27 Abstract

28 Aerosol optical depths (AOD) used for the Edition 4.1 Clouds and the Earth's Radiant
29 Energy System (CERES) Synoptic (SYN1deg) are evaluated. AODs are derived from
30 Moderate Resolution Imaging Spectroradiometer (MODIS) observations and assimilated
31 by an aerosol transport model (MATCH). As a consequence, clear-sky AODs closely
32 match with those derived from MODIS instruments. AODs under all-sky conditions are
33 larger than AODs under clear-sky conditions, which is supported by ground-based
34 AERONET observations. When all-sky MATCH AODs are compared with Modern-Era
35 Retrospective Analysis for Research and Applications (MERRA2) AODs, MATCH
36 AODs are generally larger than MERRA2 AODS especially over convective regions (e.g.
37 Amazon, central Africa, and eastern Asia). The difference is largely caused by MODIS
38 AODs used for assimilation. Including AODs with larger retrieval uncertainty makes
39 AODs over the convective regions larger. When AODs are used for clear-sky irradiance
40 computations and computed downward shortwave irradiances are compared with ground-
41 based observations, the computed instantaneous irradiances are 1% to 2% larger than
42 observed irradiances. The comparison of top-of-atmosphere clear-sky irradiances with
43 those derived from CERES observations suggests that AODs used for surface radiation
44 observation sites are larger by 0.01 to 0.03, which is within the uncertainty of
45 instantaneous MODIS AODs. However, the comparison with AERONET AOD suggests
46 AODs used for computations over desert sites are 0.08 larger. The cause of positive
47 biases of downward shortwave irradiance and AODs for the desert sites is under
48 investigation.

49

50

51 **1. Introduction**

52 Accurate estimates of the radiative effects of clouds and aerosols are essential for
53 an understanding the radiative forcing to the Earth's climate system (Bauer and Menon,
54 2012, Boucher et al. 2013). In addition, through the reflection and absorption of solar
55 radiation, and the absorption and emission of terrestrial thermal radiation, clouds and
56 aerosols affect the radiative heating of both the atmosphere and the surface, which in turn
57 governs the atmospheric circulation and the hydrological cycle (e.g. Stephens et al. 2020,
58 L'Ecuyer et al. 2015). Under the Earth Observing System (EOS) program, the National
59 Aeronautics and Space Administration (NASA) has placed into orbit a series of satellites
60 devoted to long term observations of the climate state. Among these are Terra and Aqua,
61 the flagship satellites of the EOS. Central to observation of climate evolution are
62 Moderate Resolution Imaging Spectroradiometer (MODIS) and the Clouds and the
63 Earth's Radiant Energy System (CERES) instrument pairs that fly on both the Terra
64 (March 2000 - present) and the Aqua (July 2002 - present) platforms (Wielicki et al.
65 1996). Additional CERES instruments were launched (October 2011) upon the Suomi
66 National Polar-orbiting Partnership (NPP) satellite along with the MODIS successor, the
67 Visible Infrared Imager Radiometer Suite (VIIRS), and on the NOAA-20 satellite
68 (November 2017). In addition to observations from these satellites, the CERES mission
69 also integrates observations from the Geostationary Operational Environmental Satellites
70 (GOES) (West and East), as well as other geostationary satellites around the globe, for
71 full diurnal coverage of clouds and radiation.

72 The CERES instruments measure broadband radiances over the solar spectrum
73 (shortwave), the thermal infrared (longwave radiance is obtained from a total channel
74 minus the shortwave channel), and the near infrared atmospheric window, with frequent
75 on-board calibration. CERES measurements, in conjunction with MODIS information,
76 are used to infer broadband irradiances through empirical angular distribution_models
77 (ADMs). Geosynchronous satellite imagery observes the diurnal cycle of clouds, which is
78 not fully sampled by the polar orbiting satellites upon which CERES and MODIS reside.

79 While top-of-atmosphere (TOA) irradiances are derived from broadband
80 radiances measured by CERES instruments (Loeb et al. 2005; Su et al. 2015), surface and
81 in atmosphere irradiances are computed with a radiative transfer model. Inputs used for
82 the computations include cloud properties derived from MODIS and geostationary
83 satellites, aerosol optical depth derived from MODIS radiances, and surface albedo
84 derived from MODIS and CERES observations (Rutan et al. 2009). Temperature and
85 humidity profiles are provided by a reanalysis product produced by the NASA Goddard
86 Modeling and Assimilation Office (GMAO).

87 Irradiances at the surface produced by the CERES team have been compared with
88 surface observations (Rutan et al. 2015; Kato et al. 2013, 2018). These comparisons are
89 for all-sky conditions (i.e. including any clouds). Irradiances under clear-sky conditions
90 are not explicitly separated from all-sky conditions in the evaluations. There are several
91 reasons that impede efforts at rigorous validation of clear-sky irradiances with surface
92 observations; 1) a clear-sky condition at a given site does not persist over a long time
93 (e.g. a month or longer), 2) there are mismatches of clear-sky conditions determined by

94 satellite- and ground-based instruments, and 3) field-of-view size between CERES
95 instruments and ground-based radiometers differ.

96 Despite difficulties in evaluating computed clear-sky irradiances, they play an
97 important role in quantifying aerosol and cloud radiative effects (Loeb and Su 2010;
98 Soden and Chung 2017). Therefore, the uncertainty in surface irradiances need to be
99 understood in order to assess the uncertainty in aerosol and cloud radiative effect. This
100 work is the first attempt by the CERES team to evaluate clear-sky surface irradiances
101 provided by its data products. One of the essential variables in computing clear-sky
102 irradiances is aerosol optical depth. In this paper, we evaluate aerosol optical depth used
103 for irradiance computations in the CERES project and analyze how the error propagates
104 to clear-sky surface irradiances. Computations of surface irradiances provided by Edition
105 4.1 SYN1deg data products use aerosol optical depth derived by a chemical transport
106 model [The Model for Atmospheric Transport and Chemistry (MATCH, Collins et al.
107 2001)] that assimilates MODIS-derived aerosol optical depth. In Section 2, we explain in
108 the MATCH aerosol transport model and the assimilation of aerosol optical depth with
109 MODIS. We then compare MATCH AOD to MODIS and MERRA2 aerosol products, as
110 well as to AOD from the Aerosol Robotic Network (AERONET, Holben et al. 1998).
111 Section 3 discusses differences found between the various estimates of AOD. Section 4
112 looks at clear sky surface irradiance calculations from the SYN1deg product compared to
113 observed values and the impact of AOD and particle size on the results. Conclusions are
114 presented in section 5.

115

116

117 **2. Description of MATCH model**

118 The Model for Atmospheric Transport and Chemistry (MATCH) is a transport
119 model of intermediate complexity driven by offline meteorological fields from the
120 National Centers for Environmental Prediction (NCEP) reanalysis. It is run on a 194×96
121 (1.9°×1.9°) spatial grid with a vertical resolution of 28 sigma-p levels. Temporally, the
122 meteorological fields are linearly interpolated to 30-minute times at which time the
123 chemical processes are run. One exception is that the sulfur model is interpolated again to
124 run at 2-min subscale time steps. MATCH is one of the many aerosol transport models
125 that participated in the AeroCom model inter-comparison project (Textor et al., 2006;
126 Kinne et al. 2006; Textor et al. 2007) and the AeroCom carbon inter-comparison project
127 (Koch et al., 2009; Huneus et al., 2011).

128 Aerosol types included in MATCH are dust, sulfate, sea salt, soot, sulfates,
129 carbon, and volcanic particles (**Table 1**). Model physics included in MATCH are
130 parameterizations for convection and boundary layer processes that include prognostic
131 cloud and precipitation schemes for aqueous chemistry and the scavenging of soluble
132 species. MATCH also includes the ability to resolve the transport of aerosols via
133 convection, boundary layer transport, and scavenging and deposition of soluble gases and
134 aerosols. MATCH can simulate most cloud processes currently in use in a GCM (eg.
135 cloud fraction, cloud water and ice content, fraction of water converted to rain and snow,
136 and evaporation of condensate and precipitate). It also includes vertical turbulent eddy
137 processes. These processes are then used for convective transport, wet scavenging, wet
138 deposition and dry deposition of the MATCH aerosols. These various parameterizations
139 were developed, originally, for the NCAR Community Climate Model (CCM) and

140 subsequently incorporated into the MATCH model. Descriptions of these
 141 parameterizations are given by Rasch et. al (1997, 2001), Collins et. al (2001) and
 142 additional papers described therein.

143 The MATCH aerosol suite includes a detailed mineral dust scheme in the Dust
 144 Entrainment and Deposition model, (Zender et al., 2003), and a diagnostic
 145 parameterization for sea-salt aerosol based on the 10m wind speed (Blanchard and
 146 Woodcock, 1980). The sulfur cycle and the chemical reactions for sulfate aerosol creation
 147 rely on monthly climatological oxidant fields and emission inventories (**Table 1**) for
 148 sulfur oxides and oceanic dimethyl sulfide (photochemistry and nitrate aerosol are
 149 omitted). The reaction scheme is similar to that of the Model for Ozone and Related
 150 Chemical Tracers (MOZART), (Emmons et al., 2010). Carbon aerosols (both organic
 151 compounds and soot) evolve with simple mean lifetime e-foldings from surface fluxes
 152 specified through natural, biomass burning and fossil fuel burning emission inventories
 153 (also monthly climatologies given in **Table 1**).

