Abstract. Ozone pollution and high temperatures have adverse health impacts that can be amplified by the combined effects of ozone and temperature. Moreover, changes in weather patterns are expected to alter ozone pollution episodes and temperature extremes. In particular, atmospheric blocking is a high-impact large-scale phenomenon at mid-high latitudes that has been associated with temperature extremes. This study examines the impact of atmospheric blocking on the ozone and temperature dependence among measurement stations over Europe during the period 1999-2015. We use a copula-based method to model the dependence between both variables under blocking and non blocking conditions. This approach allows to examine the impact of blocks on the joint probability distribution. Our results showed that blocks lead to an increasing strength in the upper tail dependence of ozone and temperature extremes (>95th) in north-west and central Europe (e.g the UK, Belgium, Netherlands, Luxembourg, north-west of France and Germany). The analysis of the probability hazard scenarios revealed that blocks generally enhance the probability of compound ozone and temperature events by 20% in a large number of stations over central Europe. The probability of ozone or temperature exceedances increases 30% (on average) under the presence of atmospheric blocking. Furthermore, we found that in a number of stations over north-western Europe atmospheric blocking increases the probability of ozone exceedances by 30% given high temperatures. Our results point out the strong influence of atmospheric blocking on the compounding effect of ozone and temperature events, suggesting that blocks might be considered as a relevant predicting factor when assessing the risks of ozone-heat related health effects.

1 Introduction

Air pollution and heat waves pose a serious risk to health globally (Analitis et al., 2014; WHO, 2015) and evidence suggests that when extreme weather and air pollution episodes occur in coincidence, their health effects are nonlinearly amplified beyond the sum of their individual effects (Willers et al., 2016). Climate change is expected to increase the probability of heat extremes (Seneviratne et al., 2014) and alter air quality (Doherty et al., 2018). Tropospheric ozone is recognised as a harmful pollutant with negative impacts not only to human health, but also to ecosystems (EEA, 2019). Tropospheric ozone is a secondary pollutant formed from complex photochemical reactions of nitrogen oxides (NO_x), carbon monoxide (CO) and volatile organic compounds (VOCs) (Seinfeld and Pandis, 2006). The combination of emissions of ozone precursors and specific weather conditions, such as high temperatures, low wind and persistent slow-moving high-pressure systems, favour

25 high ozone pollution episodes (Jacob et al., 1993). Temperature has been identified as one of the main meteorological drivers of high ozone episodes in polluted regions over the US (Porter et al., 2015) and most of central Europe (Otero et al., 2016).

Several studies examined the relationship between ozone and temperature extremes and their joint occurrences over the US (Shen et al., 2016; Phalitinonkiat et al., 2018). Phalitinonkiat et al. (2018) measured the joint extremal dependence of ozone and temperature using the spectral dependence of their extremes. They found that temperature and ozone were overall well
30 correlated across many areas over the US, but they noted a reduced correlation when examining the tail of the distribution. Schnell and Prather (2017) examined the co-occurrence of extreme temperatures and air pollution (ozone and fine particulate matter) and they found temperature extremes to be consistently associated in space and time with high levels of ozone over the contiguous US. Sun et al. (2017) estimated a 50% of conditional probability of high ozone levels given high temperatures in the northeastern US, while less than 20% was found in the western US. Zhang et al. (2017) compared ozone levels during extreme
35 weather events and non-extreme events and they reported higher ozone levels during extreme weather events, including heat waves, atmospheric stagnation and their compound extremes over the US. Specifically, they pointed out an enhancement of ozone concentrations when heat waves and atmospheric stagnation events occur simultaneously. Recently, Hertig et al. (2020) analysed combined episodes of heat and ozone pollution waves in two European regions (Germany and Portugal) and their association with mortality rates. This study confirmed the strong impact of compounded heat-ozone waves on excess mortality
40 rates in those regions.

The co-occurrence of extremes are known as a combination of extreme events, which can potentially have a greater impact than the independent hazard event (Zscheischler and Seneviratne, 2017). The compounding effects from high temperature and ozone pollution levels greatly increase the risk to human health (Hertig et al., 2020). Furthermore, the extremes of temperature and high ozone episodes might be exacerbated by underlying climatological drivers (Schnell and Prather, 2017). Large-scale
45 atmospheric circulation is a key driver factor of the variability of surface meteorological variables, including air temperature and extreme temperature events (Pfahl., 2014) and plays an important role in air quality (Russo et al., 2014; Hertig et al., 2020). Extreme weather events are closely linked to anomalies of the atmospheric circulation that can be categorized by “weather regimes” such as cyclones, and atmospheric blocking (Pfahl., 2014). For instance, the extreme temperatures and the lack of precipitation during the summer of 2003 in Europe have been related to the persistent anticyclonic conditions over central
50 Europe (Fink et al., 2004; Solberg et al., 2008). This particular episode led to exceptionally long-lasting and spatially extensive periods of high levels of ozone pollution over Europe (Fiala et al., 2003). Dole et al. (2011) suggested that the persistent blocking of westerly flow was essential during the 2010 heatwave in Russia that killed tens of thousands of people.

Atmospheric blocking is a large-scale phenomenon defined by persistent anticyclones that interrupt the westerly flow in mid-latitudes (Barriopedro et al., 2006), and it has been associated with temperature extreme events (Sillmann et al., 2011; Brunner
55 et al., 2017). Pfahl and Wernli. (2012) showed that warm temperature extremes often co-occur with atmospheric blocking at the same location and recently, Röthlisberger and Martius (2019) found that atmospheric blocking also increases the persistence of periods with hot and dry weather conditions that occur concomitantly during summer. A few number of studies have examined the impact of blocks on air pollution. Ordóñez et al. (2017) focused on the regional responses of maximum daily average of 8h ozone (MDA8O₃) to the persistence of blocks and ridges over Europe. They showed that blocks within the European

60 sector (defined as $0-30^{\circ}$ E) led to positive anomalies of MDA8O_3 over central Europe in spring and summer and found that a
considerable proportion of the variability of MDA8O_3 exceedances could be explained by blocking patterns. Cai et al. (2020)
analysed the influence of persistent blocking conditions on several high pollution episodes of fine particulate matter over
northern China. They showed that blocking structures lead to 62.5% of persistent air pollution events during winter in northern
China and pointed out that blocks might be used as an indicative of persistent heavy air pollution in northern China during
65 winter.

