Abstract. The atmospheric multiphase reaction of dinitrogen pentoxide (N_2O_5) with chloride-containing
aerosol particles produces nitryl chloride (ClNO_2), which has been observed across the globe. The
photolysis of ClNO_2 produces chlorine radicals and nitrogen dioxide (NO_2), which alter pollutant fates
and air quality. However, the effects of local meteorology on near-surface ClNO_2 production are not yet
20 well understood, as most observational and modeling studies focus on periods of clear conditions. During
a field campaign in Kalamazoo, Michigan from January-February 2018, N_2O_5 and ClNO_2 were measured
using chemical ionization mass spectrometry, with simultaneous measurements of atmospheric
particulate matter and meteorological parameters. We examine the impacts of atmospheric turbulence,
precipitation (snow, rain) and fog, and ground cover (snow-covered and bare ground) on the abundances
25 of ClNO_2 and N_2O_5 . N_2O_5 mole ratios were lowest during periods of lower turbulence and were not

statistically significantly different between snow-covered and bare ground. In contrast, ClNO₂ mole ratios were highest, on average, over snow-covered ground, due to saline snowpack ClNO₂ production. Both N₂O₅ and ClNO₂ mole ratios were lowest, on average, during rainfall and fog because of scavenging, with N₂O₅ scavenging by fog droplets likely contributing to observed increased particulate nitrate concentrations. These observations, specifically those during active precipitation and with snow-covered ground, highlight important processes, including N₂O₅ and ClNO₂ wet scavenging, fog nitrate production, and snowpack ClNO₂ production, that govern the variability in observed atmospheric chlorine and nitrogen chemistry and are missed when considering only clear conditions.

1 Introduction

Atmospheric halogen radicals are highly oxidizing agents of tropospheric pollutants (Simpson et al., 2015). Following nighttime formation, the photolysis of nitryl chloride (ClNO₂) upon sunrise is a source of chlorine radicals (**R1**) at a time when other oxidants, including the hydroxyl radical (OH), are less abundant (Young et al., 2014), leading to enhanced oxidation of volatile organic compounds (Osthoff et al., 2008). ClNO₂ photolysis also releases NO₂ (**R1**), thus recycling nitrogen oxides (NO_x=NO+NO₂) that drive ozone formation (Crutzen, 1979).

R1

ClNO₂ is formed by the multiphase reaction of dinitrogen pentoxide (N₂O₅) on a chloride-containing surface (**R2**), particularly sea spray aerosol (Finlayson-Pitts and Pitts, 1989; Osthoff et al., 2008).

R2

In the Northern Hemisphere, surface-level ClNO₂ abundance is simulated to be highest during winter; this is thought to be due to greater N₂O₅ abundances, shallower mixed layer heights or even stable boundary layers, lower air temperatures, and higher ClNO₂ yields (Sarwar et al., 2014). ClNO₂ production has been previously studied in the laboratory following the reaction of N₂O₅ with aqueous aerosols (e.g.

Behnke et al., 1997; Bertram and Thornton, 2009; Roberts et al., 2009; Thornton and Abbatt, 2005) and frozen solutions (Lopez-Hilfiker et al., 2012). A recent modeling study suggests that ClNO₂ may be produced from heterogeneous reaction on the snowpack, in addition to aerosols (Wang et al., 2020). In addition to marine and coastal environments, ClNO₂ has been measured in inland environments, including Boulder, Colorado, USA (Riedel et al., 2013; Thornton et al., 2010), , Calgary, Alberta, Canada (Mielke et al., 2011), Frankfurt, Germany (Phillips et al., 2012), Ji'nan, Shandong, China (e.g. Wang et al., 2017), and southwest of Baoding, Hebei, China (e.g. Tham et al., 2018); in these inland environments, ClNO₂ abundance is typically hundreds of parts per trillion (ppt). Recently, a study in Ann Arbor, Michigan identified road salt aerosol as the dominant aerosol chloride source for ClNO₂ production during winter (McNamara et al., 2020). Measurements in Kalamazoo, Michigan also identified the road salt-contaminated snowpack as a ClNO₂ source (McNamara et al., 2021). A study in coastal British Columbia, Canada suggested scavenging of ClNO₂ by rain and/or fog droplets as a potential loss process (Osthoff et al., 2018). However, the authors pointed out that scavenging of the nitrate radical (NO₃), N₂O₅, and ClNO₂ have not been constrained by laboratory investigations (in contrast to other gases like sulfur dioxide (SO₂) and ammonia (NH₃)) and so periods of precipitation were excluded from subsequent calculations of N₂O₅ uptake and ClNO₂ yield (Osthoff et al., 2018).

