16 **Abstract.**

17 Residential biomass burning for heating purposes is an important source of air pollutants during
18 winter. Here we test the hypothesis that significant secondary organic aerosol production can take
19 place even during winter nights through oxidation of the emitted organic vapors by the nitrate
20 (NO_3) radical produced during the reaction of ozone and nitrogen oxides. We use a mobile dual
21 smog chamber system which allows the study of chemical aging of ambient air against a control
22 reference. Ambient urban air sampled during a wintertime campaign during night-time periods
23 with high concentrations of biomass burning organic aerosol was used as the starting point of the
24 aging experiments. Ozone was added in the perturbed chamber to simulate mixing with
25 background air (and subsequent NO_3 radical production and aging), while the second chamber was
26 used as a reference. Following the injection of ozone rapid organic aerosol (OA) formation was
27 observed in all experiments leading to increases of the OA concentration by 20-70%. The oxygen-
28 to-carbon ratio of the OA increased on average by 50% and the mass spectra of the produced OA
29 was quite similar to the oxidized OA mass spectra reported during winter in urban areas. Further,
30 good correlation was found for the OA mass spectra between the ambient-derived emissions in
31 this study and the nocturnal aged laboratory-derived biomass burning emissions from previous
32 work. Concentrations of NO_3 radicals as high as 25 ppt were measured in the perturbed chamber

33 with an accompanying production of 0.1-3.2 $\mu\text{g m}^{-3}$ of organic nitrate in the aerosol phase. These
34 results strongly indicate that the OA in biomass burning plumes can chemically evolve rapidly
35 even during wintertime periods with low photochemical activity.

36

37 **1 Introduction**

38 Biomass burning from residential heating, agricultural fires, prescribed burning, and
39 wildfires is a major source of atmospheric pollutants worldwide (Watson 2002, Bond et al. 2004,
40 Robinson et al. 2006). Emissions from biomass burning contribute both primary organic aerosol
41 (POA) and organic vapors that upon further reactions in the atmosphere can produce secondary
42 organic aerosol (SOA) (Andreae & Merlet 2001, Akagi et al., 2011, Bruns et al., 2016, Akherati
43 et al., 2020). The use of wood burning for domestic heating purposes is one of the major sources
44 of OA in many countries and is a major contributor to the violation of daily PM standards in
45 European cities (Alfarra et al., 2007, Favez et al., 2010, Fuller et al., 2014). Biomass burning
46 emissions and their products have significant but still uncertain impacts on human health and
47 climate (Ford et al., 2018; O'Dell et al., 2019).

48 The organic aerosol emitted during biomass burning undergoes extensive physical and
49 chemical changes in the atmosphere. More volatile components evaporate as emissions dilute in
50 the atmosphere (Tkacik et al., 2017); these semivolatile organic compounds (SVOCs) together
51 with the other emitted intermediate volatility (IVOCs) and volatile organic compounds (VOCs)
52 are subsequently oxidized leading to the production of SOA. Photochemical oxidation of biomass
53 burning emissions and the resulting SOA production have been studied both in the laboratory
54 (Hennigan et al., 2011; Ortega et al., 2013; Tkacik et al., 2017; Ahern et al., 2019; Kodros et al.,
55 2020) and in the field (Capes et al., 2008; Jolleys et al., 2015; Vakkari et al., 2018). The reactions
56 of VOCs, IVOCs and SVOCs with the OH radical are considered to be the dominant chemical
57 pathway for oxidation, but reactions of emitted monoterpenes with ozone can also contribute (Yu
58 et al., 1999, Zhao et al., 2015). Despite considerable uncertainties remaining on the amount of
59 SOA that can be produced, and the net change of the biomass burning OA concentration when
60 evaporation is considered, it is clear that this daytime processing is important for converting the
61 fresh biomass burning OA to oxidized OA (OOA) (Bougiatioti et al., 2014).