The significant linkage between warm extremes and blocking and the strong temperature dependence of ozone motivates the
present work that aims to assess the impact of persistent blocks on the compounding effect of ozone and temperature. While
previous studies have examined the relationship between extremes of surface ozone and temperature (Schnell and Prather,
2017) and have provided a comprehensive analysis of seasonal impacts of blocks on European surface ozone pollution, (e.g.
70 Ordóñez et al. (2017)) we present for the first time (to the authors knowledge) a quantification of the effect of blocks on the
co-occurrence of temperature and ozone exceedances over Europe. To do that, we measure the dependence structure between
ozone and temperature, examining the impact of blocks on the joint distribution. In the context of multivariate processes that
may lead to compound events, the application of copula-based probability has been widely used in the recent years (see Hao
et al. (2018) and references therein). Copula methods have been extensively applied in hydrological extremes (Salvadori and
75 Michelle, 2010; Hao et al., 2018) and provide a flexible way of construction for a joint distribution with arbitrary marginal
distributions (AghaKouchak et al., 2014). Copulas describe the dependence between random variables (Nelsen, 2006) and
besides characterizing the overall dependence structure, copulas allow to measure the tail dependence, which is particularly
important to assess extreme events (Zscheischler and Seneviratne, 2017; Serinaldi, 2016). In this study, we adopt a copula-
based approach to model the joint distribution of temperature and ozone concentrations over Europe during the ozone season
80 (April-September) and quantify the impact of blocks on the joint probability of exceedances.

2 Data and methods

Daily maxima of 8h average (MDA8O_3) of ozone concentrations were extracted from the European Environment Agency's
air quality database (AirBase) (<https://www.eea.europa.eu/data-and-maps/data/>) during the period 1999-2015 focusing on the
ozone season that spans from April to September. A total of 300 background monitoring stations, including rural, urban and
85 suburban, with altitude < 1000 m and with at least 75% of valid data available for each ozone season were used. The number
of stations for which measurements are available vary greatly in space, with the major density of stations over central Europe.
However, a representative number of stations over northern and southern Europe are also included (Fig. S1).

Daily maximum temperature was derived from the 6-hourly of the 2 m-temperature values extracted from the ERA-Interim
(Dee et al., 2011) reanalysis of the European Center for Medium-range Weather Forecasts (ECMWF) for the same period 1999-
90 2015. The temperature dataset was available at $1^{\circ} \times 1^{\circ}$ regular (latitude/longitude) resolution. Daily 500 hPa geopotential height
(Z500) field was obtained from the ERA-Interim reanalysis at a coarser horizontal resolution $2.5^{\circ} \times 2.5^{\circ}$ (latitude/longitude),
which is appropriate to characterise large-scale atmospheric circulation.

2.1 Blocking detection

A 2-dimensional blocking index (BI) derived from daily Z500 was used to identify instantaneously blocked grid points. This
95 blocking index is calculated according to the one-dimensional index proposed by Tibaldi and Molteni (1990) but expanded to
every latitude and longitude (Scherrer et al., 2006). Similarly as in Barnes et al. (2014), we apply a spatio-temporal filter that
allows to exclude small-scale and short-term blocking situations accounting for large-scale and persistent systems between 35°
and 80°N. Thus, we select contiguously blocked regions with a minimum zonal and meridional extension of 15° and an area of
at least $1.5 \times 10^6 \text{ km}^2$. A persistent blocking event is considered if the duration of the blocking system lasts a minimum of
100 4 days. In addition, the tracking algorithm includes possible merging and splittings of the blocking event in time by adopting
a blocking overlap area criterion of $7.5 \times 10^6 \text{ km}^2$ between two consecutive days and a maximum distance between blocking
centers of 1000 km (Schuster et al., 2019).

The BI was computed through the Free Evaluation System Framework (see Richling et al. (2015) for more details), specifically
with the single plug-in corresponding to the blocking-2d (Freva, 2017).

105 2.2 Joint distribution analysis

Recently, copula-based approaches have become very popular to assess interrelations between several random variables (Ribeiro
et al., 2019; Salvadori et al., 2016; Hao et al., 2018). A copula is a joint distribution function in which the marginal distribu-
tions are independent from the dependence structure and can be modeled separately (Nelsen, 2006). For two ~~random variables~~
random variables X (temperature) and Y (MDA8O₃) with marginal distributions $F_X(x) = \Pr(X \leq x)$ and $F_Y(y) = \Pr(Y \leq y)$
110 respectively, a copula function allows to construct their joint cumulative distribution as follows:

$$F_{XY}(x, y) = C(F_X(x), F_Y(y)) \quad (1)$$

where C is the copula of the transformed random variables $U = F_X(X)$ and $V = F_Y(Y)$, with the marginals U and V being
uniformly distributed on the interval $[0,1]$. According to the Sklar's theorem, if the marginal distributions are continuous, then
the copula function C is unique (Sklar, 1996). The main advantage of using copula functions is the flexibility to model the de-
115 pendence between multiple variables with different univariate marginal distributions. For each station we use bivariate copulas
to model the dependence between temperature and ozone and estimate their joint probability distribution under two different
synoptic situations: 1) when there is a co-located block in the same location of MDA8O₃ and temperature (i.g BI=1), 2) without
the presence of blocking (i.e. BI=0). We fit a total of four commonly used copulas: t-student (from the Archimedean family),
Clayton, Gumbel and Joe (from the elliptical family) (Table 1). The Archimedean copulas are able to describe asymmetric tail
120 behavior, while elliptical copulas capture symmetric dependence (Tilloy et al., 2019). Among the different copulas, we selected
the structures that are able to capture tail dependence: Gumbel and Joe model upper tail dependence, while Clayton can cap-
ture lower tail dependence. (Salvadori and Michelle, 2010). The t-student copula allows dependence in both upper and lower
tails. Before modelling the joint probability distribution we fit the most appropriate marginal distribution for both temperature