N₂O₅, the precursor to ClNO₂, is formed from the reaction of NO₂ with NO₃ (**R3**), which is formed from the reaction of NO₂ with ozone (O₃, **R4**). The formation of N₂O₅ from NO₂ and NO₃ is a temperature-dependent equilibrium, with N₂O₅ production favored at lower temperatures (Asaf et al., 2010; Wagner et al., 2013). At a NO₂ background level of 1 parts per billion (ppb), the ratio of N₂O₅:NO₃ (**R3**) is ~1 at 295 K, but this N₂O₅:NO₃ ratio is ~10 at 278 K (Chang et al., 2011). Loss of N₂O₅ is an important terminal sink for nitrogen oxides (NO_x = NO + NO₂) in the troposphere (Simpson et al., 2015). Long-term data show that direct N₂O₅ loss via hydrolysis, to produce nitric acid (HNO₃, **R5**), is most important during winter, and indirect N₂O₅ loss (removal of NO₃ via reaction with hydrocarbons and NO, **R6-R7**) is most important during summer (Allan et al., 1999; Geyer et al., 2001; Heintz et al., 1996).

Experimental investigations of the impacts of meteorology on N_2O_5 abundance are primarily limited to observations of uptake by fog in coastal regions (Brown et al., 2016; Osthoff et al., 2006; Sommariva et al., 2009; Wood et al., 2005). In addition to forming HNO_3 , hydrolysis of N_2O_5 can produce particle-phase nitrate (NO_3^-) (Brown et al., 2004; Osthoff et al., 2006). Particle-phase nitrate has been observed to increase, then subsequently decrease, during fog episodes, which is hypothesized to be the result of N_2O_5 hydrolysis to form nitrate, followed by wet removal of nitrate from the fog layer (Lillis et al., 1999).

The review by Chang et al. (2011) stated that future observation-based research is needed to further investigate how N_2O_5 is affected by meteorological conditions, due to its impacts on ClNO_2 and particulate matter abundances, as well as on the oxidative capacity of the atmosphere. Many gaps remain in our understanding of the fates and production of N_2O_5 and ClNO_2 , especially in inland locations, and how they are influenced by meteorological conditions such as precipitation events, fog, and turbulent mixing. Notably, Stanier et al. (2012) identified the impacts of fog and snow cover as important knowledge gaps in understanding wintertime atmospheric composition, and nitrate formation in particular, in the Midwest United States.

The SNow and Atmospheric Chemistry in Kalamazoo (SNACK) field campaign was conducted during January and February 2018 in Kalamazoo, MI on the campus of Western Michigan University (WMU). In our previous publication from this study, we showed photochemical snowpack HONO production due to snow nitrate photolysis (Chen et al., 2019). Through vertical gradient measurements on select nights of the SNACK field campaign, we showed that N_2O_5 deposits at the same rates over bare and snow-covered ground; whereas, while ClNO_2 deposits on bare ground, it can be emitted from the saline snow-covered ground, with snow chamber experiments confirming saline snow ClNO_2 production (McNamara et al., 2021). Here, we focus on the observational time series of near-surface ClNO_2 and its precursor N_2O_5 and examine the influences of precipitation (rain, snow) and fog, atmospheric turbulence,

ground cover (snow-covered vs bare ground), particulate chloride and nitrate, temperature, and relative humidity (RH) on the night-time abundances of these compounds, measured by chemical ionization mass spectrometry. This study provides new insights into the biases associated with modeling and observations
100 focused on cloudless (clear) conditions, which has been shown to impact predictions of aerosol chemical composition (Christiansen et al., 2020).