154

Table 1. Aerosol Types & Climatological Sources

<i>Aerosol Type</i>	<i>Source</i>	<i>Description</i>
<i>Sea Salt</i>	Blanchard and Woodcock, 1980	Wind Driven
<i>Dust</i>	Ginoux et al. (2001); Zender et al. (2003)	NCEP soil moisture, wind driven
<i>Sulfate (natural & anthropogenic)</i>	Benkovitz et al. (1996); Barth et al. (2000)	monthly climatological
<i>Carbon (organic & Soot)</i>	Liousse et al. (1996)	monthly climatological
<i>Volcanic</i>	Episodic inclusion of Sulfur dioxide	Processed by model

155

156 The optical properties of the various aerosol types (e.g. mass extinction
 157 coefficient, single scatter albedo), which are key parameters for aerosol assimilation, are

158 drawn from the standard Optical Properties of Clouds and Aerosols (OPAC, Hess et al.
 159 1998) database. However, scattering properties of maritime and dust aerosols used
 160 in the radiative transfer calculations in the SYN1deg are not from MATCH. Instead,
 161 aerosol types from MATCH are mapped to a similar set of scattering properties, per
 162 Table 2, embedded in the Langley Fu & Liou radiative transfer (LFLRT) code (Fu and
 163 Liou, 1993; Fu et. al 1998; Rose et. al 2013). These include OPAC as in MATCH for all
 164 but the small and large dust particles. Dust scattering and absorption properties in the
 165 LFLRT code are from Sinyuk et al. (2003).
 166

Table 2. Mapping of MATCH aerosol types into Radiative Transfer code.

MATCH Constituent	Langley Fu & Liou Constituent	Langley Fu & Liou Spectral Properties
Sea Salt	Maritime	d’Almeida 1991
Hydrophobic Organic Carbon	Insoluble	OPAC
Hydrophilic Black Carbon	Soot	OPAC
Hydrophobic Black Carbon		
Hydrophilic Organic Carbon	Water Soluble (WASO)	OPAC
Tropospheric Sulfate		
Volcanic	Suspended Organic (SUSO)	OPAC
Stratospheric Sulfate		
Dust < 1.0 μ m	“Small” Dust	Sinyuk et al. (2003)
Dust 1.0 -2.5 μ m	“Large” Dust	Sinyuk et al. (2003)
Dust 2.5-5.0 μ m		
Dust 5.0-10.0 μ m		

167

168 **Figure 1** shows the single scatter albedo (SSA) and asymmetry parameter (ASY)
 169 for the seven constituents in the LFLRT code at 500 μ m. Constituents with constant SSA
 170 and/or ASY are given as numbers while those that vary with relative humidity are
 171 plotted. The spectral properties for sea salt shown in Figure 1 were taken directly from

172 tables in d’Almeida et al., (1991). Note that the asymmetry parameter of maritime
 173 aerosol decreases with humidity. This is likely an error in the original Table A.30 of
 174 d’Almeida et al. (1991).

Figure 1. Single scatter albedo and asymmetry parameter for the seven aerosol types available in the Langley Fu & Liou Model SYN1deg calculations. Only those that vary with relative humidity are plotted. Others are listed as constants. All values are for properties at 550 μm .

175

176 2.1 MATCH Assimilation of MODIS Aerosol Optical Depths

177 One major advantage of the MATCH model is its ability to reliably assimilate
 178 satellite-based retrievals of aerosol optical depth (AOD) to constrain the climatologically
 179 forced aerosols generated within the chemical transport portion of the code. Edition 4
 180 MATCH algorithms ingest MODIS Collection 6.1 AOD (Remer et al., 2005), beginning
 181 in March 2000 from the Terra satellite and June 2002 from both Terra and Aqua
 182 satellites. The MATCH assimilates MODIS AOD at the green wavelength of 550 nm.
 183 MATCH combines AOD derived by the Dark Target (Levy et al. 2013) and Deep Blue
 184 algorithms (Hsu et al., 2006). A global daily mean AOD in a 1.9°x1.9° grid is derived
 185 from Terra and Aqua observations by simply averaging available Terra and Aqua dark

186 target and deep blue derived AODs in a grid box. Unlike dark target and deep blue
187 merged product (MOD08), we do not use a quality assurance confidence (QAC) score to
188 screen AOD.

189 The assimilation process begins by combining the dark target and deep blue AOD
190 from MODIS (both Terra and Aqua when available) and creating daily averages. As
191 MATCH progresses through time the AOD at local solar noon are assimilated by taking a
192 15° longitude width of retrieved AOD from the daily mean map. Examples of the
193 magnitude of AOD adjustments by the assimilation are shown in **Fig. 2. Figure 2a** shows
194 hourly AOD field differences, 4 UT minus 3 UT on February 1st, 2020. Similarly, **Figure**
195 **2b** shows 10 UT minus 9 UT of the same day. The 15° vertical band is clearly visible
196 where red (blue) colors indicate total column aerosol is increased (decreased) by the
197 MODIS AOD assimilation. Following the AOD adjustment, aerosol masses in the
198 atmospheric column through the troposphere are scaled to closely match the AOD
199 derived from MODIS. Neither the vertical profile nor the relative abundance of the
200 aerosol species is adjusted. Once aerosol mass is adjusted at the local noon for the regions
201 where MODIS AOD is available, the adjusted aerosol mass is carried on to the next time
202 step. Besides the MODIS adjustments, wind driven sea-salt creation and deposition are
203 found along frontal boundaries in the North Atlantic and Southern Oceans. The maps also
204 indicate hourly increases and decreases in high aerosol loading areas such as those found
205 around China and SE Asia. Episodic events such as intense fires or volcanic eruptions
206 are not specifically included in the MATCH aerosol package. Such events are captured
207 by the assimilation of MODIS AOD and total column aerosol loading is adjusted upward.
208 The adjustment is applied to AOD only. The aerosol type (and so scattering properties) is

209 not adjusted to reflect the reality of the scattering or absorbing aerosol during such an
210 event.

211

212 2.2 MATCH and MERRA2 comparison

213 In this section, we compare AODs between MATCH and MERRA2 (Randles et
214 al., 2017) in which MODIS clear-sky radiances are assimilated. MERRA2 also
215 assimilates surface observed AOD by AERONET and ship born AOD observations as
216 well as AVHRR and MISR retrievals for the years 2000-2002 and 2000-2014
217 respectively. We compare AODs in two different ways. First, MATCH and MERRA2
218 AODs are compared with MODIS AODs. The first comparison tests the consistency of
219 daily means when MODIS aerosol optical depth is available (i.e. clear somewhere in the
220 grid box at Terra and Aqua overpass time). Second, MATCH and MERRA2 AODs are
221 compared under all-sky conditions, which is only possible with modeled AODs.

Figure 3: Climatological mean aerosol optical depth (AOD, i.e. $\langle AOD_{MODIS}^{clr} \rangle$ see texts for the definition) difference of left) MERRA2 – MODIS and right) MATCH – MODIS averaged over Mar 2000 through Feb 2020. MERRA2 and MATCH daily mean AODs are sampled when daily mean MODIS AOD from the same $1^\circ \times 1^\circ$ grid is available. Sampled daily mean AODs are subsequently averaged. MODIS AODs are averages of MODIS dark target and deep blue algorithms from both Terra (MOD08) and Aqua (MYD08) data products.

222

223 **Figure 3** shows differences of climatological mean AOD between MERRA2 and
 224 MODIS on the left and MATCH and MODIS on the right. To compute the monthly mean
 225 AOD differences, both MERRA2 and MATCH daily mean AODs are sampled when
 226 daily mean MODIS AOD (MODIS products MOD08 and MYD08) from the same $1^\circ \times 1^\circ$
 227 grid is available (hereinafter AOD_{MODIS}^{clr}). Sampled daily mean AODs (AOD_{MODIS}^{clr}) are
 228 subsequently averaged (hereinafter $\langle AOD_{MODIS}^{clr} \rangle$, where the bracket indicates a simple
 229 arithmetic mean). Although both products assimilate MODIS observations, each shows
 230 fairly significant differences from MODIS values. Differences arise because MODIS
 231 daily mean AOD is clear sky at Terra and Aqua overpass time while MERRA2 and
 232 MATCH daily mean AOD includes AOD from other times of the day. When the non-
 233 overpass time is also clear, MATCH AOD_{MODIS}^{clr} should be close to MODIS AOD_{MODIS}^{clr} .
 234 However, when clouds are present in MATCH during non-overpass times, modeled AOD
 235 are used, hence the daily mean AOD can deviate from MODIS AOD_{MODIS}^{clr} . In addition,

236 AOD differences for MERRA2 at Terra and Aqua overpass times might be larger than
237 MATCH even for clear-sky conditions as MERRA2 assimilates observed AOD data
238 other than MODIS AOD when and where these events might occur.

239 While MATCH shows large positive differences over land, especially China and
240 southeast Asia, Australia, Amazon, and north Africa, MERRA2 shows significant
241 negative differences over major rain-forest regions of south America, Africa, and the
242 tropical western Pacific. Both products are closer to MODIS AOD over ocean compared
243 to $\langle AOD_{MODIS}^{clr} \rangle$ over land except MERRA2 shows a negative difference across the Indian
244 ocean and off the west coast of Africa in the Atlantic Ocean. When MODIS AOD_{MODIS}^{clr} is
245 available in the grid box, MATCH weighs MODIS AOD heavily in its assimilation at
246 local solar noon so that MATCH AOD is nearly identical to MODIS AOD at the local
247 noon under clear-sky regions. Consequently, the difference of climatological global mean
248 MATCH and MODIS AOD_{MODIS}^{clr} (-0.015) is smaller than the difference of MERRA2 and
249 MODIS AOD_{MODIS}^{clr} (-0.036).