and MDA8O₃, including Gaussian, gamma, Weibull and lognormal distributions. The parameters for the marginal distribution were obtained by the maximum likelihood method separately for each site. The marginal distributions were selected using the Kolmogorov–Smirnov goodness-of-fit test. Then, for each station and synoptic case (BI=1 and BI=0) the bivariate copulas were selected based on the Akaike’s Information Criteria (AIC) (Akaike, 1974) and the copula parameters were estimated via maximum likelihood estimation (MLE). The copula analyses were carried out with the VineCopula and the copula R packages (Schepsmeier et al., 2016; Hofert et al., 2020).

Table 1. Equations of the copula functions, where u and v are univariate variables (uniform distributed), θ and ρ are the dependence parameters and df is the degree of freedom.

Copula Family	Function	Parameter range	Upper tail	Lower tail
Gumbel	$C(u, v) = \exp(-[(-\ln u)^\theta + (-\ln v)^\theta])^\theta$	$[1, \infty)$	Yes	No
Clayton	$C(u, v) = [\max(u)^\theta - \theta + v)^\theta - \theta; 0]^\theta / \theta$	$[-1, \infty)$ and $(0, 1]$	No	Yes
Joe	$C(u, v) = 1 - ((1-u)^\theta + (1-v)^\theta - (1-u)^\theta(1-v)^\theta)^{1/\theta}$	$[1, \infty)$	Yes	No
t-student	$C(u, v) = \int_{-\infty}^{t_{df}^{-1}(u)} \int_{-\infty}^{t_{df}^{-1}(v)} \frac{1}{2\pi\sqrt{1-\rho^2}} \exp\left(1 + \frac{u^2+v^2-2\rho uv}{df(1+\rho^2)}\right) - \frac{df+2}{2} dudv$	$-1 \leq \rho \leq 1; 1 \leq df$	Yes	Yes

The copula models were used to assess the relationship between temperature and ozone exceedances under blocking (BI=1) and non blocking (BI=0) conditions by constructing the corresponding joint probability distribution ($P(X \leq x, Y \leq y)$). Apart from the general dependence structure, some copulas can measure the dependence of the extremes through the tail dependence parameter (λ_u) (Nelsen, 2006). As linear or rank dependence measures might not be accurate when focusing on extremes (Hao and Singh, 2016), we have further assessed the upper tail dependence of ozone and temperature extremes derived from the copulas under blocking (BI=1) and non blocking (BI=0). We estimate the probability of a compound event at each station, in which Tmax and MDA8O₃ exceed the 95th percentile of their respective distribution. Note that we define compound extremes at each station considering the thresholds over the whole distribution (e.g. including non blocked and blocked days) of ozone and temperature. The use of absolute thresholds allows us to quantify the impact of blocks on the probability of exceedances. The probability of exceedances over a certain multivariate threshold was examined based on three different hazard scenarios described by the following joint and conditional joint probabilities, which can be expressed using copula notation (see further details in Serinaldi (2015)):

$$P_{AND} = P(U > u \cap V > v) = 1 - u - v + C(u, v) \quad (2)$$

$$P_{OR} = P(U > u \cup V > v) = 1 - C(u, v) \quad (3)$$

$$P_{COND} = P(U > u | V > v) = (1 - u - v + C(u, v)) / (1 - v) \quad (4)$$

145 The probabilities in equations 2 and 3 have been widely applied in the literature to assess compound extremes (Zscheischler and Seneviratne, 2017; Hao et al., 2018). Equation 2 represents the scenario in which both variables temperature (Tmax) and ozone (MDA8O₃) exceed the 95th percentile, while equation 3 considers the events occurred when either temperature or ozone or both exceed their respective threshold (95th). As blocks normally lead to persistent positive surface temperature anomalies during summer over Europe (Pfahl and Wernli., 2012), it is of interest to evaluate the influence of blocking on the probability
150 of ozone exceedances given high temperatures, which is assessed in the *COND* scenario.

To quantify the significant impact of blocks on the compound ozone and temperature events, we estimated the differences between the probabilities derived from the copulas (i.e. $\Delta P = P_1 - P_0$). Then, we assess whether the difference between the probabilities when BI=1 and BI=0 are significantly different from zero. To do so, we apply a bootstrap procedure for each probability scenario (i.e. *AND*, *OR*, *COND*) in which we drew 100 bootstrapped samples and derived the respective probabilities P_1 and
155 P_0 when BI=1 and BI=0, respectively. For the null hypothesis (H_0) there is no difference between the probabilities obtained from the cases BI=1 and BI=0, while the alternative hypothesis indicates that the probability of an extreme event conditioned to a blocking situation is significantly different from the probability under non blocking conditions.