2 Methods

The sampling site (42.28°N, 85.61°W) on the campus of WMU in Kalamazoo, MI was located next to a field and was approximately 90 m from a major roadway, as previously described by McNamara
105 et al. (2021). As described below, measurements of trace gases (N_2O_5 and ClNO_2), $\text{PM}_{2.5}$ (particulate matter with a diameter $\leq 2.5 \mu\text{m}$) inorganic chemical composition, three-dimensional wind speed, and temperature were conducted at the field site from January 20 to February 24, 2018. Daily photographs and field notes were used to determine ground cover and spatial extent of snow cover.

Because N_2O_5 and ClNO_2 were present almost exclusively at night, we define
110 “nocturnal”/“nighttime” as the period between 18:00 and 8:00 Eastern Standard Time (EST, Coordinated Universal Time (UTC)-5 h), which was approximately ± 30 min from sunrise and sunset during the campaign. At the start of the campaign (January 20) sunrise was at 08:05 local time (eastern standard time, EST), and sunset was at 17:42. At the end of the campaign (February 24) sunrise was at 07:23 EST, and sunset was at 18:27.

115 2.1 Meteorological measurements

Air temperature and three-dimensional wind speed (u , v , and w) were measured from a height of 1.4 m and at a frequency of 20 Hz using a sonic anemometer (model CSAT3, Campbell Scientific Inc., Logan, UT). The sonic anemometer was not operational from February 20-21 due to complications associated with heavy rainfall. Friction velocity (u^*) was calculated from turbulent covariance of three-
120 dimensional wind speed based on 30 minute averaging, where u' , v' , and w' are fluctuations about the 30

min mean wind speed in its zonal (u), meridional (v), and vertical (w) components, respectively (E1) (Stull, 1988).

$$u^* = (\overline{u'w'^2} + \overline{v'w'^2})^{\frac{1}{4}} \quad \text{E1}$$

Kinematic heat flux ($w'T'$) was also calculated from sonic anemometer data, where w' and T' are deviations in vertical velocity and temperature from five-minute averages, respectively (Monin and Obukhov, 1954). Kinematic heat flux values were then further averaged to obtain 30 min time resolution quantities. This heat flux value describes the transport of thermal energy by eddies; negative values of $w'T'$ indicate heat transport from the atmosphere to the surface and are associated with a temperature inversion (Stull, 1988).

Weather conditions (rain, snow, and fog) and pressure were recorded at the Kalamazoo–Battle Creek International Airport (KAZO), which was located ~7 km to the southeast; data were retrieved from Weather Underground (<https://www.wunderground.com/history/daily/us/mi/kalamazoo/KAZO>). Weather conditions were reported with a maximum time resolution of 1 h. This relatively long time resolution limits the use of higher frequency data from other measurements, and therefore, we use 30 min averaged data, with the assumption that the weather condition lasted the entire hour. Weather conditions were classified using reported National Weather Service designations: clear weather conditions include fair, cloudy, mostly cloudy, and partly cloudy; snowfall includes light snow, snow, heavy snow, and wintry mix; fog includes fog and haze; and rainfall refers to light rain, rain, heavy rain, and thunderstorms. Wind speed and temperature data were also obtained from this weather station to supplement the rain case study (February 20-21), during which data from the sonic anemometer were unavailable.

140 **2.2 Chemical ionization mass spectrometry measurements**

Measurements of N_2O_5 and $ClNO_2$ were conducted using a chemical ionization mass spectrometer (CIMS, THS Instruments) (Liao et al., 2011). The CIMS instrument uses iodide-water reagent ion clusters, $I(H_2O)^-$, to ionize analyte molecules, which are separated and quantified using a quadrupole mass analyzer. The CIMS was housed in a mobile laboratory trailer at the field site, and sampled ambient air at $\sim 300 \text{ L min}^{-1}$ through a specialized inlet. The inlet was designed to prevent wall