250 **Figure 4** shows the difference of AOD_{MODIS}^{clr} more clearly. In **Fig. 4** AOD_{MODIS}^{clr} are
251 compared directly in a log-density plot where each point represents a comparison for the
252 daily average of a given grid box; MERRA2 versus MODIS on the left and MATCH
253 versus MODIS on the right. **Figure 4** indicates that MATCH AOD_{MODIS}^{clr} has a smaller
254 bias with respect to the MODIS AOD than the MERRA2 AOD but has approximately the
255 same RMS compared to the MERRA2 AOD_{MODIS}^{clr} .

256

257

Figure 4: Scatter plot of daily $1^\circ \times 1^\circ$ mean aerosol optical depth from a) MERRA2 and b) MATCH versus AOD derived from MODIS on Terra and Aqua for Mar 2000 through Feb 2020. MODIS AODs are $1^\circ \times 1^\circ$ daily averages derived by the dark target and deep blue algorithms. Only days and grid boxes that have MODIS AOD (i.e. AOD_{MODIS}^{clr} defined in the texts) are used.

258
259
260

We now consider more directly, differences between the MATCH and MERRA2

261 climatological AOD fields for all-sky and *estimated* clear sky conditions. **Figure 5** shows

262 $1^\circ \times 1^\circ$ climatological mean maps of MATCH AOD on the left and its difference from

263 MERRA2 on the right for all sky (top maps) and estimated clear sky (bottom maps)

264 conditions for March 2000 through February 2020. A clear-sky area weighted monthly

265 mean aerosol optical depth is derived by averaging daily mean aerosol optical depth

266 weighted by clear fraction (hereinafter $\overline{AOD_{MODIS}^{clr}}$, overbar indicates monthly mean),

267 where the clear fraction is derived from MODIS on Terra and Aqua (Loeb et al. 2020,

268 Minnis et al. 2020). MATCH all-sky AOD (hereinafter $\overline{AOD^{all}}$) is larger than MERRA2

269 $\overline{AOD^{all}}$, particularly over the rain forest regions of the globe as well as India and China.

270 Although the difference is smaller, the difference of $\overline{AOD_{MODIS}^{clr}}$ shows a similar spatial
271 pattern (**Fig. 5** bottom right) to the all-sky difference. This is consistent with **Fig. 3**,
272 showing that MERRA2 AOD_{MODIS}^{clr} underestimates AOD with respect to MODIS
273 AOD_{MODIS}^{clr} . A larger difference in MATCH AOD over convective regions (e.g. Amazon,
274 central Africa, and south east Asia) is caused by how dark target and deep blue AOD are
275 merged. As mentioned earlier, we do not use QAC to screen AOD. Convective clouds
276 introduce a larger uncertainty to AOD because of a 3D radiation effect or poor fit to
277 observations with retrieved AOD (personal communication with R. Levy 2020). For
278 these situations, AODs associated with QA confidence scores less than 2 are screened out
279 in the MOD08 dark target and deep blue merged product (Levy et al. 2013).

280 **2.3 Comparison with AERONET**

281 The above results indicate that both MATCH AOD_{MODIS}^{clr} and MERRA2
282 $\overline{AOD_{MODIS}^{clr}}$ are generally smaller than MODIS $\overline{AOD_{MODIS}^{clr}}$. Larger difference between
283 MATCH and MERRA2 $\overline{AOD^{all}}$ over convective regions originated from merged AOD
284 product used for the assimilation. Of primary importance to radiative transfer calculations
285 within the SYN1deg product is the ability of the MATCH model to accurately represent
286 total column aerosol optical depth. To test the overall accuracy, we use observations from
287 the AERosol RObotic NETwork (AERONET). AERONET is a global federation of
288 ground-based remotes sensing sites developed by NASA and now supported by a number
289 of institutions around the world (Holben et al. 1998). Each site maintains a CIMEL sun-
290 photometer that scans the daytime sky every 20 minutes. Collected data are processed
291 according to standards of calibration and processing maintained by the AERONET

292 project. Here we utilize Level 2.0, data that have been screened for clouds and quality
 293 assured (Smirnov et al. 2000).

294

295

296 **Figure 6** shows an hourly time series of AOD from MATCH, MERRA2 and
 297 AERONET for January 2010 at the Beijing China AERONET site. The top plot shows
 298 cloud fraction time series derived from MODIS and GEOs from the SYN1deg Ed4.1
 299 product (Rutan et al. 2015), and the bottom plot shows AOD time series. Generally, both
 300 models produce a large variability of AOD at this site fairly well over the course of the

301 month. While both MERRA2 and MATCH AODs increase near times when cloud
302 fraction approaches 100%, the increase of MATCH AOD, which correlates with the
303 increase of AERONET AOD relatively well, is larger than the increase of MERRA2
304 AOD. Although the temporal correlation coefficient of the MATCH and AERONET
305 AODs is smaller at this site during summer months than during winter months (not
306 shown), a good temporal correlation between MATCH and AERONET AODs is
307 consistent across most locations and times we considered. To show this statistically, in
308 the following, we extend this analysis to a number of AERONET sites grouped
309 geographically based on general aerosol type.
310

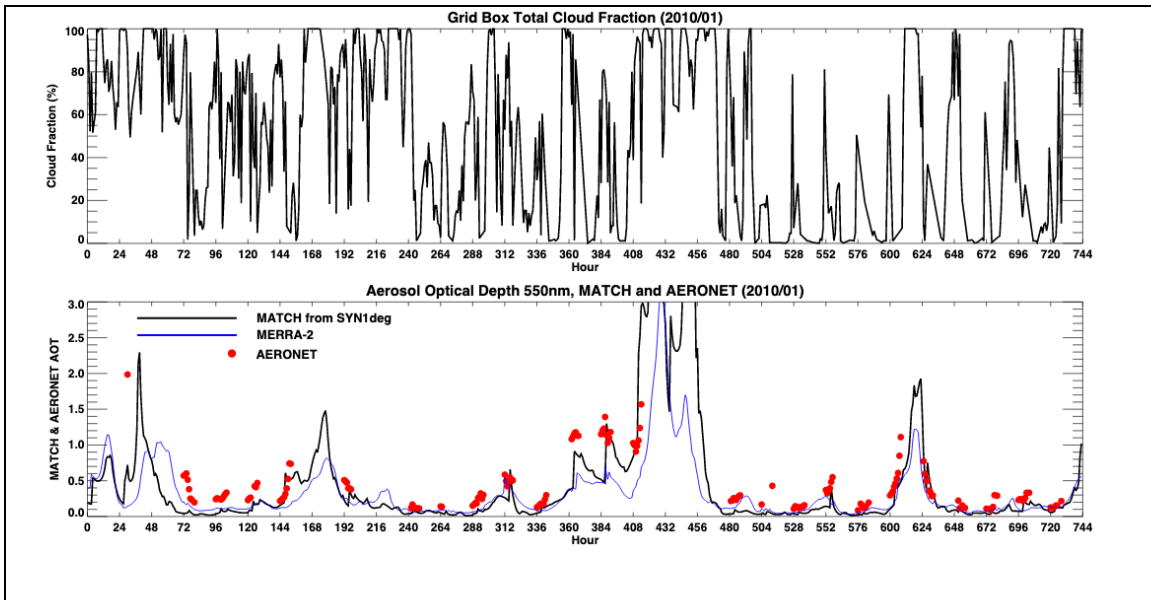

Figure 6. Hourly time series of grid box cloud fraction (top) from SYN1deg Ed4.1 CERES product and AOD (bottom). Results are from the grid box containing the AERONET Beijing, CH site. Black line MATCH, blue line MERRA-2, red dots, AERONET observations. MATCH and, to a lesser degree MERRA-2 often have large increases in AOD when cloud fraction nears 100%.

311

312

313

Aerosol optical depths from AERONET are nominally provided at 8 spectral channels, every 20 minutes given favorable conditions. We use two channels to derive

314 observed AOD at 550 nm to compare to the AOD provided by the MATCH model.
315 Because the SYN1deg radiative transfer calculation is done hourly, we average any
316 observations within a given hour period centered at the 30th minute for each site
317 collocated within a SYN1deg grid box. AERONET sites chosen are shown in **Figure 7**
318 with a complete listing of all sites in Appendix 1. Though we examine 55 sites over 20+
319 years, we aggregate the statistics within continental regions which naturally isolates them
320 by general climatic conditions. Tables 3 and 4 show comparisons for each site grouping,
321 respectively, for clear sky (less than 1% cloud identified by MODIS and geostationary
322 satellites in the SYN1deg grid box) conditions and for all sky (any cloud condition within
323 the SYN1deg grid box) conditions. Using clear-sky scenes identified by MODIS only
324 gives the same statistical results with fewer number of samples. Statistics shown in
325 Tables 3 and 4 are the average observed value, mean bias (MATCH – Observation), root
326 mean square (RMS) difference and the correlation coefficient (R) over the time period
327 from March 2000 through February 2020. The actual time period varies depending on the
328 site due to AERONET data availability. The RMS difference and correlation coefficient
329 are computed by each site with hourly mean values where observations are available
330 from March 2000 through February 2020. For comparison purposes we show the same
331 statistics derived from observations compared to MERRA2 AODs using the identical
332 hours. We note, however, that MERRA2 assimilates AERONET while MATCH AODs
333 are independent from AERONET AODs. MATCH AOD for the Brazil group is biased
334 high by 0.02, and the China/Korea group has no appreciable bias compared with
335 AERONET AODs. These two regions have relatively large bias of $\langle AOD_{MODIS}^{clr} \rangle$ from