62 Atmospheric processing of biomass burning OA during periods of low photochemical
63 activity (such as in winter or at night), known also as “dark” aging, has received substantially less

64 attention than photochemical processing. Recent aircraft measurements during agricultural
65 biomass burning periods indicated that nighttime oxidation of biomass burning VOCs is dominated
66 by NO_3 (Decker et al., 2019). Hartikainen et al. (2018) reported high amounts of nitrogen-
67 containing organic compounds both in the gas and particle phase after dark aging of residential
68 wood combustion emissions. Kodros et al. (2020) reported significant and rapid OOA production
69 in laboratory experiments in which fresh biomass burning emissions were exposed to NO_3 and
70 suggested that dark oxidation may be an important process on regional scales. In the same study,
71 ambient measurements in an urban area suggested that the mixing of O_3 from the residual layer
72 down to the nocturnal boundary layer can enhance the formation of NO_3 and the nighttime
73 oxidation of biomass burning emissions. The mixing of ozone from the residual layer and the
74 importance to nighttime chemistry was also suggested in studies on nighttime oxidation of biogenic
75 VOCs (Brown et al., 2009; Brown et al., 2013). Despite this important finding, the degree to which
76 biomass burning plumes undergo night-time aging and produce significant amounts of SOA
77 remains poorly understood. Lacking consideration of such nocturnal chemistry in transport models
78 has been suggested as a possible source of the under prediction oxidized organic aerosol mass by
79 a factor of 3-5 (Fountoukis et al., 2016; Tsimpidi et al., 2014) during wintertime in polluted areas
80 with low photochemical activity.

81 In this study, we take advantage of the high levels of OA from residential biomass burning
82 in Patras, Greece (the country's third-largest city), to investigate the importance of night-time
83 chemistry in the processing of biomass burning OA. Biomass burning leads to concentrations of
84 OA exceeding $50 \mu\text{g m}^{-3}$ in Patras in the early evening (Florou et al., 2017). A dual atmospheric
85 simulation chamber system is used to elucidate the formation of SOA during winter periods in
86 urban areas with high biomass burning organic aerosol concentrations. Usually chamber studies
87 use fresh biomass burning emissions generated in the laboratory. The use of the dual chamber
88 system offers the capability of aging realistic biomass burning emissions mixed with other
89 pollutants. It therefore offers a bridge between laboratory experiments and ambient observations.
90

91 **2 Experimental Methods**

92 **2.1 Dual chamber system**

93 The dual chamber system developed by Kaltsonoudis et al. (2019) was used for
94 experiments in early 2020 in Patras, Greece during the PyroTRACH-PANACEA Wintertime 2020

95 experiment. The system consists of two 1.5 m³ Teflon (PTFE) reactors attached to metallic frames.
96 Use of the second reactor as a reference (control chamber) allows the identification and potential
97 correction for any major experimental artifacts that could be due to the walls of the chamber and
98 the other complexities of this experimental system. The dual chamber system was deployed from
99 January 10 till February 15, 2020 in the city of Patras. The chambers along with the available
100 instrumentation were located indoors, in the campus of the University of Peloponnese,
101 approximately a few kilometers away from the center of the city. The windows of the laboratory
102 were kept open before and during the experiments, so the temperature of the system was only a
103 few degrees higher than that of the outdoor environment.

104

105 **2.2 Experimental description**

106 Both chambers were flushed with ambient air before each experiment using a metal bellows
107 pump (Senior Aerospace, MB-602) for 1-2 h. This process is used to achieve higher sampling
108 efficiency and brings the system (chamber walls, tubing) close to equilibrium with ambient air
109 reducing losses of vapors to the sampling lines and walls of the chamber. Ambient air during
110 nighttime cold periods was introduced inside both chambers. In one of the chambers, (perturbed
111 chamber) ozone was added and upon reaction with the existing NO_x in the chamber formed NO₃
112 radicals. The second chamber (control chamber) was used as the reference in order to help us
113 understand the unperturbed evolution of the system inside the chamber. During all experiments
114 the chambers were under dark conditions. Ambient air was flushed through each of the chambers
115 with a flow of 80 L min⁻¹. More than 70% of the ambient PM was transferred to the chambers and
116 the concentrations of the measured VOCs were within 5% of their ambient values.