3 Results

3.1 Impact of atmospheric blocking on ozone and temperature

160 For the period of study (1999-2015) a total of 3111 days were analysed during the ozone season (April-September). The blocking frequency (% of days) ranges between 5% in the southern latitudes (30-45° N) and 14% in the northern latitudes (60-70° N) (Fig. S1). In central Europe, where the density of stations is higher, the frequency of blocked days is ~ 8%. Typically, blocking presents a well established climatology in terms of frequency in the North Hemisphere, being more frequent in winter and spring, and less frequent in autumn (Barnes et al., 2014; Wollings et al., 2018). During summer, blocking events have
165 shown a tendency to occur at high latitudes over continental areas (Barriopedro et al., 2010). In contrast with previous related studies analysing the seasonal responses of air pollution to blocks (Ordóñez et al., 2017; Garrido-Perez et al., 2017), our study focuses on the whole ozone season during which the compounding effect ozone and temperature is particularly relevant for human health (Hertig et al., 2020). Moreover, atmospheric blocking events are likely to have a major impact due to their connection with heatwaves in spring and summer (Brunner et al., 2017). Before presenting the copula modeling results, we
170 begin by examining the individual effect of atmospheric blocking on both variables, MDA8O₃ and Tmax and their relationship under the influence of blocking. We focus first on the impact of blocks on ozone pollution and examine the anomalies of MDA8O₃ under blocking conditions. For both variables, we have calculated the anomalies with respect their corresponding climatology during the ozone season (i.e. April-September) for the whole period of study 1999-2015. Figure 1 illustrates the anomalies of both MDA8O₃ and Tmax during blocking days. Please note that the number of blocking days might differ across
175 the different stations. In general, most of the stations show positive anomalies of MDA8O₃ under blocking days, (Fig.1, left). The strongest positive anomalies > 30 µgm⁻³ are observed over the south of Germany, north-east of France and north-west of Italy, while weaker anomalies are found over Scandinavia, west of the UK and north of Spain. Similarly, Ordóñez et al. (2017)

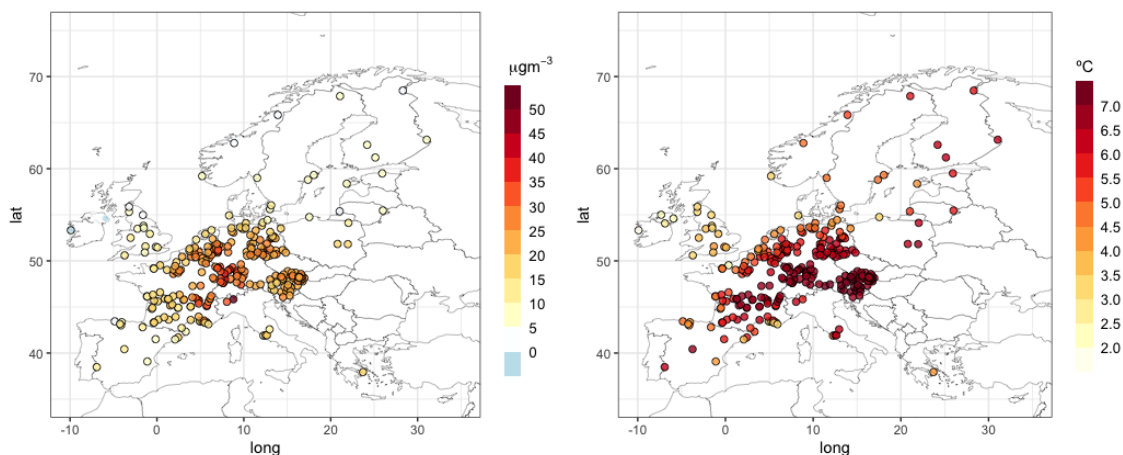

Figure 1. Anomalies of MDAO3 (left) and Tmax (right) for blocking days (i.e. BI=1). Anomalies of MDAO3 were calculated with respect to the MDAO3 concentrations over the whole period 1999-2015 during the ozone season, April-September. Similarly, anomalies of temperature were obtained with respect to the temperature over the whole period of study (as for MDAO3). Black contour indicates statistically significant anomalies at the 95% confidence level of a two-sided t test.

reported strong positive anomalies over large areas of central and northern Europe in spring and summer respectively. In the case of temperature anomalies, blocks led to positive anomalies of Tmax over all of the stations included in this study (Fig. 1
 180 right). The largest values of temperature anomalies ($>7^{\circ}\text{C}$) are observed over the central and western stations (north-east of France, south of Germany and Austria). This is consistent with the radiative heating due to enhanced clear sky conditions over continental areas under atmospheric blocking conditions, especially in summertime (Brunner et al., 2017).

We further examined the impact of blocking on individual extremes of ozone and temperature defined as the exceedances of the 95th percentile of MDA8O₃ and Tmax, respectively. It must be noticed that the spatial variability of high levels of ozone is
 185 very heterogeneous (Fig. S2). The 95th percentile of MDA8O₃ exceeds the European target value of MDA8O₃ ($120\ \mu\text{gm}^{-3}$, EEA (2019)) in a large number of stations in central and south Europe. Only in the case of northern stations (UK, Scandinavia) MDA8O₃ would not often exceed the mentioned target value (Fig. S2).

Figure 2 illustrates the frequency of blocked single extremes of ozone and temperature (i.e. the percentage of exceedances of MDA8O₃ and Tmax with respect the total number of blocked days). More than 40% of MDA8O₃ extremes coincide with
 190 blocked days over most of the central stations. The frequency of blocked days of MDA8O₃ extremes is generally lower in the southern stations. The percentage of Tmax extremes coincident with blocks increases northwards and eastwards, which is consistent with subsidence processes and clear-sky radiative forcing associated with summer blocking events (Pfahl and Wernli., 2012; Sousa et al., 2018). Moreover, as stated above the strong seasonal variability of the blocking activity in the Northern Hemisphere must be noted, with a reduced number of occurrences late in summer and autumn, but being considerable
 195 more frequent in eastern Europe than in the Euro-Atlantic region (Barriopedro et al., 2006). This pattern is also reflected in our results that show the largest number of blocked temperature extremes north and easterward.