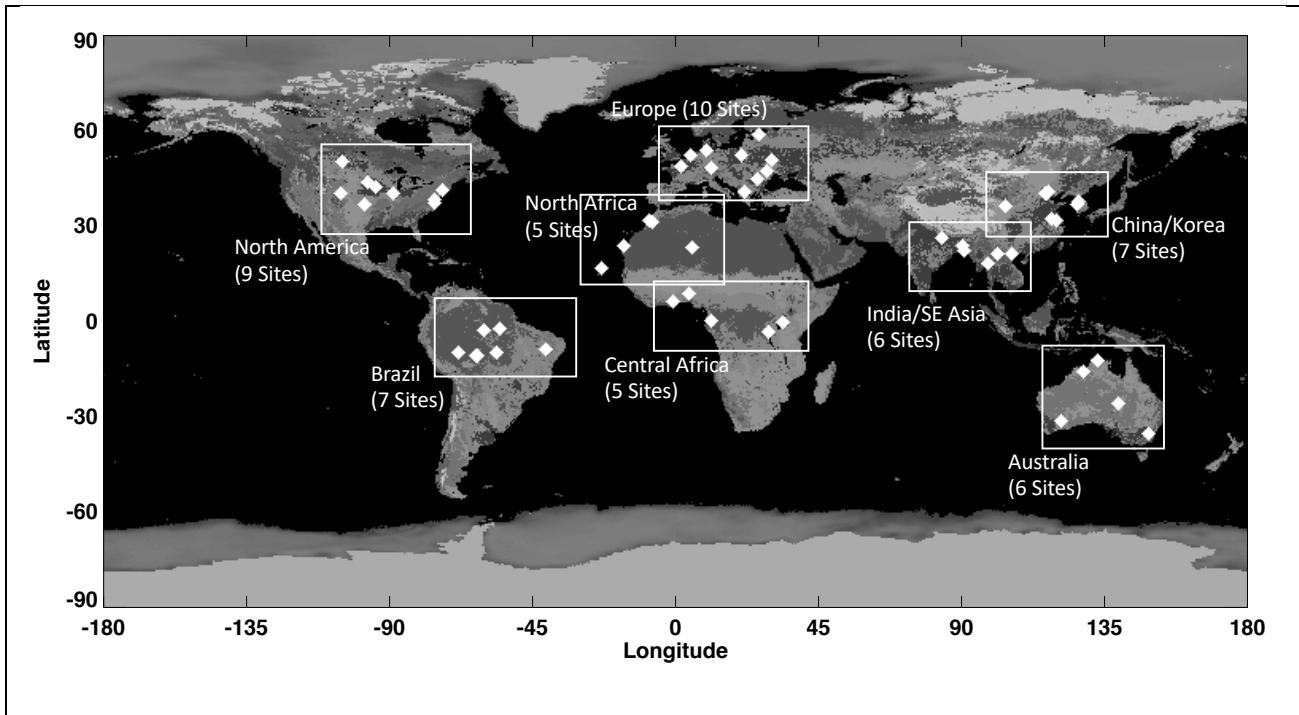

Figure 7. Location of AERONET sites and how they grouped for calculations of mean/bias/RMS with respect to MATCH and MERRA-2 optical depths found in tables 3 and 4.

336

337 MATCH compared with MODIS AODs (**Fig. 3** right). In contrast, negative bias of
 338 MERRA2 AODs compared with AERONET AODs for Brazil, central Africa, and
 339 China/Korea groups are consistent with negative bias of MERRA2 $\langle AOD_{MODIS}^{clr} \rangle$
 340 compared with MODIS AODs (**Fig. 3** left). For the China/Korea group, the RMS
 341 difference between MATCH AODs and AERONET AODs is 0.18 and correlation
 342 coefficient is 0.7. These are worse than the counterpart values of MERRA2 versus
 343 AERONET AODs because summertime agreement between MATCH and AERONET
 344 AODs is worse if a similar plot as **Fig. 6** is plotted for summertime when hygroscopic
 345 aerosols are dominant under high relative humidity conditions.

346 The sign of the MATCH AODs compared to AERONET AODs for all-sky
 347 conditions is generally consistent with the sign of clear-sky counterparts. The RMS
 348 difference under all-sky conditions is generally larger than the clear-sky RMS difference

349 while the correlation coefficient is nearly the same. The biases for MERRA2
 350 comparisons are generally comparable to MATCH though RMS for MERRA2 tend to be
 351 slightly smaller and correlations tend to be higher due in part to the assimilation of
 352 AERONET into the MERRA2 model.
 353

Table 3. Hourly AERONET station statistics for MATCH and MERRA-2.
 Continental Groups, Clear Sky conditions¹

Site	MATCH						MERRA-2		
	Predominant Aerosol Type	Number	Observed Average	Bias	RMS	R ²	Bias	RMS	R ²

¹The time period used is from Mar 2000 through Apr 2020. Actual period varies by site depending on AERONET data availability. Clear Sky is identified by MODIS and geostationary satellites and the cloud fraction is less than 1% over a SYN1deg grid box.

354
 355 Results for all points across all sites and times are shown in **Figure 8**. The color density
 356 plots are in log scale and indicate the vast majority of observations have an AOD of less
 357 than one for both clear and all sky conditions observed within the SYN1deg grid box.
 358 Biases are less than 10% of the mean value but RMS is large relative to the mean
 359 observed value. Overall correlation is approximately 0.8. The ‘clear sky’ hours (where
 360 SYN1deg estimated less than 1% cloud in the grid box based on MODIS and GEO

361 observations) is a little more than 10% of the overall points. When MATCH AOD is
 362 compared to MERRA2 AOD (not shown) MATCH is biased approximately 10% higher.
 363

Table 4. Hourly AERONET station statistics for MATCH and MERRA-2.

¹ The time period used for the statistics is from March 2000 through April 2020. Total sample varies by site depending on AERONET data availability.

364

365 **3. Discussion of AOD Differences**

366 In this section, we investigate the reason for the AOD differences shown in the
 367 previous section. In addition, we estimate the effect of the AOD differences to surface
 368 irradiances when MATCH AODs are used for surface irradiance computations.

369 Generally, cloud contamination in MODIS AODs is caused by unresolved sub-pixel scale
 370 clouds (Kaufman et al. 2005; Martins et al. 2002). The difference shown over convective
 371 regions, therefore, seems to be caused by the uncertainty due to 3D radiative effects that
 372 impact retrieved AODs by unknown amounts (Wen et al. 2007), by errors in estimating

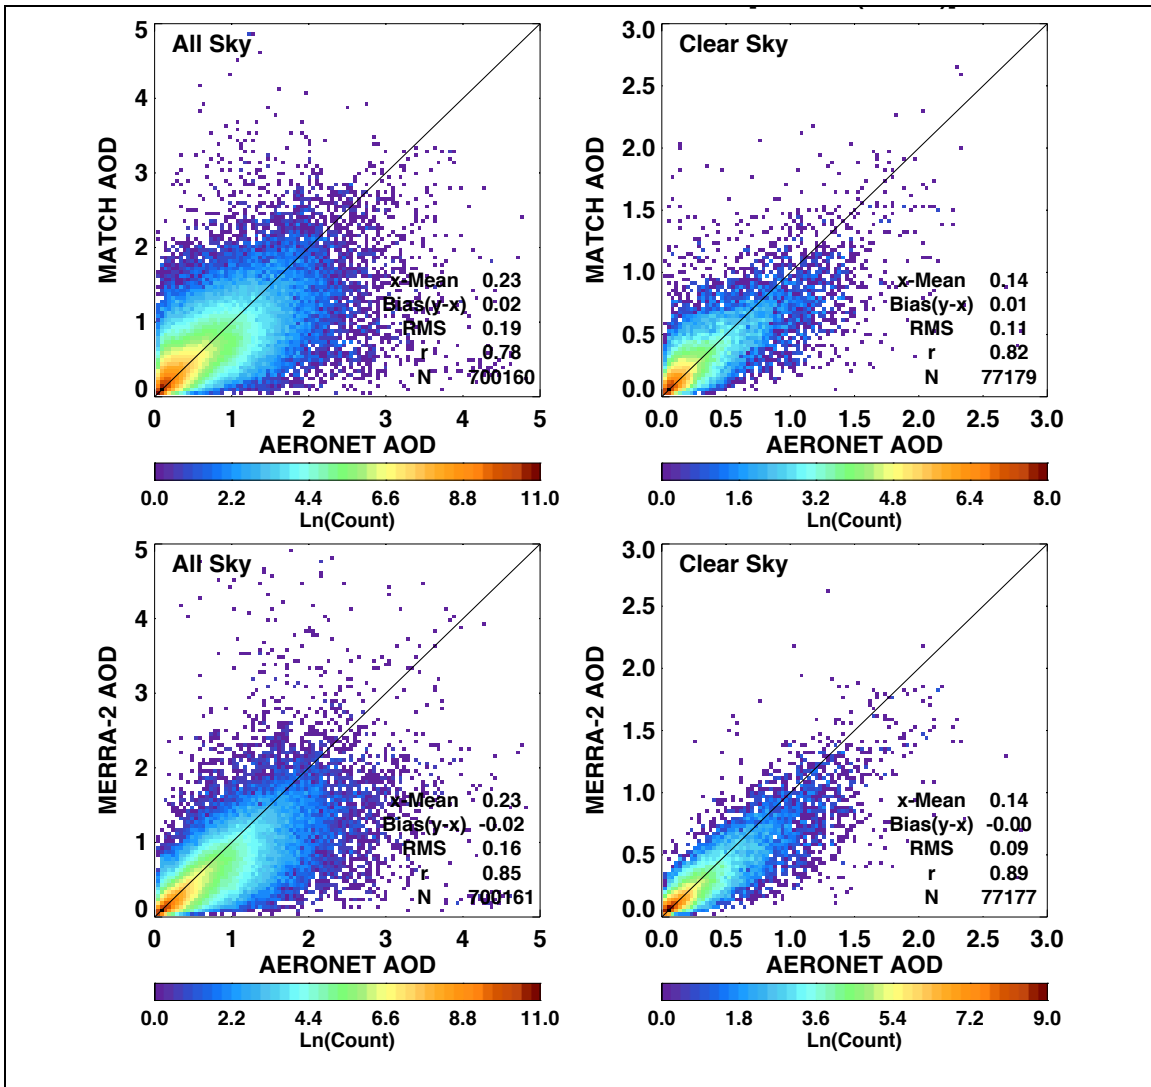

Figure 8. All sky (left) and clear sky (right) comparisons of observed (AERONET) hour mean optical depths to estimates from the MATCH model for 20+ years at 55 AERONET sites shown in Fig 7.