117 Using an automated valve switching between the two reactors, the particle and gas
118 concentrations in both chambers were measured. Data were collected 1.5 min after the switching
119 of the valve to avoid any memory effects related to the sampling lines. For the gas phase
120 measurements PTFE tubing (0.25 in) was used, while for the particle phase the tubing was copper
121 (0.25 in).

122 After filling the chambers with ambient air, the content of each chamber was characterized
123 for approximately one hour. The ozone added in the perturbed chamber after the characterization
124 period was in the range of 50-250 ppb. These values are higher than the 20 ppb measured during
125 the nighttime in Patras in this campaign, but some acceleration of the corresponding chemical

126 processes is necessary to reduce the effects of the walls and to limit the duration of the experiments
127 in the relatively small chambers used.

128 In selected experiments, approximately 40 ppb of d9-butanol was added in both chambers
129 to measure the OH concentration. Following Barnett et al. (2012), the OH concentration in the
130 chambers was estimated with the measured decay of the butanol concentration assuming a reaction
131 rate constant with OH of $3.4 \times 10^{12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$.

132 An incoherent broad-band cavity-enhanced absorption spectroscopy (IBB-CEAS) was
133 used to measure the NO_3 radical concentration. Detailed information about the technique can be
134 found elsewhere (Venables et al., 2006; Ventrillard-Courtillot et al., 2010; Chen and Venables,
135 2011; Fouqueau et al., 2020). Briefly the light from a LED source centered on the 662 nm
136 absorption cross section of NO_3 radical is focused and introduced into a high-finesse optical cavity
137 composed of two high reflectivity ($\sim 99.98\%$) and 1 m curvature mirrors. The optical cavity has a
138 length of 0.61 m and allows up to 4.5 km (at 662 nm) optical path and a detection limit up to 3 ppt
139 (integration time of 10 seconds). Particle-free air is passed through the cavity at 2.5 L min^{-1} .
140 Spectra between 640 and 685 nm were recorded with an OceanOptics QE-65 Pro spectrometer. A
141 time resolution of one minute was selected for these experiments. Calibration with NO_2 (800 ppb
142 in dry nitrogen, Air Liquide) was performed daily in order to precisely determine the reflectivity
143 of the mirrors and estimate the optical path. The sample spectra were fitted against standard spectra
144 of gas species absorbing in the spectral region of the instrument: NO_3 radical (Orphal et al., 2003),
145 NO_2 (Vandaele et al., 1998) and H_2O (reference spectrum recorded with the instrument) using the
146 DOASIS software.

147 A quadrupole proton-transfer reaction mass spectrometer (PTR-MS, Ionicon Analytik) was
148 used to measure the concentration of VOCs including d9-butanol. We calculated the initial VOC
149 levels in the chambers using the concentrations of m/z 42 (acetonitrile), 69 (isoprene), 71 (MVK
150 & MACR), 73 (MEK), 79 (benzene), 93 (toluene) and 107 (xylene). We used the above m/z peaks,
151 because the PTR-MS was calibrated for those values. For the experiments that the PTR-MS was
152 not available we scaled the initial VOCs concentration using the BC levels. Using a series of gas
153 monitors the concentration of nitrogen oxides (NO and NO_2) and ozone (O_3) were measured
154 (Teledyne models: T201 and 400E respectively).

155 A TSI scanning mobility particle sizer (SMPS, classifier model 3080; DMA model 3081
156 CPC model 3775) was used for measuring the particle number distribution in the 15-700 nm range.

157 An Aerodyne high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) was
158 measuring the composition and mass spectrum of OA. For the analysis of the HR-ToF-AMS data
159 we used the AMS software toolkit (SQUIRREL v1.57I) and for the high-resolution data the Peak
160 Integration by Key Analysis (PIKA v1.6I) software. The elemental ratios were calculated using
161 the improved method of Canagaratna et al. (2015). The mass concentration and particle distribution
162 of black carbon (BC) were measured using a single-particle soot photometer (SP2, Droplet
163 Measurement Techniques).