losses of reactive species by allowing for the sampled air at the center of the ring to be de-coupled from the inlet walls (laminar flow), thereby avoiding wall surfaces (Huey et al., 2004; Neuman et al., 2002), as in previous campaigns (e.g., McNamara et al., 2019). The inlet consisted of a 30 cm long, 4.6 cm i.d. aluminum pipe attached to a stainless-steel ring torus 1.5 m above ground level. The airflow from this inlet was subsampled at 6.6 L min^{-1} into a 48 cm long, 0.95 cm i.d. FEP Teflon tube and through a custom three-way heated valve (30°C) used to obtain calibration and background measurements. Of this airflow, an ozone monitor (model 205, 2B Technologies, Boulder, CO) sub-sampled 1.7 L min^{-1} , and 0.9 L min^{-1} was sub-sampled into the CIMS ion-molecule reaction region, which was held at a constant pressure of 15.5 Torr. $\text{I}(\text{H}_2\text{O})^-$ reagent ions (Slusher et al., 2004) were generated by passing iodomethane (CH_3I) in nitrogen (N_2) through a ^{210}Po radioactive ion source. The ion-molecule reaction region was humidified using water vapor from an impinger to prevent changes in ambient RH from altering CIMS sensitivity (Kercher et al., 2009; McNamara et al., 2019).

CIMS background measurements were conducted for 2 min every 15 min by passing the ambient air flow through a scrubber containing glass wool and stainless-steel wool (heated to 120°C) which removed N_2O_5 and ClNO_2 with $96.4\pm 0.8\%$ and $89\pm 1\%$ efficiency (mean \pm 95% confidence interval), respectively (McNamara et al., 2021). N_2O_5 was monitored at m/z 235 (IN_2O_5^-), and ClNO_2 was monitored at m/z 208 ($\text{I}^{35}\text{ClNO}_2^-$) and m/z 210 ($\text{I}^{37}\text{ClNO}_2^-$), each with dwell times of 1.5 s. ClNO_2 was positively identified using its measured isotopic ratio (**Fig. S1**). The 3σ limits of detection (LOD), corresponding to the 2 min background periods, were 1.3 ppt and 0.4 ppt for N_2O_5 and ClNO_2 , respectively. We report mole ratios as 30 min averages, for which the 3σ LODs for N_2O_5 and ClNO_2 are estimated to be 0.3 ppt and 0.1 ppt for N_2O_5 and ClNO_2 , respectively, calculated in the same manner as Liao et al. (2011). CIMS measurement uncertainties, which include propagated uncertainties associated with calibrations and fluctuations in the background signal, are estimated as $22\%+0.3$ ppt and $22\%+0.1$ ppt for 30 min averaged N_2O_5 and ClNO_2 mole ratios, respectively. Calibrations in the field were conducted every 2 h by adding 0.2 L min^{-1} of 12.3 ± 0.2 ppb Cl_2 (in N_2) from a permeation source (VICI Metronics, Inc., Poulsbo, WA) to the ambient airflow. The permeation rate was measured by bubbling the permeation output into a solution of potassium iodide and measuring the oxidation product, triiodide (I_3^-), using UV-visible spectrophotometry at 352 nm (Liao et al., 2011). The instrument responses for N_2O_5 and ClNO_2 were

calibrated in the laboratory, with calibration factors relative to the response to Cl₂ obtained, as described
175 in McNamara et al. (2019b).

Cl₂ was monitored as I(Cl₂)⁻ at *m/z* 197 and 199, each with dwell times of 0.5 s. The LOD for Cl₂
at *m/z* 197 was 2.4 ppt (0.6 ppt for 30 min averaged data). Cl₂ was below its estimated LOD for 30 min
averaging for 96% of the nighttime periods (and 91% of daytime periods), and therefore these limited
data are not discussed. HNO₃ was also monitored as I(HNO₃)⁻ at *m/z* 190 with a dwell time of 0.5 s and
180 calibrated offline relative to Cl₂ (McNamara et al., 2020). However, there was a high background signal
due to poor scrubbing efficiency (12±1%), resulting in a high LOD of 43 ppt (11 ppt for 30 min averaged
data). 40% of the nighttime HNO₃ data during the campaign were below the LOD estimated for 30 min
averaging, and therefore these data are not discussed in detail in this work. These upper limits for Cl₂ and
HNO₃ mole ratios are important to report, given limited measurements of these compounds in urban,
185 snow-covered environments.