373

374 the fraction of hygroscopic aerosols or by the errors in estimating water uptake by
 375 hygroscopic aerosols (Su et al 2008, Marshak et al., 2021). Larger AODs are screened out
 376 in the MOD08 data product while the CERES team uses all retrieved AODs regardless of
 377 the QAC score, likely increasing MATCH AOD overall. The comparison with
 378 AERONET AODs is not decisive to determine how to screen MODIS AODs because
 379 MATCH AODs are positively biased and MERRA2 AODs are negatively biased for the

380 Brazil group. The result underscores the difficulty of deriving accurate AODs, which
381 appear to involve requirements in addition to identification of clear-sky scenes. Levy et
382 al. (2013) list reasons lowering the QAC score as 1) pixels are thrown out due to cloud
383 masking, 2) retrieval solution does not fit the observation well, and 3) the solution is not
384 physically plausible given the observed situation. Therefore, even though the difficulty of
385 identifying clear-sky scenes is driven by cloud contamination by trade cumulus (Loeb et
386 al. 2018), the difficulty of deriving AODs exists over convective regions (Varnai et al.,
387 2017) as well.

388 Larger positive biases of MATCH AODs compared with AERONET AODs exist
389 over Africa (Tables 3 and 4). For North Africa, the bias is known to be caused by
390 excessive dust generated by the MATCH algorithm. Even though modeled aerosols are
391 not often used over north Africa owing to the abundance of clear-sky conditions, the dust
392 problem leads to a larger positive AOD bias. In addition, MATCH uses fixed aerosol
393 sources in time. Therefore, it tends to miss large aerosol events, such as forest fires, until
394 clear-sky conditions occur, allowing observations of the event by MODIS. This leads to a
395 larger RMS difference and lower correlation coefficient with AERONET AODs
396 compared with those from MERRA2 versus AERONET.

397 Because MODIS AOD are not generally available under overcast conditions, the
398 reliance on modeled AOD increases as the cloud fraction over a $1^\circ \times 1^\circ$ grid increases.
399 **Figure 6**, which shows that AERONET AOD increases with cloud fraction derived from
400 satellites, indicates that as the cloud fraction over a $1^\circ \times 1^\circ$ grid increases, AOD over the
401 clear-sky portion of the grid increases. In addition, **Fig. 6** suggests that modeled AODs
402 under near overcast conditions are significantly larger than clear-sky AODs that are

403 constrained by MODIS observations. Because we are unable to evaluate AODs for
 404 overcast conditions, here we assess AOD changes with cloud fraction using ground-based
 405 observations. **Figure 9** shows the distribution of AERONET AODs for clear-sky and all-
 406 sky conditions, as well as precipitable water derived from a microwave radiometer
 407 separated by these two conditions. Clear-sky is identified by the Long-Ackerman
 408 algorithm (Long et al. 2006) that uses surface direct and diffuse irradiances. **Figure 9**
 409 shows that AOD and precipitable water under all-sky conditions are significantly larger

Figure 9. a) 15-minute mean precipitable water distributions from Microwave radiometer observations at ARM/SGP E13 site under all sky and clear sky conditions. b) 15-minute mean aerosol optical depth distributions from AERONET sun-photometer at 550nm. ‘Clear sky’ is here defined as when a 15-minute time period where the SWFA, surface radiometry-based cloud fraction, equals 0.

410
 411 than those under clear-sky conditions. When we use cloud fraction derived from satellite
 412 and plot AOD and precipitable water as a function of the cloud fraction using the same
 413 grid box where the ground site is located, AOD and precipitable water increase with the
 414 cloud fraction (**Fig. 10**). Therefore, increasing AOD with cloud fraction shown in **Fig. 6**

415 is qualitatively explained by increasing AOD of hygroscopic aerosols with relative
 416 humidity. However, **Fig. 10** indicates that either the growth of MATCH AOD is too
 417 strong or modeled MATCH AOD under all-sky conditions is too large.

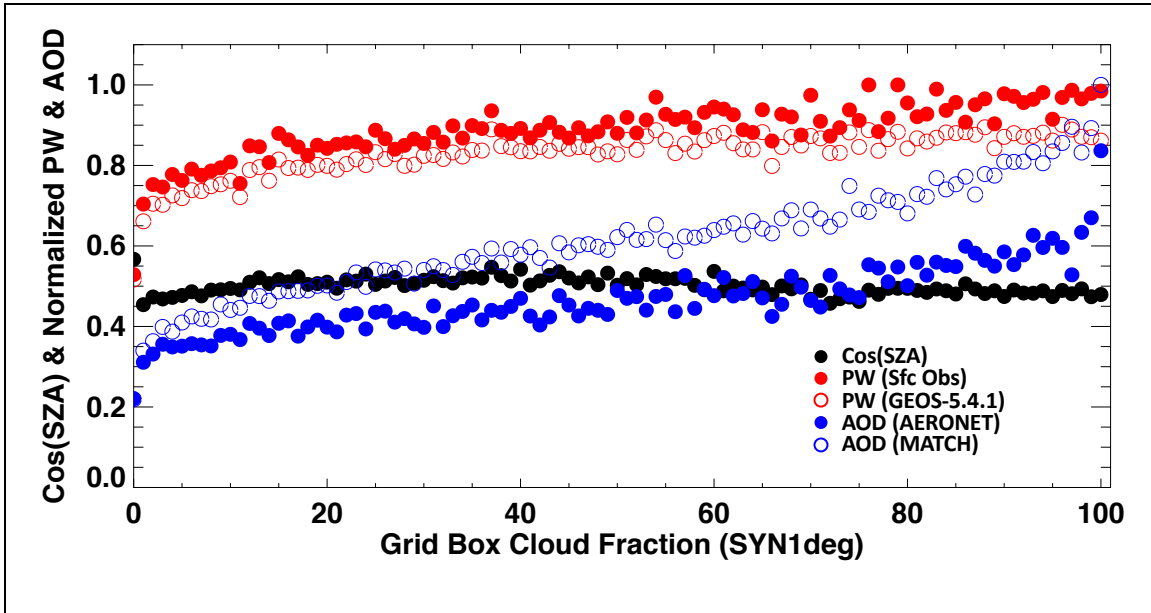

Figure 10. Aerosol optical depth (AOD) and precipitable water (PW) as a function of cloud fraction over the $1^{\circ} \times 1^{\circ}$ grid box where the ARM/SGP E13 and SURFRAD Bondville IL sites are located. Closed and open blue circles are, respectively, AOD derived from AERONET and MATCH AOD. Closed and open red circles are, respectively, PW derived from microwave radiometer and CIMEL sun photometer and GEOS-5.4.1 PW. Cloud fractions are derived from MODIS and geostationary satellites. Black dots are mean cosine solar zenith angle of the time of AOD and PW observations. AOD and PW are normalized to their maximum value for display.

418

419 **4. Clear Sky Comparisons of SYN1deg and Surface Observed Irradiances**

420 We consider the impact of MATCH aerosols on computed surface irradiances by

421 comparing calculated hourly mean surface downward irradiances from the Ed4.1

422 SYN1deg-Hour product to observations of downward irradiance. In a $1^{\circ} \times 1^{\circ}$ grid box

423 with an approximate size of 111 km², 100% clear sky sampled over one hour as

424 determined by MODIS or geostationary satellites is relatively rare. None the less, by

425 grouping sites based on general surface conditions and analyzing 20 years of data

426 sufficient samples are found. **Figure 11** shows the sites, grouped by color, including 15
427 land sites labeled “Mid-Latitude” (Green), 6 sites labeled “Desert” (Red), 6 sites labeled
428 “Polar” (White) and 46 buoys (Blue). Surface observed SW irradiance from the land
429 sites comes from the Baseline Surface Radiation Network (Ohmura et al. 1998; Dreimel
430 et al. 2018) and buoy data are made available

Figure 11. Location of surface observations of downwelling shortwave irradiance used to compare the SYN1deg Ed4.1 calculations to observations for all available hours (from Mar 2000 through Dec 2019) where the SYN1deg cloud analysis determines the hour and grid box to be 100% clear sky.

431
432 from the Pacific Marine Environmental Lab (PMEL) (McPhaden et al. 2002, 2009) and
433 the Woods Hole Oceanographic Institute (WHOI) (Colbo and Weller, 2009). A complete
434 listing is given in Appendix A.