164 The collection efficiency (CE) of the AMS was calculated applying the algorithm of
165 Kostenidou et al. (2007), comparing the SMPS volume distributions and the AMS mass
166 distributions. The CE ranged between 0.40-0.45 depending on the experiment. Using the same
167 algorithm, the density of the OA was calculated to be in the range of 1.25-1.4 g cm⁻³.

168 Using the theta (θ) angle (Kostenidou et al., 2009) a comparison between the OA spectra
169 of the ambient and the chamber content after filling, we concluded that the OA composition
170 injected in the chambers was the same as in the ambient air. The theta angle between the two
171 chambers and the ambient OA spectra was always less than 4 degrees, suggesting excellent
172 agreement. Also, the OA mass spectra in the two chambers right after their filling was in very good
173 agreement ($\theta=3-4^\circ$), confirming that both chambers had the same OA composition initially.

174 Following the completion of each perturbation experiment, a wall-loss characterization
175 experiment was conducted to measure the size-dependent particle wall-loss rate constant inside
176 the two chambers (Wang et al., 2018). The particles were produced by the atomization (TSI, model
177 3076) of an aqueous solution of ammonium sulfate (5 g L⁻¹) and subsequent diffusion drying and
178 were injected into both chambers. Using an ionizing fan, the chamber walls were swept before the
179 start of each experiment to keep the particle loss rates low (Jorga et al., 2020).

180 The perturbation experiments started around 18:00 LT each evening, when the OA
181 concentration was elevated from local nocturnal biomass burning emissions in the area for heating.
182 The initial conditions in the experiments are summarized in Table 1. Thirteen experiments, eleven
183 involving perturbation and two blank experiments, in which no ozone was injected in either
184 chamber, were performed during January and February 2020 using ambient air from Patras.

185

186

187

188 3 Results of a Typical Perturbation Experiment

189 The average PM₁ concentration in the chambers during the filling process of Exp. 1 was
190 approximately 50 µg m⁻³. The concentration of OA during that period was 44 µg m⁻³ with 2.4 µg
191 m⁻³ of BC. The positive matrix factorization (PMF) analysis of the full campaign ambient data set
192 suggested that 70% of the OA at the time of filling originated from biomass burning. Other OA
193 sources included cooking OA (15%), oxygenated OA (10%) and hydrocarbon-like OA (5%). The
194 initial concentration of O₃ in the two chambers was 10 ppb, of NO 17 ppb and of NO₂ 24 ppb,
195 values within 5% of their ambient concentrations. The measured initial VOC levels were
196 approximately 150 µg m⁻³. The rest of the conditions are summarized in Table 1.

197 In Exp.1 NO₂ increased to 30 ppb in the perturbed chamber in approximately 30 min after
198 the ozone injection while at the same time NO levels dropped to close to zero. In the perturbed
199 chamber 2 hours after the injection the mixing ratio of NO₂ was 18 ppb and of ozone 220 ppb. In
200 the control chamber the concentrations of the above mentioned gases remained within 10% of their
201 initial levels. Due to the time needed for mixing and the rapid reaction of NO and O₃ it is difficult
202 to measure accurately the injected O₃ concentration. A zeroth order estimate can be made assuming
203 that the injected amount of ozone is equal to the final (equilibrated) amount of ozone in the
204 perturbed chamber plus the reacted NO_x (Table S1). Based on this zeroth order estimate, the
205 injected ozone in Exp. 1 was approximately 240 ppb.

206 Following the injection of ozone in the perturbed chamber (t=0 h) there was a rapid increase
207 of OA (Fig. 1). Approximately 33 µg m⁻³ of SOA was produced in 2.5 hours (70% increase from
208 the initial injected OA levels). In just one hour after the injection of ozone, the OA concentration
209 increased by approximately 25 µg m⁻³. This roughly corresponds to an initial OA formation rate
210 of 25 µg m⁻³ h⁻¹, indicating the strong potential of the ambient air in an urban area with strong
211 biomass burning emissions to form SOA even under dark conditions. The change of OA in the
212 control chamber after the particle wall-loss corrections was less than 7% at all times. This strongly
213 indicates that the OA changes in the perturbation chamber were not due to experimental artifacts.

