September. Composite-mean cloud top heights and bases included in panel **a)** in km. Composite-mean (median) rBC mass concentrations on left panel of **b)**. **c)** and **d)**: HYSPLIT 7-day back trajectories initialized at 2 km over Ascension at noon for September (red lines) for days with **c)** more and **d)** less smoke, overlaid on composite-mean ACAOD (colored contours), 700 hPa ERA5 geopotential heights (m, grey contours) and winds (purple vectors). **e)** Low-high smoke composite difference in 800 hPa geopotential heights (m, black countours), winds (blue vectors) and vertical velocity (hPa day⁻¹, colored background). **f)** Low-high smoke composite difference in MODIS daily liquid cloud fraction (LCF; filled-contours, overlaid with September-mean LCF (black contours). **g)** Height cross-section of the vertical velocity low-high smoke composite difference (colored background) and zonal/meridional winds (vectors; free-tropospheric differences < 2 m s⁻¹ are omitted) between St. Helena and Ascension (red and blue stars respectively in panels **c-g)**.

September

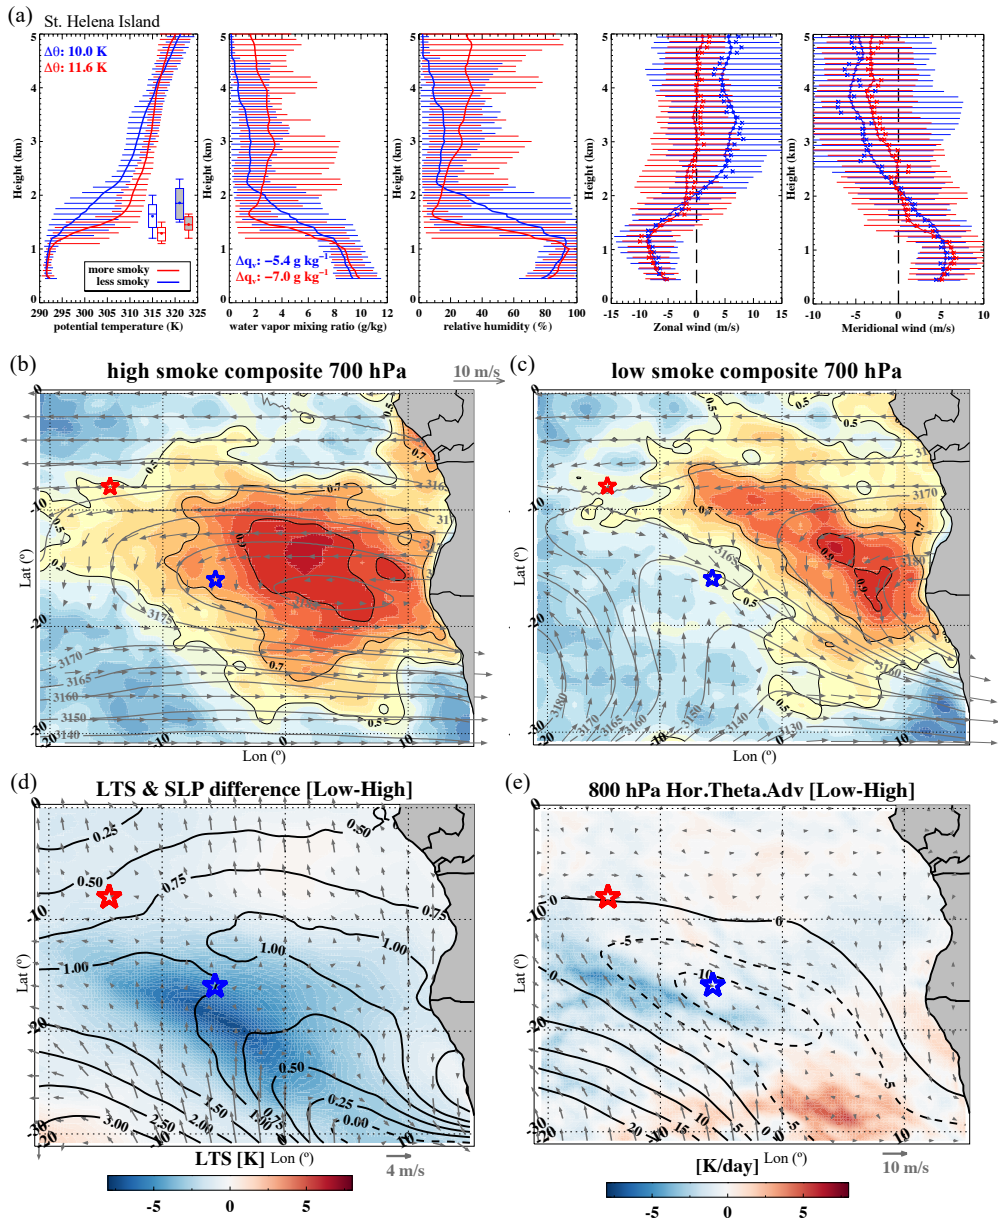

Figure 8. **a)** Similar to Fig. 7b, but for St. Helena from 2 days prior to those with high and low smoke loadings at Ascension. Zonal and meridional components of the winds are shown instead of wind speed. **b)** and **c)** Corresponding composite-mean MODIS daily liquid cloud fraction (colored contours), 700 hPa ERA5 geopotential heights (m, gray contours) and winds (gray vectors). **d)** Difference (low-high) in composite-mean lower tropospheric stability (LTS; defined as $\theta_{800hPa} - \theta_{1000hPa}$, colored contours), sea level pressure (SLP; hPa, black contours), and 10-m winds (gray vectors). **e)** Low-high smoke composite difference in 800 hPa horizontal temperature advection (colored contours), geopotential heights (m, black contours) and winds (gray vectors). Locations of Ascension and St. Helena indicated in red and blue stars respectively in panels **b-e**.