435 4.1 Shortwave Comparisons

436 We begin with a simple sensitivity calculation of AOD on surface Downward
437 Shortwave Irradiance (DSI). **Figure 12** shows a series of radiative transfer calculations
438 using the “On-Line Langley Fu & Liou radiative transfer code

439 ([https:// cloudsgate2.larc.nasa.gov/cgi-bin/fuliou/runfl.cgi](https://cloudsgate2.larc.nasa.gov/cgi-bin/fuliou/runfl.cgi)) with an open shrub spectral
 440 albedo (broadband albedo of 0.14 at $\mu_0=1.0$), “continental” aerosol, and no clouds.
 441 Values on the solid black line are calculated DSI with an AOD of 0.09 at six different
 442 solar zenith angles. Calculations were then done for AODs of 0.0 and 0.18, at the same
 443 solar zenith angles, representing 100% error bounds of mean AODs derived from
 444 AERONET as found in Tables 3 and 4 for the Australia sites where the RMS is
 445 approximately equal to the observed average of AOD. Orange and red shaded areas
 446 indicate potential bias of DSI at a given solar zenith angle. Irradiance values scale nearly
 447 linearly with $\text{Cos}(\text{SZA})$ between these limits. **Figure 12** shows the error remains nearly
 448 constant until a $\mu_0=0.5$ where it begins to decrease as insolation decreases. However, due
 449 to small downward irradiances at large solar zenith angles, the percentage error increases.
 450

Figure 12. Calculated DSI error at the surface computed with the LFLRT model due to the error in AODs. AOD is assumed to be 0.09. Light and dark orange envelope indicate, respectively, positive and negative errors in Wm^{-2} (left axis) due to 100% AOD errors. Envelopes are computed with AODs of 0.0 (a -100% error) and 0.18 (a +100% error), at the same solar zenith angles, representing 100% error bounds. Values on the solid black line are calculated DSI (right axis) with an AOD = 0.09 at six solar zenith angles.

451

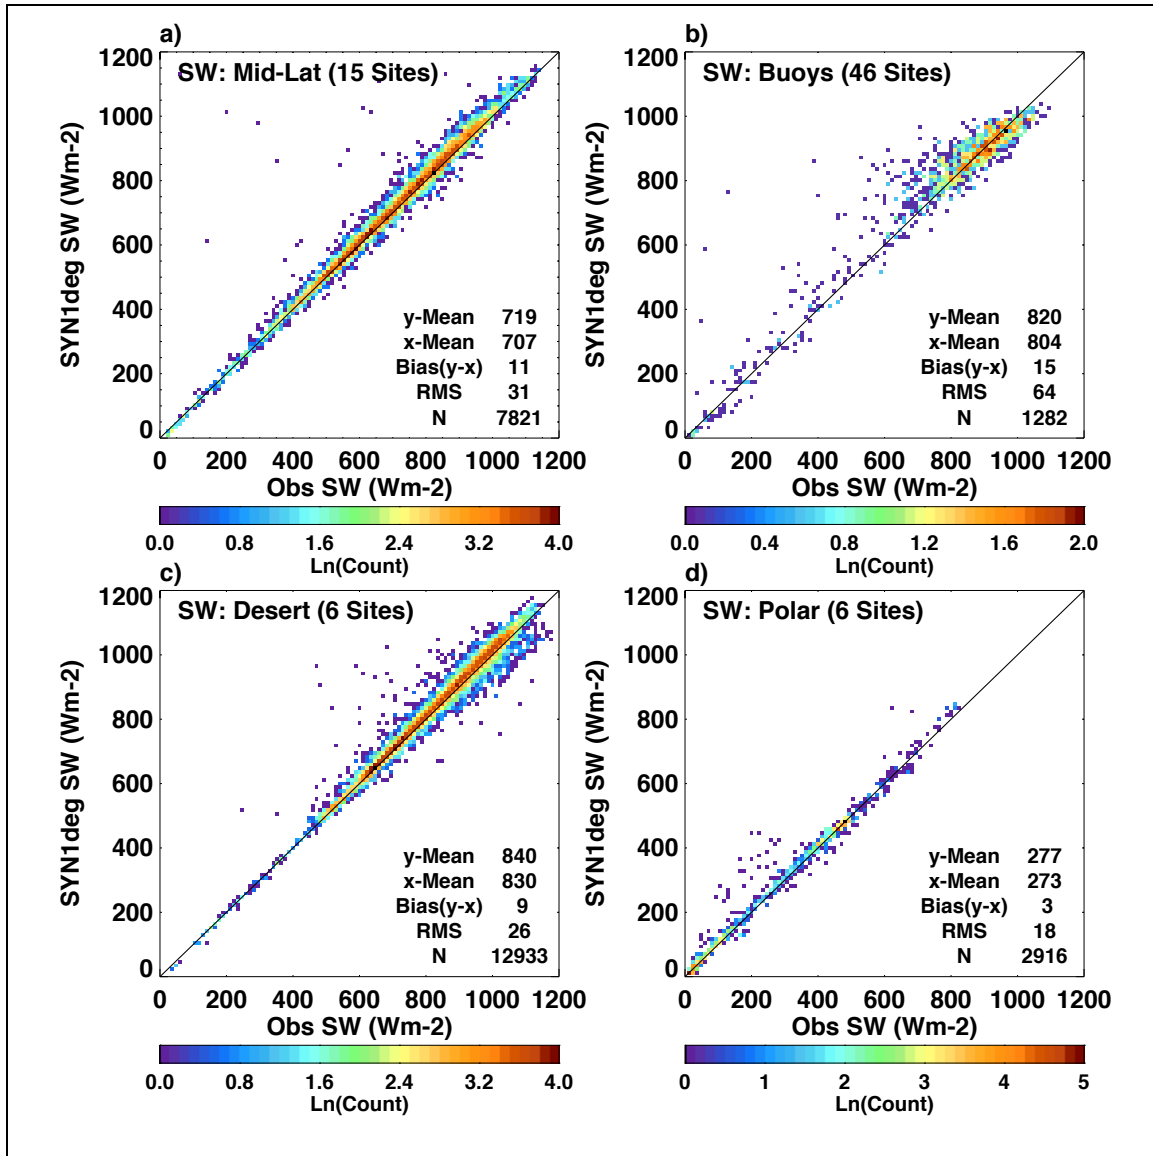

Figure 13. Comparisons of DSI at the surface from the SYN1deg Ed4.1 calculations (y-axis for all plots) and BSRN and buoy surface sites (x-axis all plots). Data are from Mar 2000 through Feb 2020 and only include hours when a 1° grid box is 100% clear sky according to SYN1deg cloud fraction.

452

453

454

455

456

457

Figure 13 shows hourly comparisons of computed clear-sky downward shortwave irradiance compared to observations for the groups of sites shown in **Fig. 11**. In general, calculated irradiance is larger than observed. We find that in every grouping, SYN1deg calculations tend to be too transmissive, overestimating DSI by between 3 Wm⁻² (polar sites) and 15 Wm⁻² (ocean buoys) with mid-latitude and desert sites each

458 overestimating DSI by $\sim 10 \text{ Wm}^{-2}$. This points to the possibility that MATCH is weighted
 459 too far towards scattering aerosols and too few absorbing aerosols.

460 Clear-sky scenes used for **Fig. 13** are those identified by MODIS and
 461 geostationary satellites over the 1° grid box where the ground site is located. That is,
 462 when satellites did not detect clouds over the one-hour period within the grid box, we
 463 compared computed and observed hourly mean downward shortwave irradiances. DSI is
 464 nominally measured by a shaded pyranometer combined with the direct insolation
 465 measured by a pyrhelimeter on a solar tracker. Though satellites may indicate clear,
 466 clouds might have been present within the field-of-view of the pyranometer increasing
 467 diffuse radiation. This would increase observed DSI, hence modeled irradiance would be
 468 smaller. To verify, we used the ground-based cloud screening algorithm developed by
 469 Long and Ackerman (Long et al. 2006) to further screen clouds. For the land groupings,
 470 Table 5 shows bias (RMS) of the DSI where both satellite and surface based observed
 471 cloud fraction equal 0.0. Though mean bias did not change significantly, the RMS in both
 472 the Mid-Latitude and Desert sites was reduced by half due to the more stringent cloud
 473 screening.

Table 5. Bias (RMS) of clear sky surface shortwave calculation compared to observation¹.
 All in Wm^{-2}

<i>Cloud Analysis</i>	Mid Latitude	Desert	Polar
<i>Satellite</i>	11 (31)	9 (26)	3 (18)
<i>Satellite And Surface</i>	11 (16)	8 (15)	4 (19)

¹Sample is based on 20 years of calculations when either satellite or satellite and surface cloud analysis indicates 0% cloud.