214 The sulfate concentration remained practically the same (within 10%) in both the perturbed
215 and the control chambers after accounting for particle wall-losses. The initial nitrate in the
216 perturbed chamber was 1 µg m⁻³ more than in the control. This small difference can be an artifact
217 of the sampling system in this specific experiment. Production of approximately 6 µg m⁻³ of aerosol
218 nitrate was observed in the perturbed chamber with the majority of this increase in the form of

219 organic nitrate. Using the method described in Farmer et al. (2010) using the $\text{NO}^+/\text{NO}_2^+$ ratio from
220 the AMS, we estimate that close to 60% of the formed secondary aerosol nitrate in the perturbed
221 chamber was organic. Taking into account the organic nitrate, there was a 77% increase of the OA
222 compared to the initial concentration.

223 An increase of the ammonium concentration by close to $1 \mu\text{g m}^{-3}$ was observed in the
224 perturbed chamber while in the control its concentration remained within 8% of the initial value.
225 The relative humidity (RH) during Exp. 1 inside the chambers was approximately 45%.

226

227 3.1 Organic aerosol spectra

228 Comparing the OA mass spectra in the perturbed chamber at the beginning (after the air
229 injection) and at the end (2.5 hours after the ozone injection) of Exp. 1 there was an increase in the
230 fractional signal of m/z : 28 (CO^+), 29 (CHO^+), 30 (CH_2O^+), 43 ($\text{C}_2\text{H}_3\text{O}^+$), and 44 (CO_2^+). The
231 highest decrease was observed in 55 (C_4H_7^+), 57 (C_4H_9^+), 60 ($\text{C}_2\text{H}_4\text{O}_2^+$), 69 (C_5H_9^+), 91 (C_7H_7^+)
232 and 95 ($\text{C}_7\text{H}_{11}^+$). The theta angle between the spectra was 19 degrees, indicating significant change.
233 The initial and final spectra in the control chamber had a θ angle of 8 degrees, with changes in m/z
234 28, 44, 57 and 60. Figure 2 represents the OA mass spectra in the two chambers at the start and
235 end of Exp. 1.

236 The O:C ratio during Exp. 1 in the control chamber increased slightly from 0.4 to 0.41
237 during the experiment (Fig. 3). This suggests that there was relatively low but probably non-zero
238 chemical activity in this chamber. This is consistent with the small change in the OA mass
239 spectrum. This activity is probably due to the O_3 that existed in this chamber. On the contrary in
240 the perturbed chamber after the injection of ozone the O:C ratio increased rapidly reaching 0.52
241 after 30 min. At the end of the experiment, the O:C ratio in the perturbed chamber reached a value
242 of 0.61, similar to the measured ambient value around 3:00 LT at night.

243 To calculate the mass spectrum of the produced OA in the perturbed chamber, we used a
244 simple mass balance approach. Details about this method can be found in Jorga et al. (2020).
245 Concisely, assuming that the main processes in the chamber are losses of particles to the chamber
246 walls and SOA formation, we estimate the initial (before the injection of ozone) and produced OA
247 mass spectra. Using the particle rate loss constant measured at the end of each experiment, the
248 concentration of the preexisting OA as a function of time can be calculated. The produced OA is

249 then the difference between the total measured OA and the initial OA. Figure 4 shows the estimated
250 produced OA in Exp. 1 and Figure 5 the corresponding AMS spectrum.

251 The produced OA mass spectra from the perturbed chamber were compared with the
252 produced OA factor from dark aging of biomass burning emissions in the laboratory (Kodros et
253 al., 2020). Although the present study deals with ambient emissions with more complex air mixture
254 and conditions than the laboratory work that we are comparing with, that used specific biomass
255 burning emissions under idealized conditions, a comparison can provide us with information about
256 the consistency of the two studies. Kodros et al. (2020) performed chamber experiments in which
257 they exposed residential biomass burning emissions from a residential wood stove to NO₂ and O₃
258 under different RH conditions. Here we compare the produced OA from a medium RH
259 (approximately 45%) experiment with those of the ambient perturbation experiments that had
260 similar RH. The θ angle between the produced OA from perturbation Exp.1 and the one from the
261 laboratory chamber experiment was 11 degrees, indicating a considerable degree of similarity (Fig.
262 6).