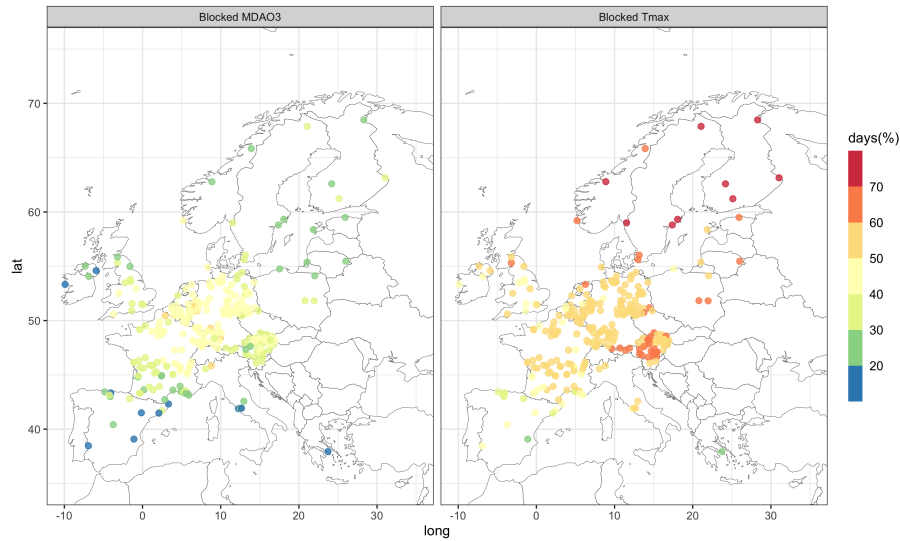

Figure 2. Percentage of days with MDA8O₃ (left) and Tmax (right) exceedances (>95th) that are blocked days.

To investigate the impact of blocks on the relationship between MDA8O₃ and Tmax, the Kendall's tau coefficient (τ) was calculated during blocking and non blocking days as well as the difference between the correlations obtained when BI=1 and BI=0 (Fig.3 a and b). The correlations are weaker under non-blocking days (BI=0) and a few number of northern stations show negative values (Fig. 3 a). In general, the dependence between MDA8O₃ and Tmax is higher under the influence of blocks. The positive differences between the correlation values (Fig.3 b) clearly reflect the strong impact of blocks at most of the stations. The largest differences are found over the north-west of Europe. Consistent with previous work, the central stations show the strongest relationship between ozone and temperature (Otero et al., 2016), which significantly increases when BI=1 with the largest correlation values (>0.6). Blocks seem to have a great influence over the north-west of Europe, in particular, the UK, north of France and Benelux (i.e. Belgium, Netherlands and Luxembourg), where the correlations are higher and mostly positive under blocking conditions, while negative correlations are found under non blocking. A similar pattern was found when calculating the correlations for the respective extremes based on the 95th percentile that showed the strongest relationship under the influence of blocks over a large number of stations of France, Germany and the UK (Fig. S3). The impact of blocks in the relationship between MDA8O₃ and Tmax is smaller in the south and north-east, which is reflected by not significant and weaker correlations that show similar magnitude values when BI=1 and BI=0. Ordóñez et al. (2017) analysed the impact of subtropical ridges on ozone, and they found a major impact of subtropical ridges in the central-south European sectors. Nevertheless, they pointed out that influence of ridges for the build-up of ozone pollution is not as clear as in the case of blocks and its impact is more sensitive to the location. Blocks play an important role in warm temperature anomalies in spring and summer over central Europe, while the impact is generally lower over south, mostly due to the position of the block (Sousa et al., 2018). Consistent with our results that show a weaker relationship between MDA8O₃ and Tmax, we

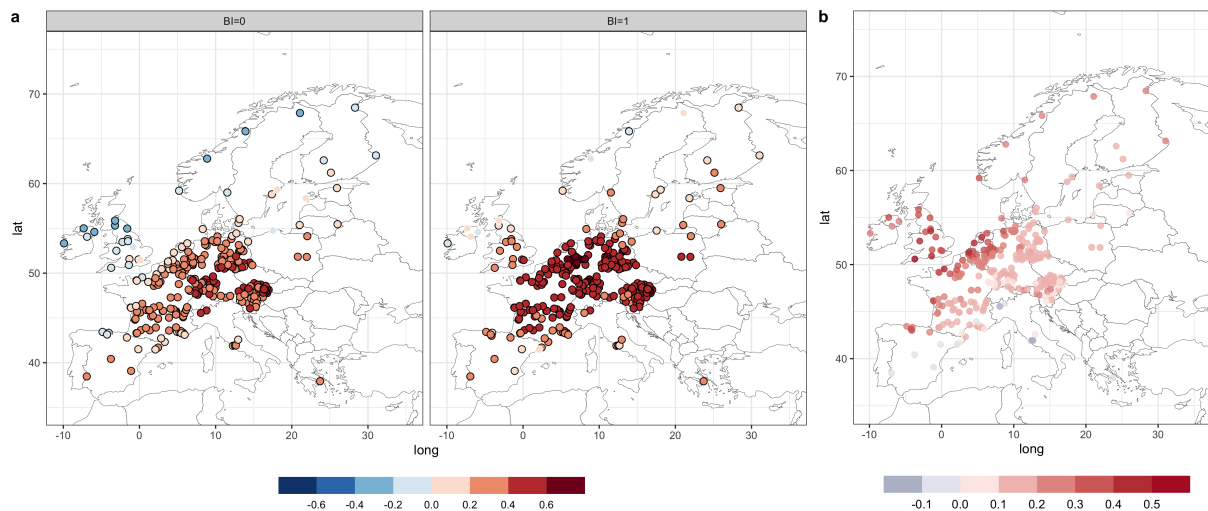

Figure 3. a): Spatial distribution of the Kendall's correlation coefficient between MDA8O₃ and Tmax under non blocking conditions (i.e. BI=0) and blocking conditions (i.e BI=1). Black contour indicates statistically significant anomalies at the 95% confidence level of a two-sided t test. b): Differences between the correlation values obtained when BI=1 minus the correlations when BI=0.

can anticipate significant spatial differences in the impact of blocks on the compound extremes of ozone and temperature and their joint distribution.