474

475 **4.2 Longwave Comparisons**

476 In this section we consider the implications of errors in AOD and aerosol type on

477 longwave LFLRT calculations as found in the SYN1deg product. **Figure 14** shows
 478 SYN1deg surface downward longwave irradiance (DLI) calculations compared to surface
 479

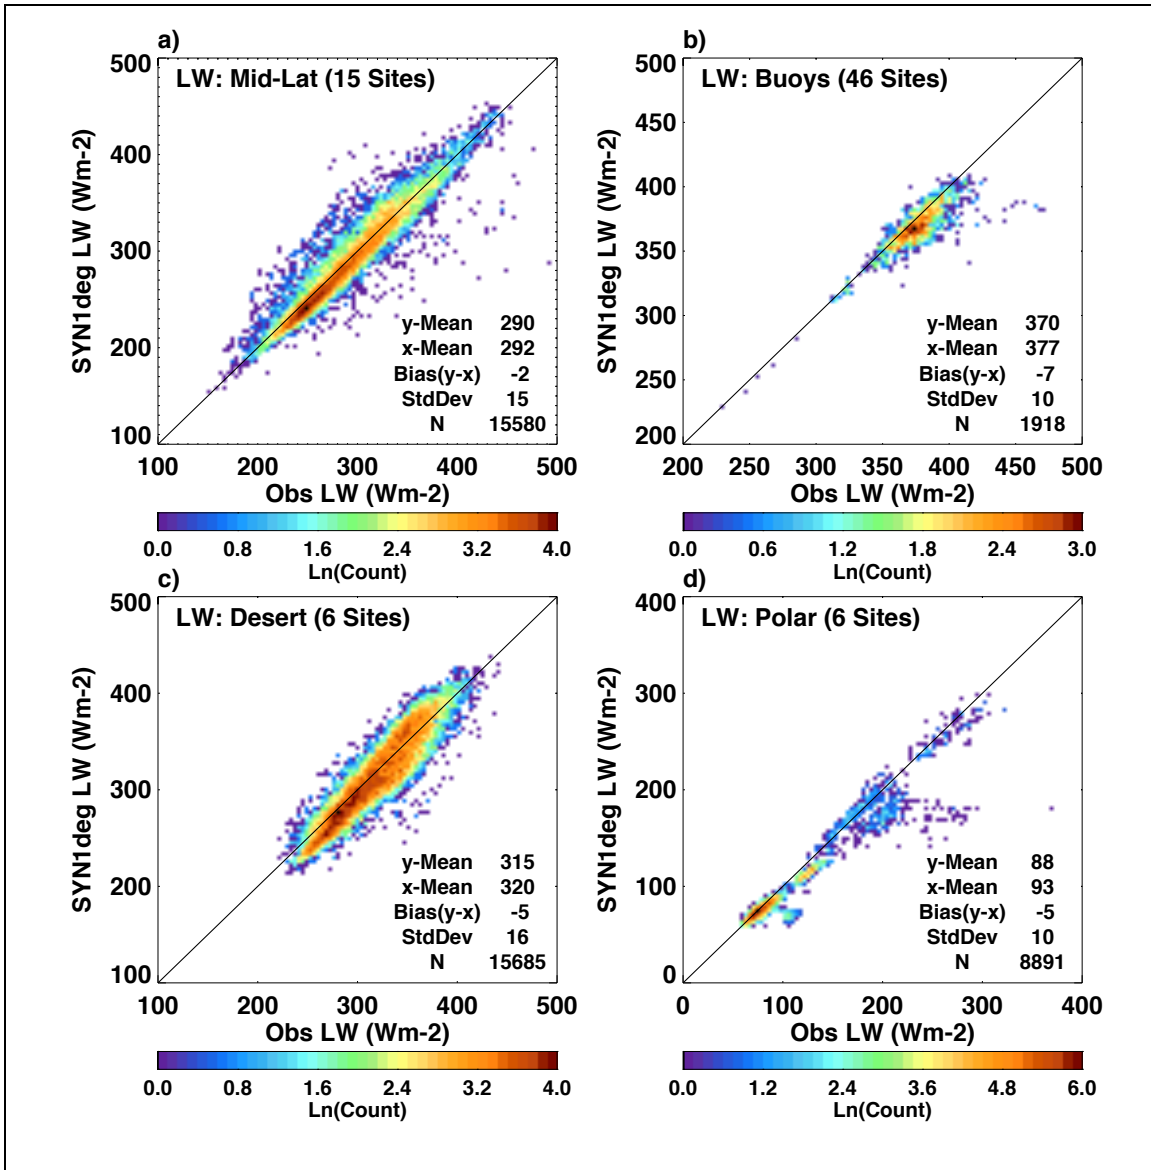

Figure 14. Comparisons of LW downward irradiance at the surface from the SYN1deg Ed4.1 calculations (y-axis for all plots) and BSRN and buoy surface sites (x-axis all plots). Data are from Mar 2000 through Feb 2020 and only include hours when a 1x1 grid box is 100% clear sky according to SYN1deg cloud fraction.

480
 481 observations similar to those shown in **Fig. 13**. Except for the polar region, where DLI is
 482 very sensitive to near surface air temperature, the bias and standard deviations of the DLI

483 is smaller than the SW equivalents in terms of both Wm^{-2} and percentage of the mean
 484 observation. Depending on aerosol type, DLI is less sensitive to total AOD. For example,
 485 a doubling of AOD (0.2 to 0.4) for a continental type results in a DLI change of only 0.2
 486 W m^{-2} . Table 6, however, shows the sensitivity of DLI (and DSI) to changes in dust
 487 particle size and shows that for LW, a change in aerosol type results in up to a 10 Wm^{-2}
 488 change in DLI.

Table 6. Effect of Dust Particle size on Surface Irradiance Calculations¹

	Dust Particle Size (microns)		
	0.5	2.0	8.0
<i>DLI</i>	352 Wm^{-2}	359 Wm^{-2} (+2.0%)	362 Wm^{-2} (+2.8%)
<i>DSI</i>	1046 Wm^{-2}	1028 Wm^{-2} (-1.7%)	1020 Wm^{-2} (-2.5%)

¹The radiative transfer code is run for a Mid-Latitude Summer atmosphere, open shrub surface albedo, aerosol scale height of 1.5km, clear sky, and cosine solar zenith angle of 1.0. Aerosol optical depth is fixed at 0.2 for all calculations.

489
 490 DLI is thus more sensitive to aerosol type in certain regions of the globe where there is
 491 substantial dust. To see the potential impact on DLI **Figure 15** shows calculated LW
 492 downward radiative forcing (clear minus pristine calculations) at 57 AERONET sites
 493 across the 20 years of SYN1deg data under consideration. The Northwest Africa sites
 494 (where dust is found seasonally) are shown as red boxes where one clearly sees larger
 495 LW forcing at these sites. Given the importance of particle size to LW effect we check
 496 MATCH particle size against AERONET fine/coarse mode retrievals for several of the
 497 African AERONET sites. **Figure 16** plots canonical mean observations of fine and coarse
 498 mode AOD from three AERONET sites along with groupings of AOD species from the
 499 MATCH model output. To compare to AERONET fine mode observations we plot the
 500 sum of the MATCH AOD due to organic carbon (OC), black carbon (BC) and sulfate

501 (SO₄). We compare the sum of MATCH AOD large dust particles (> 1µm) along with
502 sea salt (though sea salt is essentially zero over land) to the coarse mode AERONET
503 optical depth. All AOD values are at 550nm.
504

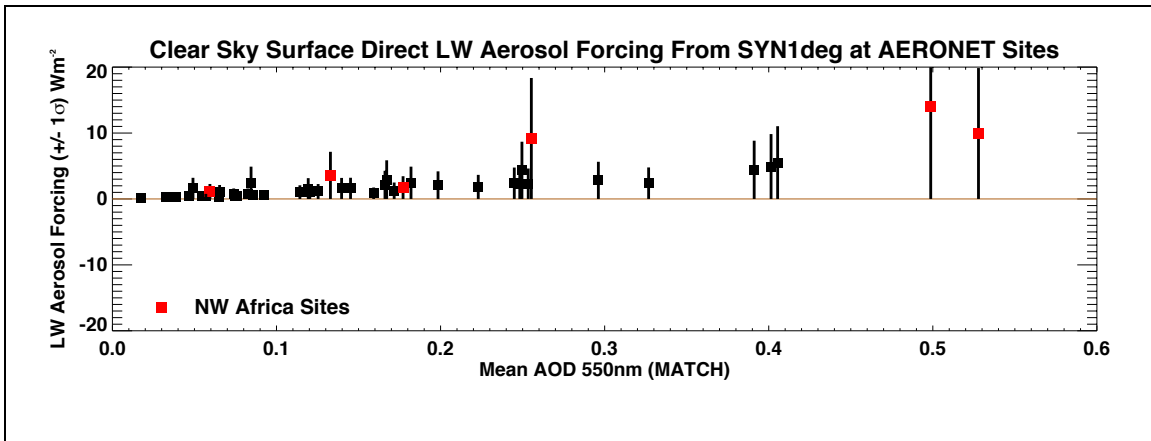

Figure 15. Clear sky direct radiative effect (clear minus pristine) in downward longwave irradiance averaged from 2000 through 2020 when AERONET observations are available. Boxes indicate average, vertical bar is +/- one standard deviation. Black boxes indicate all 57 AERONET sites and red boxes indicate Northwest Africa sites.

505

506 **Figure 16** indicates that resultant fine/coarse mode comparisons are encouraging but the
507 agreement is site dependent. In general MATCH is capturing seasonal changes in fine
508 and coarse particles at these sites but the magnitude of the AODs is biased.

509

Figure 16. Canonical monthly means across 20 years (2000-2020) showing AERONET fine (left) and coarse (right) AOD at 550nm compared to MATCH constituents. MATCH values represent summations of organic, black carbon (OC, BC) and sulfate (SO₄) for fine mode and large dust particles (> 1micron) plus sea salt for coarse mode comparisons.

510

511

4.3 CERES TOA and EBAF-surface comparison

512

CERES instruments observe TOA irradiances, which can be used to assess the

513

bias in computed irradiance. Global annual mean clear-sky TOA irradiances derived from

514

CERES observation averaged over 20 years from March 2000 through February 2020 are

515

53 Wm⁻² for reflected shortwave irradiance and 268 Wm⁻² for emitted longwave

516

irradiance. Corresponding computed reflected shortwave flux is 51 Wm⁻² and emitted

517

longwave flux is 267 Wm⁻². Insight into the surface irradiance errors may be gained by

518 considering how surface irradiance is modified via the tuning algorithm to match TOA
519 irradiance in the CERES EBAF-surface product (Kato et al. 2018). After known biases
520 are taken out, the adjustment of temperature and specific humidity profiles, surface and
521 aerosol properties are derived based on their pre-assigned uncertainty and the difference
522 of computed and observed TOA shortwave and longwave irradiance using the Lagrange
523 multiplier approach. To match the computed shortwave and longwave fluxes, AOD is
524 increased from 0.136 to 0.156 (global annual mean values) and precipitable water is
525 decreased from 2.29 cm to 2.22 cm (global annual mean values). These adjustments
526 change the downward shortwave irradiance from 244 Wm^{-2} to 243 Wm^{-2} .