263 The produced OA was also compared with the ambient oxygenated organic aerosol (OOA)
264 factor identified from the PMF analysis of the ambient data. The θ angle between the ambient
265 OOA in Patras from winter 2020 and the produced OA from Exp. 1 was 10 degrees. Similarities
266 were also observed in the produced OA and OOA from cities around the world during winter
267 periods. For Exp. 1 the θ angle was in the range of 9-18 degrees (Table S2) when compared with
268 OOA factors from Fresno, US (Ge et al., 2012), Barcelona, Spain (Mohr et al., 2012), Paris, France
269 (Crippa et al., 2013), Bologna, Italy (Gilardoni et al., 2016), Athens, Greece (Florou et al., 2017)
270 and Xi'an/Beijing, China (Elser et al., 2016).

271

272 **4 Results of Other Experiments**

273 **4.1 Secondary organic aerosol production**

274 The rapid OA production observed during Exp. 1 was also observed in all the other
275 experiments, with approximately 75% of the produced OA formed in the first hour after the ozone
276 injection. Figure 7 represents the produced OA (including organic nitrates) in all the perturbation
277 experiments. In all experiments, the majority of secondary nitrate aerosol were organonitrate,
278 representing 55-85% of the total produced nitrate. Taking into account the organic nitrates, the

279 initial OA formation rate in the perturbed chamber in the conducted experiments was on average
280 $10 \mu\text{g m}^{-3} \text{h}^{-1}$ ranging from 1 to $30 \mu\text{g m}^{-3} \text{h}^{-1}$.

281 An increase in the O:C in the perturbed chamber was observed in all experiments with an
282 average increase from the initial O:C of 45%. At the same time the O:C in the control chamber
283 remained within 6% of the initial value.

284 The mass spectra of the produced OA in the perturbed chamber were similar to that of
285 Exp.1 with the major m/z values being 28, 29, 43, 44, 55 and 69 (Fig. 5). The θ angle between the
286 different produced OA spectra in the perturbed experiments were less than 14 degrees, suggesting
287 similarities between the produced OA from the different perturbation experiments. The θ angle
288 between the produced OA mass spectra in the perturbed chamber and the one from Kodros et al.
289 (2020) was in the range of 9-16 degrees, suggesting similarity of the results of the two studies,
290 even if one relied on a single fuel burned in a single stove and the other in a mixture of emissions
291 from hundreds of fireplaces and heating stoves.

292

293 **4.2 NO₃ and OH radical levels**

294 Based on the decay of d9-butanol after the injection of ozone, the OH concentration was
295 in the range of $0.2\text{-}0.4 \times 10^6$ molecules cm^{-3} in the perturbation chamber suggesting that the addition
296 of ozone and reactions with organic vapors were not producing significant OH levels. In the control
297 chamber the corresponding OH concentrations were practically zero.

298 Nitrate radical concentrations above the detection level of a few ppt were only measured
299 in the perturbed chamber after the ozone injection. The maximum NO₃ radical concentrations in
300 the perturbed chamber ranged from 3 to 25 ppt with the highest observed during Exp. 8 (Table
301 S3). In this experiment before the ozone injection the NO₃ levels in both chambers were below the
302 detection limit of the instrument, while after the injection ($t=0$ h) the concentration of NO₃ started
303 to increase (Fig. S1). In Exp. 8 there were 44 ppb of NO_x initially and 150 ppb of O₃ were injected.
304 Approximately $15 \mu\text{g m}^{-3}$ of OA was formed in 2.5 h after the perturbation, with close to $2 \mu\text{g m}^{-3}$
305 of the OA formed being organic nitrate. The O:C reached a value of 0.6 at the end of this
306 experiment.

307 The measured NO₃ concentrations along with the low concentrations of OH in the
308 perturbed chamber suggests that the reactions of VOCs with NO₃ radicals and potentially ozone
309 were the major source of SOA production.