2.3 Ambient ion monitor-ion chromatography (AIM-IC)

PM_{2.5} chloride (Cl⁻) and nitrate (NO₃⁻) were measured by an ambient ion monitor-ion
chromatography instrument (AIM-IC; model 9000D, URG Corp., Chapel Hill, NC), as described in Chen
et al. (2019). The AIM-IC and custom outdoor sampling inlet is described in detail by Markovic et al.
190 (2012). Briefly, ambient air was sampled at 3 L min⁻¹ through a 2.5 μm cyclone at a height of 1.8 m. A
parallel-plate wet denuder (PPWD) supplied with diluted H₂O₂ separated soluble inorganic trace gases.
Particles entered a supersaturation chamber (SSC), where hygroscopic growth was initiated prior to an
inertial particle separator. The PPWD and SSC were placed outside in an insulated and heated aluminum
case to reduce the sampling line length. Trace gas and particle samples were collected every hour using
195 concentrator columns (anion, UTAC-ULP1, ultra-trace anion concentrator ultralow pressure; cation,
TCC-ULP1, trace cation concentrator ultralow pressure; Thermo Fisher Scientific, Waltham, MA) for
measurements every 2-4 h (3 h after January 24) by an ion chromatograph (ICS-2100; Dionex Inc.,
Sunnyvale, CA). LiF was used as an internal standard. The 3σ LODs for Cl⁻ and NO₃⁻ were 0.004 and
0.05 μg m⁻³, respectively, for 3 h sampling.

200 2.4 Aerosol size distribution measurements

Aerosol size distributions were measured using a scanning mobility particle sizer (SMPS, model 3082, TSI, Inc., Shoreview, MN), which measured electrical mobility diameter from 14.1-736.5 nm, and an aerodynamic particle sizer (APS, model 3321, TSI, Inc., Shoreview, MN), which measured aerodynamic diameter from 0.5-20 μm . The air was sampled through a 2.5 μm cyclone (URG Corp.,
205 Chapel Hill, NC) from an inlet height of ~ 3 m. This flow was split from a manifold with a total flow rate of 16.8 L min^{-1} into foam-insulated copper tubing for each instrument; the SMPS and APS sub-sampled at 0.3 L min^{-1} and 4.9 L min^{-1} , respectively.

3 Results and Discussion

210 The field campaign nights from January 20-February 24 were divided into categories to investigate the impacts of weather events (rain, snowfall, fog), ground cover (snow-covered and bare ground), and atmospheric turbulence on the near-surface (~ 1.5 m above ground) abundances of N_2O_5 and ClNO_2 (**Fig. 1**). Time periods that were below LOD (0.3 ppt and 0.1 ppt for 30 min averaged N_2O_5 and ClNO_2 , respectively) are included in calculations as $0.5 \times \text{LOD}$. Data after 08:00 (approximately ± 30 min
215 from sunrise, which was at 08:07 on Jan 20 and 07:25 on Feb 24) are not included such that air entrainment from the residual boundary layer, discussed elsewhere (e.g. Tham et al., 2016), does not influence the results discussed below.