3.2 Copula results

Among the different types of copulas presented in the literature, a total of four copulas (table 1) were tested to find the most appropriate fit that characterises the relationship between MDA8O₃ and Tmax at each station. Our copula choice was mainly motivated by their ability to represent joint tail dependence (upper and/or lower). After modelling the dependence between both variables when BI=1 and BI=0 separately, we quantify the effect of atmospheric blocking on compound extremes of ozone and temperature through the differences between probabilities derived from the cases mentioned above (BI=1 and BI=0) for each probability scenario. The impact of blocks on the joint behaviour between MDA8O₃ and Tmax is reflected in the selected copula (Fig S4). When BI=0 a large number of stations are characterized by an asymmetric dependence structure as it is the case of Joe and Gumbel copulas. The Gumbel copula is also selected in a number of stations when BI=1, but in this case the t copula is representative for a major number of stations. On the contrary than the Gumbel and Joe copulas, the t copula belongs to the Elliptical and radially symmetric copulas, but capturing dependence in the extremes in both lower and upper tail (Nelsen, 2006). We further investigated the influence of blocks on the upper tail dependence parameter, λ_u , obtained from the chosen copulas. The λ_u measures the tendency of concurrent extremes of MDA8O₃ and Tmax exceeding the 95th percentile. According to Fig. 4, the strongest upper tail dependence occurs under the influence of blocks over north-west and central Europe (e.g. the UK, France, Benelux and north of Germany). The impact of blocks is particularly noticeable over the UK

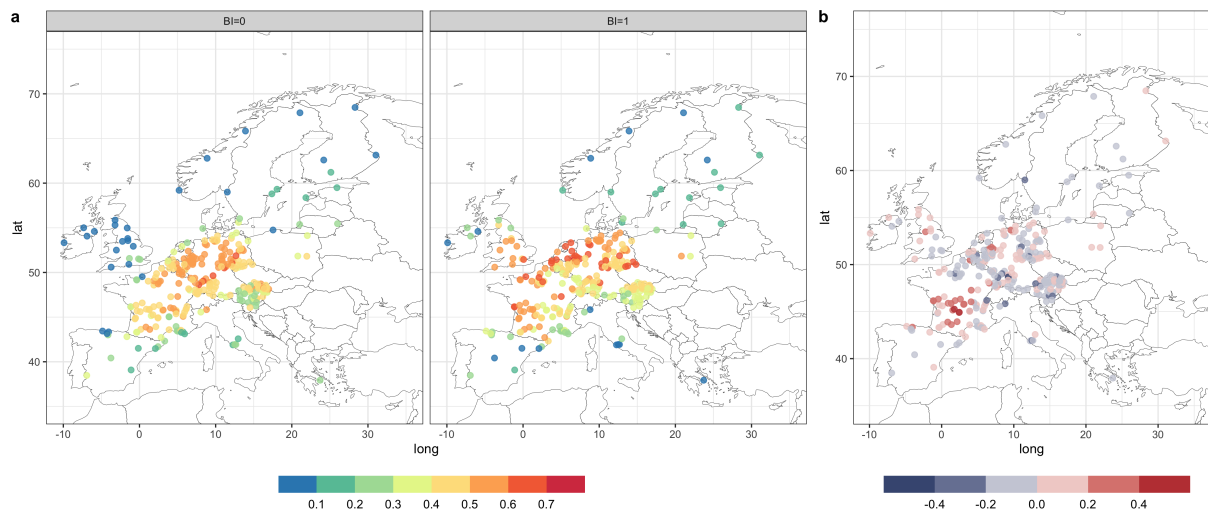

Figure 4. a) Spatial distribution of the upper tail dependence parameter derived from the copulas when BI=0 and BI=1. b) Differences between the values of the upper tail dependence parameter when BI=1 minus the values when BI=0.

and Benelux with an increase in the dependence of extremes when BI=1, which is well observed when plotting the differences between the values of λ_u obtained for both cases (Fig.4 b). This pattern is in agreement with the relationship obtained by Kendall's τ (Fig.S3) that shows a stronger relationship of extremes under the influence of blocking conditions.

We use three hazard scenarios (*AND*, *OR*, *COND*) to quantify the impacts of blocks on compound extremes of MDA8O₃ and Tmax. The probabilities associated to each type of hazard scenario are defined based on the domain where they are estimated and the critical region related to the probability type (see Fig. S5 for an illustrative example as shown in Serinaldi (2016)). We start analysing the impacts of blocks in the probability of concurrent events of high ozone pollution and hot days using the scenario *AND* (Fig. 5, a and b). While there is a very low probability in the co-occurrence of extremes when BI=0 (< 2.5%), the presence of blocking generally increases the probability of compound events of MDA8O₃ and Tmax (Fig. 5 a). Under blocking conditions (BI=1), the probability of co-occurrent extremes is ~ 20% in most of the stations over central Europe, and ~ 10% over the UK (Fig.5 a). The probability of occurrence of compound events of MDA8O₃ and Tmax significantly increases by more than 18% in a large number of stations over Europe, as shown by the ΔP (Fig. 5 b). Despite ozone concentrations being generally lower over the UK (Fig.S1) compared to other regions, it is interesting to note that blocks seem to play a significant role in the compounding effect ozone and temperature over the UK. Kalisa et al. (2018) analysed the influence of heatwaves on air pollution in the UK, specifically Birmingham and they found that ozone levels increased by more than 50% with high temperature. Here, we consistently show the combined effect ozone and temperature, and our results also indicate that such combination mainly occurs under blocks likely due to the clear-sky radiative forcing as pointed out by earlier work (Brunner et al., 2017) and subsidence processes associated with the anticyclonic circulation (Pfahl., 2014). The stations over the north-eastern and south-western stations (i.e. Scandinavia and Spain, respectively) exhibit the lowest

probability of compound of extremes of MDA8O_3 and T_{max} . As shown in Fig. 4 those stations are characterised by low or null upper tail dependence, which already indicates a weak relationship between the extremes. In addition, the distinct response of heatwaves to blocking found in northern and southern Europe is noteworthy, especially in summer (Brunner et al., 2017; 255 Sousa et al., 2018). An increasing frequency of heatwaves linked to blocks has been observed over northern Europe in summer, while an opposite response has been shown in southern Europe (Sousa et al., 2018). Therefore, one could expect a smaller impact of blocks on the compounding effect of ozone pollution and high temperatures in the case of the southern regions. Our results are in agreement with the study carried out by Hertig et al. (2020) that found a lower number of compound ozone-heat wave events in Portugal compared to the compound identified in Germany (Bavaria).