310 **4.3 Factors affecting the SOA production**

311 The highest produced SOA was observed, as expected, in experiments that had high initial
312 OA and VOC levels and therefore took place during polluted conditions. Experiments 1, 4 and 6
313 had the highest measured initial VOC levels among the conducted experiments, close to $150 \mu\text{g m}^{-3}$
314 m^{-3} (Fig. S2). Although, only a fraction of the VOCs present in the atmosphere were measured by
315 the PTR-MS in this work, these measurements provide an indication of the SOA formation
316 potential of the corresponding air masses.

317 The absolute concentration of SOA formed was also affected by the levels of NO present.
318 Experiments with low initial NO, less than 5 ppb, (Experiments 2, 3, 5, 9 and 11) had the lowest
319 SOA production. The lowest NO_3 radical concentrations were also observed in those experiments.
320 Figure 8 shows the correlation between the concentration of NO_3 radicals and the produced organic
321 nitrate levels in the perturbed chamber. The good correlation ($R^2=0.79$) supports the strong link
322 between the NO_3 chemistry occurring in the perturbed chamber and the corresponding SOA
323 production. This suggests that the oxidants levels (mainly NO_3) produced after reactions of ozone
324 with the pre-existing NO_x are affecting significantly the levels of SOA formed under these
325 conditions.

326

327 **5 Conclusions**

328 In this work, we studied the nighttime aging of urban wintertime air, strongly influenced
329 by biomass burning emissions in Patras, Greece. Using a dual chamber system and ambient air as
330 a starting point, we injected additional ozone in only one chamber to accelerate nitrate radical
331 production via reactions with the pre-existing NO_x . The other chamber was used as a reference
332 mainly as a safeguard against potential experimental artifacts.

333 After the addition of ozone, rapid SOA formation was observed in the perturbed chamber
334 with the additional OA formed reaching up to $35 \mu\text{g m}^{-3}$. The SOA formed increased the pre-
335 existing OA by 20-70%. Most of the secondary nitrate formed was attributed to organics, in some
336 cases reaching up to 85% of the total aerosol nitrate. The organic aerosol formation was rapid,
337 with 75% of the produced OA formed in the first hour after the ozone injection. The organic aerosol
338 content in the control chamber remained within 10% of the initial injected levels, suggesting
339 limited chemical oxidation without the addition of ozone in these timescales.

340 The O:C of organic aerosol increased rapidly in the perturbed chamber following the ozone
341 injection. In 2-3 h of reactions a 40-50% increase of the O:C was observed while the OA O:C in
342 the control chamber remained within approximately 5% of the initial value. The produced OA
343 mass spectra showed similarities with the produced OA factor from a previous dark aging biomass
344 burning experiments under laboratory conditions. Furthermore, the produced SOA mass spectra
345 were quite similar to those of ambient oxygenated OA factors found in urban areas during winter
346 periods.

347 Nitrate radicals were observed only in the perturbed chamber and only after the ozone
348 injection. Their levels reached up to 25 ppt. Along with the low levels of hydroxyl radical in the
349 perturbed chamber, indicates that reaction with nitrate radicals and ozone were responsible for the
350 SOA formation and the change in the OA composition.

351

352 *Author Contribution:* S.D.J., K.F., C.K., J.K.K. and C.V. conducted the experiments, collected and
353 analyzed the data. S.N.P and A.N. conceived and directed the study. M.C., A.F. and B.P.-V.
354 provided the IBB-CEAS. S.D.J. and S.N.P. wrote the manuscript with inputs from all co-authors.

610 **Figure 4:** Mass concentration of the measured OA (black points), the initial OA (red points) and
611 the produced SOA (blue points) in the perturbed chamber in Exp. 1. All concentrations refer to the
612 suspended aerosol in the chamber and do not include the material deposited on the chamber walls.

613

614 **Figure 5:** Mass spectrum of the produced SOA in the perturbed chamber for Exp. 1 (blue bars)
615 and the average spectrum of the produced SOA in all experiments (black squares).