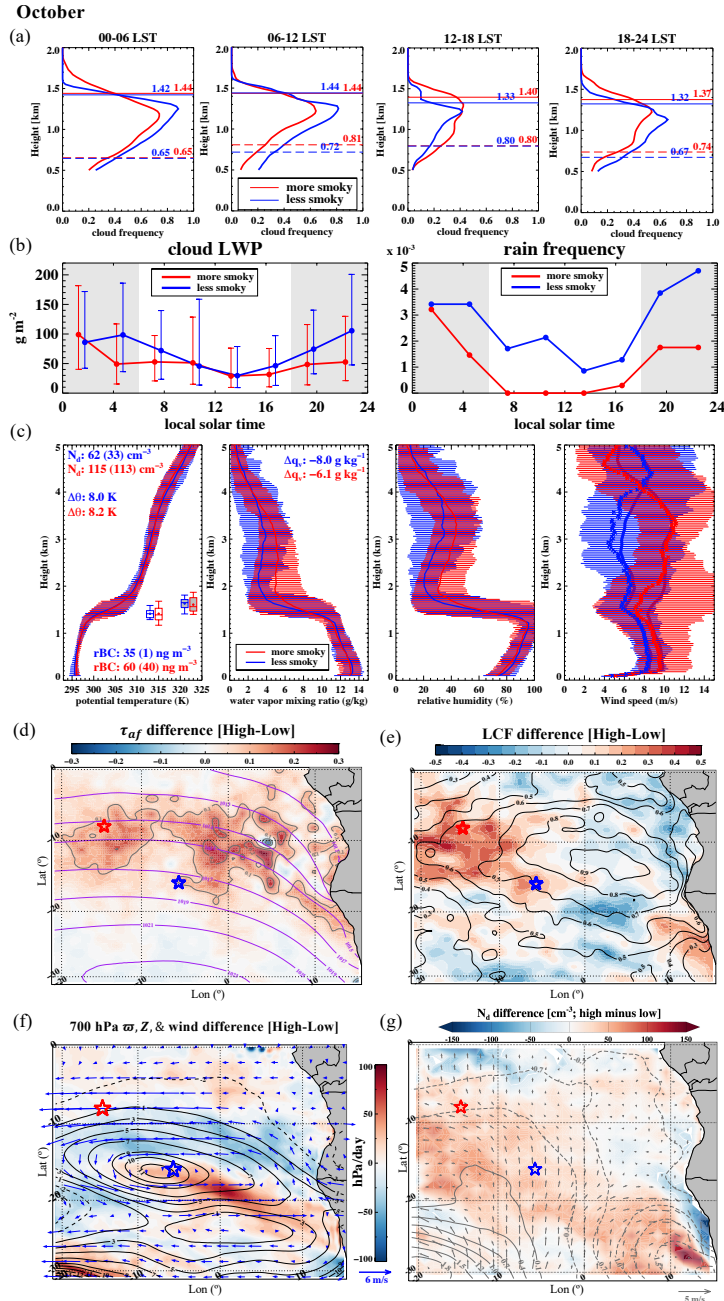

Figure 9. **a**) as in Fig. 7a, but for high-low smoke composite October 2016 only difference. **b**) as in Figs. 6b and 6c, but for October, with 3-hour rain frequencies derived from the tipping bucket. **c**) as in Fig. 7b, but for October. **d**) MODIS daily τ_{af} (color-filled contours), overlaid with October-mean sea level pressure (hPa, purple), **e**) MODIS daily liquid cloud fraction (LCF; color-filled contours), overlaid with October-mean LCF (black), **f**) ERA5 geopotential heights (m, black contours), subsidence (color-filled contours), and horizontal winds (blue vectors) at 700 hPa, and **g**) daily MODIS-Meyer N_d , overlaid on differences in sea level pressure (hPa, gray contours) and 10-m winds (gray vectors). Ascension Island and St. Helena Island locations indicated with red and blue stars respectively in panels **d-g**. Panels **b-f** are for October 2016 and 2017 combined, all represent high-low smoke composite differences.