260 We examine the *OR* scenario under the assumption that blocks might enhance the probability of either high ozone pollution levels or hot temperatures, being both relevant for health impacts (Analitis et al., 2014; Bell et al., 2004). As shown in Fig. 5 (c), the probability obtained for the *OR* scenario is considerably higher when $\text{BI}=1$, reflecting the strong impact of blocks on single extremes events. Atmospheric blocking conditions enhance the probability that either MDA8O_3 or T_{max} exceeded the 95th percentile more than 40% in a large number of stations mostly concentrated in Germany, Austria and the east of France. 265 For the rest of the stations, the probability of extremes in the *OR* scenario increases by 20-30% under blocking conditions (Fig.5, d). Consistently with previous works that showed the strong association of warm temperature extremes and blocking (Pfahl and Wernli., 2012; Brunner et al., 2017), as well as the impact of blocks on ozone pollution over some European sectors (Ordóñez et al., 2017), our results show the increasing probability of temperature *OR* ozone pollution extremes under atmospheric blocking.

270 From a risk assessment perspective, the scenario *COND* is also of interest, as it quantifies the impacts of blocks of ozone pollution extremes events conditioned on high temperature. For the *COND* probability, both the computation domain and the critical region evolve when moving along higher temperatures and then, the probability is computed over a reduced subset (e.g. conditioned on temperature extremes) (see Serinaldi (2016) for further details and Fig. S5). As illustrated in Fig. 5 (e and f), blocks generally enhance the probability of extremes of ozone pollution conditioned on temperature exceedances. Blocks 275 significantly influence the compound events in the stations over north-west and central-east of Europe that show positive and large values of ΔP (Fig. 5, f), suggesting a higher probability of ozone pollution extremes when temperature exceeds the 95th. In particular, blocks lead to an increasing probability of ozone extremes given high temperatures in the UK (>40%). In a few number of stations over south and north-eastern of Europe, blocks did not show a significant influence in the conditional probability of extremes, with low and non significant values of ΔP . For some of these stations the copula selected when $\text{BI}=1$ 280 is the Clayton copula (Fig. S1), which indicates greater probability of joint extreme low values (lower tail dependence), but not in the upper tail as shown in Fig. 5 (e and f). In such cases, the presence of blocks is not relevant for ozone pollution exceedances that seem to occur independently of temperature extremes.

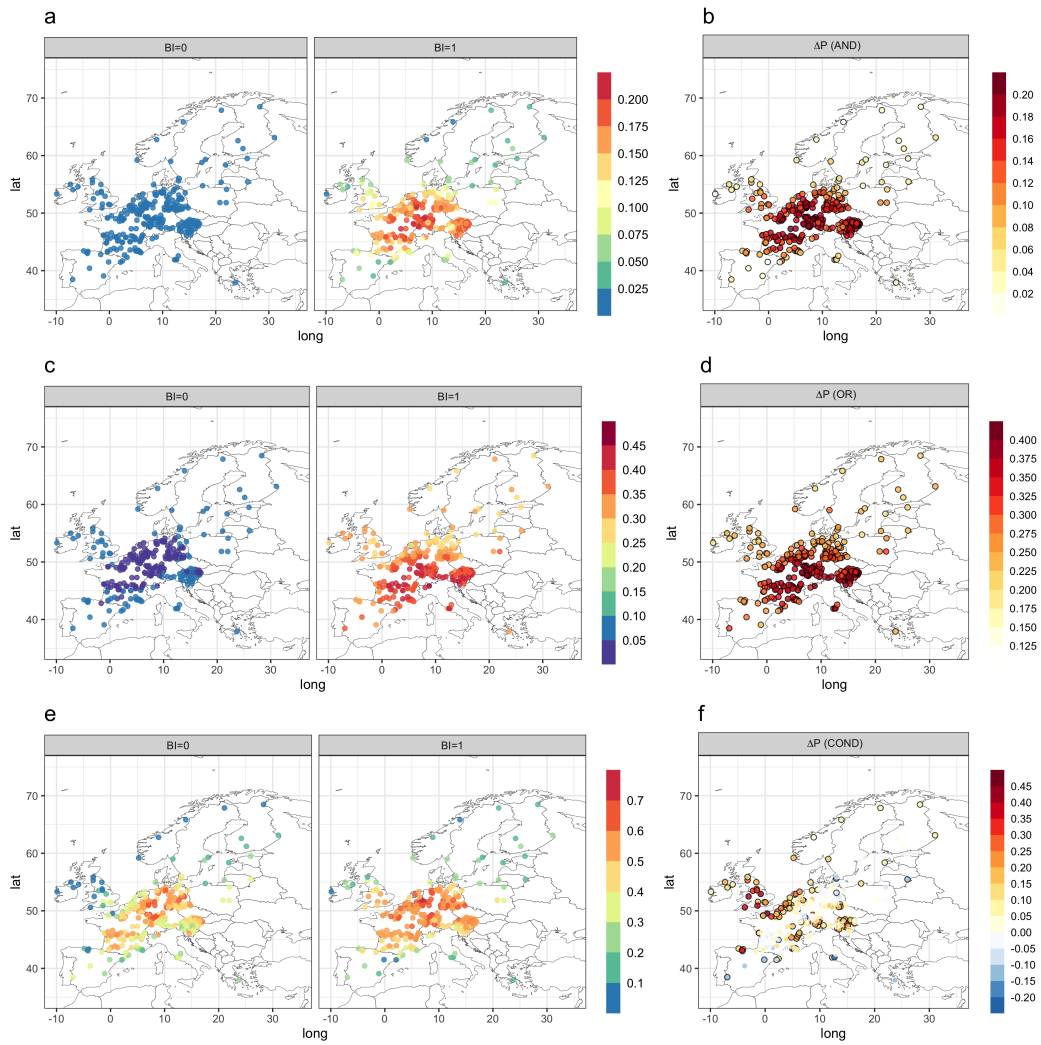

Figure 5. Probability scenarios AND (a and b), OR (c and d) and COND (e and f) derived from the copula analysis when BI=1 and BI=0 (a, c and e). ΔP (b, d and f) shows the difference between the probabilities when BI=1 and BI=0. Black contours in b), d) and f) represent locations with statistically significant differences at the confidence level of 95%.