527 To analyze how the EBAF tuning process changes surface irradiance, AOD and
528 precipitable water, we computed the mean change separated by surface group shown in
529 **Fig 11**. Generally, AOD increases and precipitable water decreases to increase reflected
530 shortwave flux, which in turn decreases surface downward shortwave irradiance over
531 these regions (**Table 6**). For the midlatitude group, on average, AOD is increased by
532 0.02, precipitable water is decreased by 0.06 cm, and surface albedo is increased by 0.03.
533 These adjustments reduce the diurnally averaged downward shortwave irradiance at the
534 surface by 2 Wm^{-2} . We do not have exact matches of BSRN and AERONET surface sites
535 but Tables 3 and 4 show MATCH AODs have either no bias (north America and China
536 and southeast Asia) or slightly negatively biased by 0.01 (Europe). Therefore, increasing
537 MATCH AODs by 0.02 on average for the mid-latitude group seems justifiable.
538 However, decreasing 2 Wm^{-2} for the diurnally averaged downward shortwave is smaller
539 than the 11 Wm^{-2} bias shown in the top left plot of **Fig. 13**, although instantaneous
540 irradiances are used for **Fig. 13**. The positive bias found in the downward shortwave

541 irradiance for the North Africa group (**Fig 13c**) is not consistent with the positive bias of
542 aerosol optical depth shown in **Table 3** under clear-sky conditions.

543 The adjustment made to match TOA shortwave irradiance, in the EBAF product,
544 is within the uncertainty of MODIS-derived AOD of ± 0.05 over land and ± 0.03 over
545 ocean (Remer et al. 2008; Levy et al. 2010, 2013). However, these are an expected error
546 of instantaneous AOD retrieval derived from the comparison of AODs with AERONET.
547 Therefore, the bias averaged over ground sites and many years is expected to be much
548 smaller. Although, the 0.03 AOD adjustment over ocean might be the upper limit of the
549 uncertainty of MODIS AODs over ocean, 16 Wm^{-2} bias in the instantaneous downward
550 shortwave irradiance seems to be larger than the reduction by 2 Wm^{-2} in the diurnally
551 averaged downward shortwave irradiance.

552 While we cannot identify the cause of the discrepancy between AOD comparison
553 and downward shortwave irradiance comparison with surface observations, potential
554 issues are following. 1) Aerosol type and optical properties used in irradiance
555 computations, and 2) bias in downward shortwave irradiance measured by pyranometer,
556 especially diffuse irradiance at smaller solar zenith angles. Because of the temperature
557 gradient within pyranometer, the downward shortwave irradiance measured by a
558 pyranometer tends to be biased low under clear-sky condition (Haeffelin et al. 2001).
559 Note that a study by Ham et al. (2020) indicates that the bias of diurnally averaged
560 surface downward shortwave irradiance computed by a four-stream model should be
561 smaller than 1%.

562

563

Table 6: Radiative flux, aerosol optical depth (AOD), precipitable water, and surface albedo change to match observed top-of-atmosphere radiative fluxes

Site	Observed TOA upward shortwave irradiance (Wm ⁻²)	Changes: Adjusted - Unadjusted				
		Clear-sky TOA upward shortwave irradiance (Wm ⁻²)	Clear-sky surface downward shortwave irradiance (Wm ⁻²)	Clear-sky AOD	Clear-sky precipitable water (cm)	Clear-sky surface albedo
<i>Mid-Latitude</i>	63.3	3.9	-2.0	0.02	-0.06	0.03
<i>Desert</i>	92.3	3.4	-1.7	0.02	-0.04	0.01

564

565 **5. Conclusions**

566 We evaluated MATCH aerosol optical depth used to produce the CERES
 567 SYN1deg product. Aerosol optical depths derived from Terra and Aqua by the dark target
 568 and deep blue algorithms were merged to produce daily gridded AODs. Daily gridded
 569 AODs were used for assimilation by MATCH at local solar noon. As a consequence,
 570 monthly mean AODs under clear-sky conditions identified by MODIS closely agree with
 571 those derived from MODIS, although MATCH uses climatological aerosol sources.
 572 Because AODs are not screened by QAC, MATCH AODs are larger over convective
 573 regions (e.g. Amazon, central Africa, and south east Asia) for both clear-sky and all-sky
 574 conditions.

575 MATCH AODs under all-sky conditions are larger than those under clear-sky
 576 conditions. Time series of AERONET AODs indicate that AODs generally increase with
 577 cloud fraction, which is consistent with, primarily, water uptake by hygroscopic aerosols
 578 (Varnai et al, 2017). In addition, surface observations at the ARM SGP site suggest that a
 579 larger AODs and larger precipitable water under all-sky conditions than those under

580 clear-sky conditions. Aerosol optical depth biases from AERONET AODs are
581 comparable to biases of MERRA2 AOD biases from AERONET AODs for both all-sky
582 and clear-sky conditions. However, MERRA2, which uses AERONET AODs to train the
583 algorithm, has better temporal correlation with AERONET AODs than MATCH AODs.

584 Once MATCH AODs are used for surface irradiance computations, downward
585 shortwave irradiances are positively biased by 1% to 2% compared to those observed at
586 surface sites. Top-of-atmosphere reflected clear-sky shortwave irradiances are negatively
587 biased compared with those derived from CERES observations. Increasing AODs by
588 ~ 0.02 , and surface albedos by 0.03, and decreasing precipitable water by 0.06 cm over
589 mid-latitude surface sites makes computed reflected TOA irradiances agree with those
590 derived from CERES. These adjustments reduce downward shortwave irradiances at the
591 surface by 2 Wm^{-2} . Decreasing MATCH AODs for the desert group is needed to match
592 computed reflected shortwave irradiances at TOA with those derived from CERES.
593 However, decreasing MATCH AODs is not consistent with generally larger MATCH
594 AODs compared with AERONET.

595 Optical properties of aerosols (i.e. aerosol type) play a role in computing
596 shortwave and longwave irradiance and changing and/or incorrect aerosol type can alter
597 the downward irradiances. Aerosol types used in the computations rely on the mapping of
598 MATCH types to those available in the radiative transfer model (Table 2). Biases in the
599 fraction of each aerosol type and their optical properties can change TOA upward and
600 surface downward shortwave irradiances without altering total AOD. A fuller evaluation
601 of aerosol type is left for future study.

602

603 **Acknowledgments**

604 This work was funded by the NASA CERES project. The products and the
605 validation could not have been accomplished without the help of the CERES TISA team.
606 These data were obtained from the NASA Langley Research Center EOSDIS Distributed
607 Active Archive Center. We also wish to acknowledge the hard work put in by the many
608 dedicated scientists maintaining surface instrumentation in many diverse climates to
609 obtain high quality observations of downwelling shortwave and longwave surface flux.
610 Those groups are noted in Appendix A.

626 **Appendix A. Surface Observation Sites Used for Validation**

627 A great deal of data used in this study was collected by dedicated site scientists
 628 measuring critical climate variables around the world. The tables included in this
 629 appendix outline the sites, in situ measurements taken and their locations and dates of
 630 available data. Table A1 lists the locations of the AERONET sites, our source for
 631 observed aerosol optical depth which can be found on-line at:
 632 https://aeronet.gsfc.nasa.gov/new_web/index.html.

	Kyiv, Ukraine	50.3N, 30.5E	2007/04 - 2018/12
	Hamburg, Germany	53.5N, 9.9E	2000/06 - 2018/06
	Munich Univ, Germany	48.1N, 11.6E	2001/11 - 2019/05
	Thessaloniki, Greece	40.6N, 22.1E	2003/06 - 2020/03
	Bucharest, Hungary	44.3N, 26.0E	2000/10 - 2019/03

640

641 Sources of surface observed downwelling irradiance are outlined in Tables
642 A2 (land) and A3 (buoys). For land we utilize data from the Baseline Surface
643 Radiation Network (BSRN) (Dreimel et al, 2018; Ohmura et al. (1998)), the US Dept.
644 of Energy's Atmospheric Radiation Measurement (ARM) program and NOAA's
645 SURFRAD network available from NOAA's Air Resources Laboratory/Surface
646 Radiation Research Branch., Augustine et al. (2000). Buoy observations come from
647 two sources through four separate projects. The Upper Ocean Processes group at
648 Woods Hole Oceanographic Institute have maintained the Stratus, North Tropical

649 Atlantic Site (NTAS) and Hawaii Ocean Time Series (HOTS) buoys for more than a
650 decade providing valuable time series of radiation observations in climatically
651 important regions of the ocean. These data can be retrieved from:
652 <http://uop.whoi.edu/index.html>. We would also like to acknowledge the Project
653 Office of NOAA's Pacific Marine Environmental Labs (PMEL) where three groups of
654 buoy data were downloaded: In the Pacific, the Tropical Atmosphere
655 Ocean/Triangle Trans-Ocean Buoy Network (TAO/TRITON) (McPhaden, 2002) data,
656 from the tropical Atlantic Ocean, the Prediction and Research Moored Array in the
657 Tropical Atlantic (PIRATA) (Servain et al. 1998), and the Research Moored Array for
658 African - Asian - Australian Monsoon Analysis and Prediction (RAMA) (McPhaden et
659 al., 2009) in the Indian Ocean. Also downloaded from PMEL are the long-term buoy
660 observations PAPA and Kuroshio Current observatory sites.