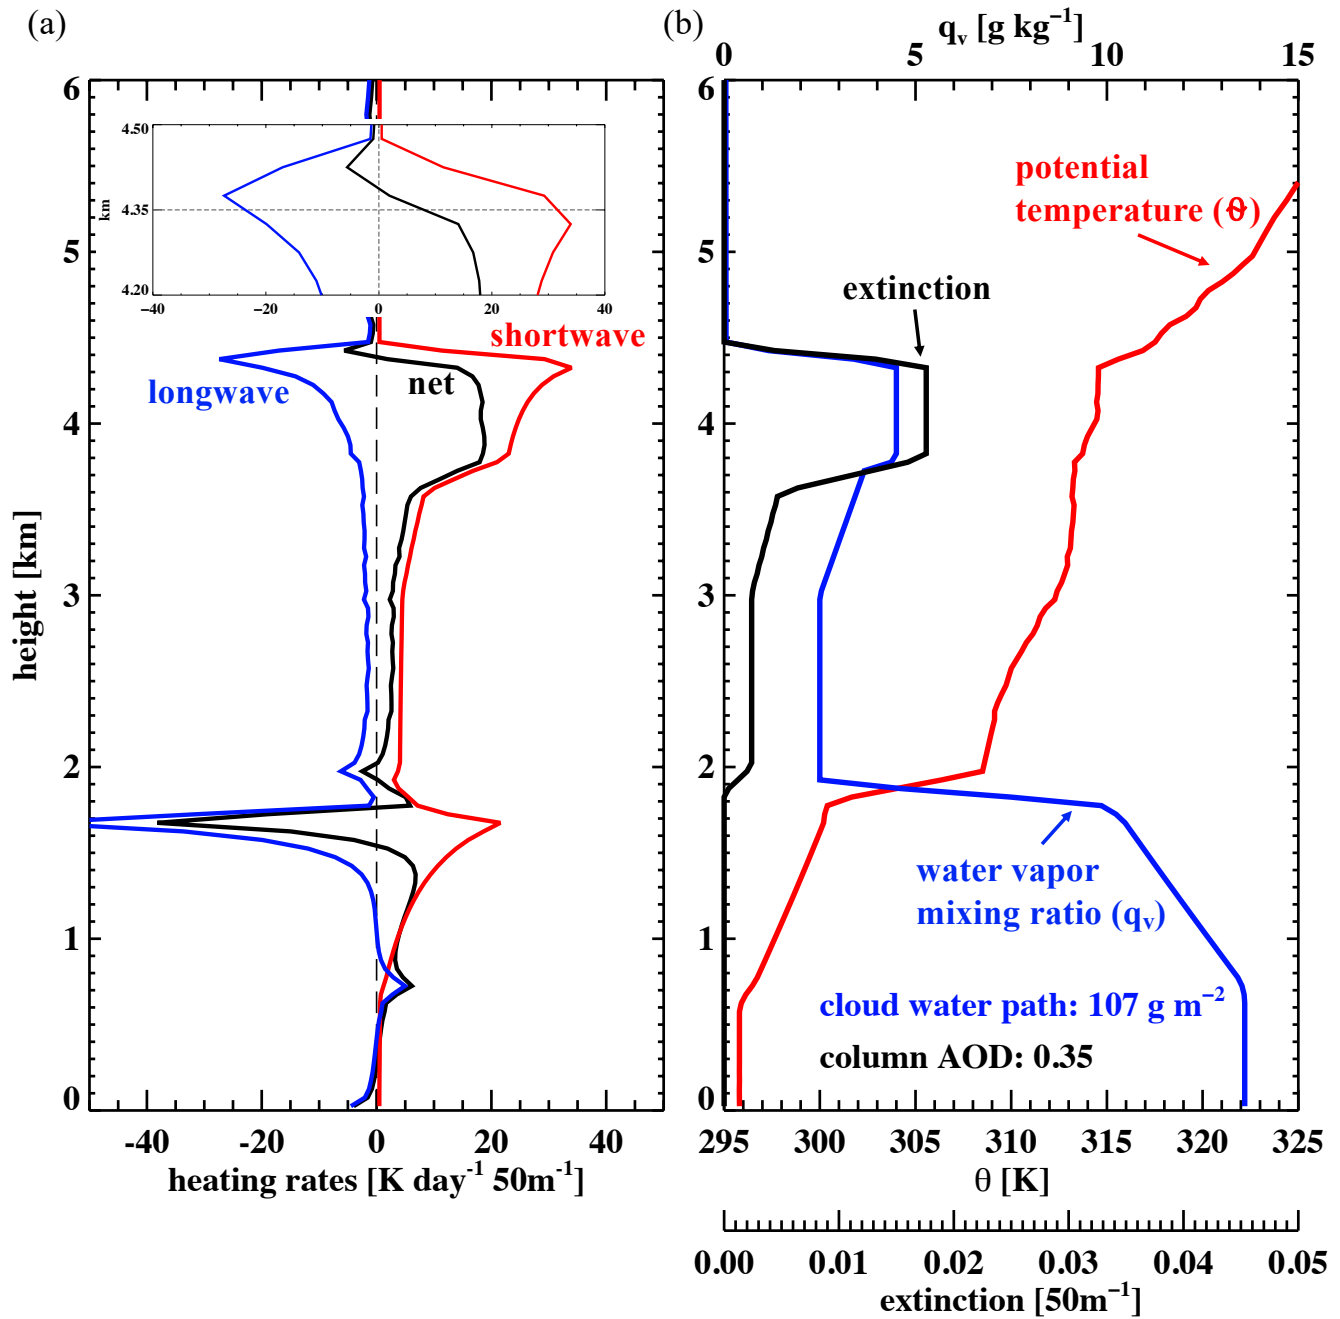

Figure 10. **a)** Calculated instantaneous shortwave (red), longwave (blue), and net (black) heating rate profiles at noon on 09/02/2017. The insert zooms into the 4.2–4.5 km range, centered on the layer top. **b)** θ (red) and q_v (blue) profiles from the noon sounding, and the MPL-derived extinction profile (black; following Delgado et al., 2018). Corresponding column-integrated AOD and cloud water path are indicated.