4 Discussion and conclusions

The present study has assessed the influence of atmospheric blocking on the dependence between daily maximum of 8h average ozone ($MDA8O_3$) and daily maximum temperature (T_{max}) for the period 1999-2015 during the ozone season (April-September). A total of 300 monitoring stations distributed over Europe were included. First, we examined the blocking influence on single extreme events of ozone pollution and temperature, defined on the basis of the 95th percentile of their distribution. Using a copula-based approach, we evaluated the impacts of blocks on compound ozone pollution and temperature events taking into account their dependence. For each station, the dependence between ozone and temperature was modelled independently under blocking ($BI=1$) and non blocking ($BI=0$) conditions. The selected copulas described the dependence structure and the joint behaviour of ozone and temperature. We investigated the impacts of blocks on the risks of compound ozone and temperature events under three different hazard scenarios of probability: *AND*, *OR* and *COND*, which are commonly used to study multivariate events.

In agreement with previous studies, our results showed that during the ozone season more than 40% of ozone exceedances (>95th) are coincident with blocked days over the central stations (including Germany, east of France and Benelux). The rest of the stations showed a lower frequency ($\sim 25\%$) of ozone exceedances during blocking conditions. The frequency of temperature extremes is larger than ozone extremes under blocking conditions and on average 55% of hot days occur under blocking conditions. The highest frequency is observed in the northern Europe (Scandinavia) with more than the 70% of temperature-blocked extremes, while the lowest frequency is observed in the southern Europe. This is consistent with the literature that showed similar patterns of temperature-blocked exceedances (e.g. Brunner et al. (2018); Sousa et al. (2018)). The analysis of the dependence between ozone and temperature revealed that atmospheric blocking is of key importance in some regions that showed a strong relationship between ozone and temperature under blocking conditions (e.g. central and eastern Europe). In particular, we found a great impact over the stations in the UK and Benelux where the blocks lead to positive and higher correlation values, while a weaker relationship is observed under non blocking conditions. The copula-based approach confirms the dependence between ozone and temperature under the influence of atmospheric blocking. Moreover, the copulas showed that blocks have a major effect on the upper tail dependence in some stations over the UK, north-west and west of France, Benelux and north of Germany, which suggests that compound ozone and temperature extremes are highly associated and influenced by atmospheric blocking.

Overall, we found that blocks enhanced the probability of occurrence of compound ozone and temperature extremes in a large number of stations included in this study. Our results showed that blocking significantly increased by $\sim 15\%-20\%$ (i.e. $\Delta P > 0.15$) the probability of co-occurrent ozone and temperature exceedances at the stations over central, north-west and east of Europe. In fact, the probability of combined ozone and temperature extremes under non blocking conditions is rather small everywhere ($P_0 < 0.025$). Blocks significantly increase the probability that either ozone or temperature (or both) exceed the 95th percentile. The highest probability values are observed over central and eastern stations in which blocking increases the probability of extreme events in ozone or temperature by more than 35%. The analysis of the joint distribution considering the conditional hazard scenario (*COND*) showed a smaller impact of blocks in some stations where the probability of ozone

pollution extremes conditioned on high temperature did not show significant differences in terms of magnitude under non blocking conditions. However, we found a significant increase in the conditional probability over the north-west stations and a slight increase over the central-east stations. This suggests that over such regions ozone extremes tend to occur given high
320 temperatures which are strongly connected with atmospheric blocking. This is likely due to the position of the block during the ozone season covering spring and summertime when the increased solar radiation lead to warm temperature in the blocked regions (Brunner et al., 2017; Sousa et al., 2018), which can also explain the high levels of ozone pollution in the blocked regions.

Our study showed a clear influence of blocks in local compound ozone and temperature extremes over a large number of
325 stations. Blocks have a significant impact over the central regions, where peaks of ozone pollution usually exceed the European target value of $120 \mu\text{gm}^{-3}$ (set for the protection of human health, EEA (2019)) and warm temperature extremes are strongly connected with atmospheric blocking (Brunner et al., 2017). Ozone levels are normally lower over northwestern Europe (e.g. the UK) as well as temperature compared to the rest of the stations (Fig. 2), however our findings showed that blocking leads to an increased strength of the general dependence between ozone and temperature, and particularly in the tail dependence
330 of extremes. This points out that blocks have a significant impact in the compounding effect of ozone and temperature over northwestern Europe, leading to higher health risks.

As discussed in the introduction, atmospheric blocking can lead to extreme weather conditions (Sillmann et al., 2011; Barnes et al., 2014), which would affect air quality. In addition, early studies have associated the Arctic sea ice loss with an increasing frequency of atmospheric blocking due to a slow-down flow (Liu et al., 2012). However, the link between the Arctic
335 amplification and weather extremes is complex and no significant trends have been reported (Wollings et al., 2018; Barnes et al., 2012). Despite such uncertainties related to the trends of atmospheric blocking frequency, its changes have important impacts, not only in weather extremes conditions, but also in future air quality. Therefore, an important implication from our findings is the significant influence of atmospheric blocking in the co-occurrence of ozone and temperature extremes in certain European regions. Given the strong linkage between atmospheric blocking and the compounding effect of ozone and
340 temperature extremes, the frequency of blocking events might be used as a key predicting factor for assessing the health-related risks of the combined effects of ozone pollution and temperature extremes.

Code and data availability. Observational ozone data used in this study are available at the Airbase database of the European Environment Agency (EEA) data service: <https://www.eea.europa.eu/data-and-maps/data/aqereporting-8>.

The ERAInterim reanalysis products are available available on the Climate Data Store (CDS) cloud server: <https://cds.climate.copernicus.eu>.