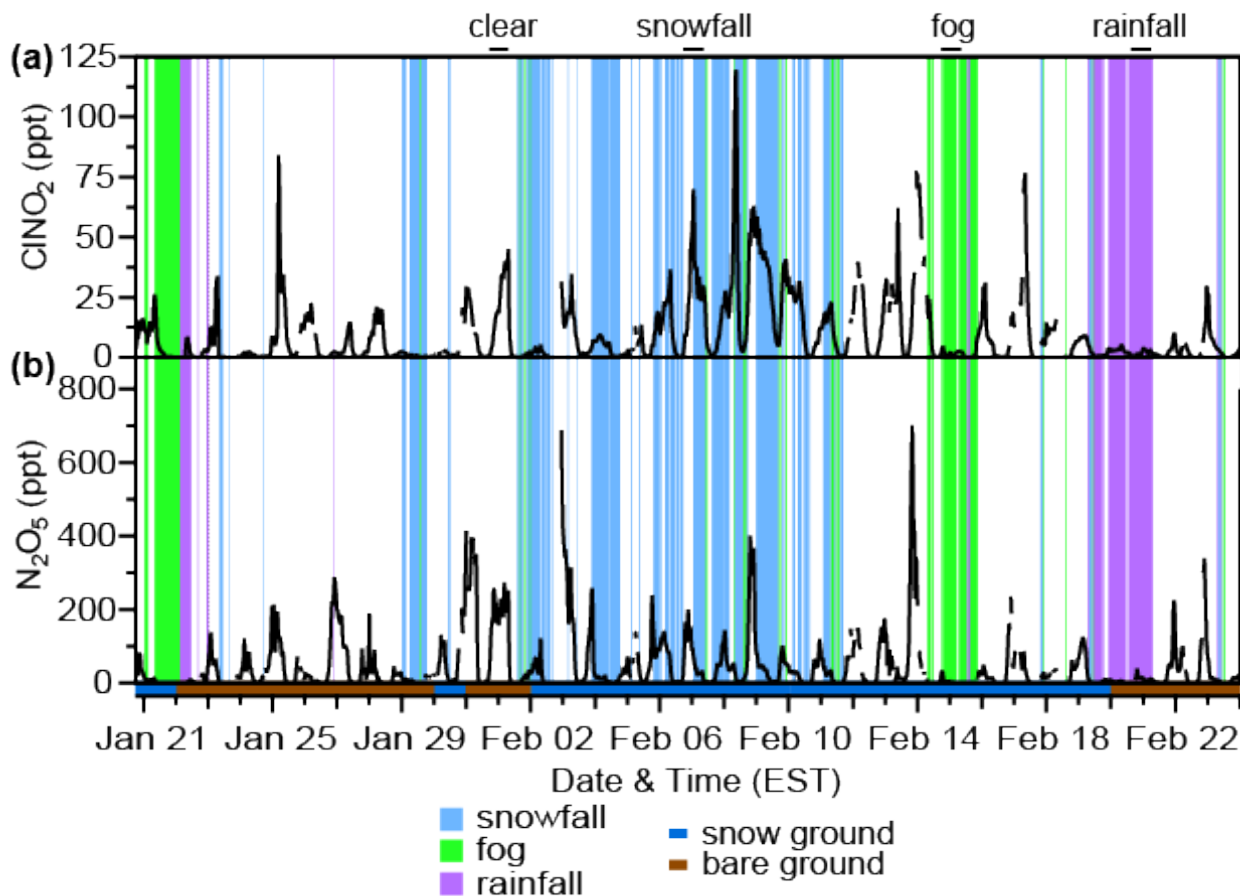

Figure 1: Mole ratios of 30 min averaged (a) ClNO_2 and (b) N_2O_5 during the campaign, and occurrence of snowfall (light blue), fog (green), and rainfall (purple). The shading below the x-axis represents ground cover – snow (blue) or bare ground (brown). The black bars on the top of the plot show the selected case study nights for each weather event type. Between 18:00 and 08:00 h EST, where n =number of 30 min periods, the air was clear 72% of the time [$n=726$; 363 h], snowfall occurred 16% of the time [$n=157$; 78.5 h], rainfall occurred 6% of the time [$n=63$; 31.5 h], and fog occurred 6% of the time [$n=58$; 29 h]. The ground was snow-covered 57% of the study [20 d] and was bare for 43% of the study [15 d]. Figure S3 gives further details about the occurrence of weather events (rainfall, fog, snowfall) in relation to friction velocity and ground cover.

3.1 Effects of rain, snow, and fog (campaign-wide)

The nighttime abundances of N_2O_5 and ClNO_2 during rain, snowfall, and fog were all significantly different ($p < 0.05$, six t-tests) from clear conditions (Fig. 2). Campaign-wide average nighttime (18:00-08:00) N_2O_5 and ClNO_2 mole ratios during clear conditions and each type of weather event are listed in

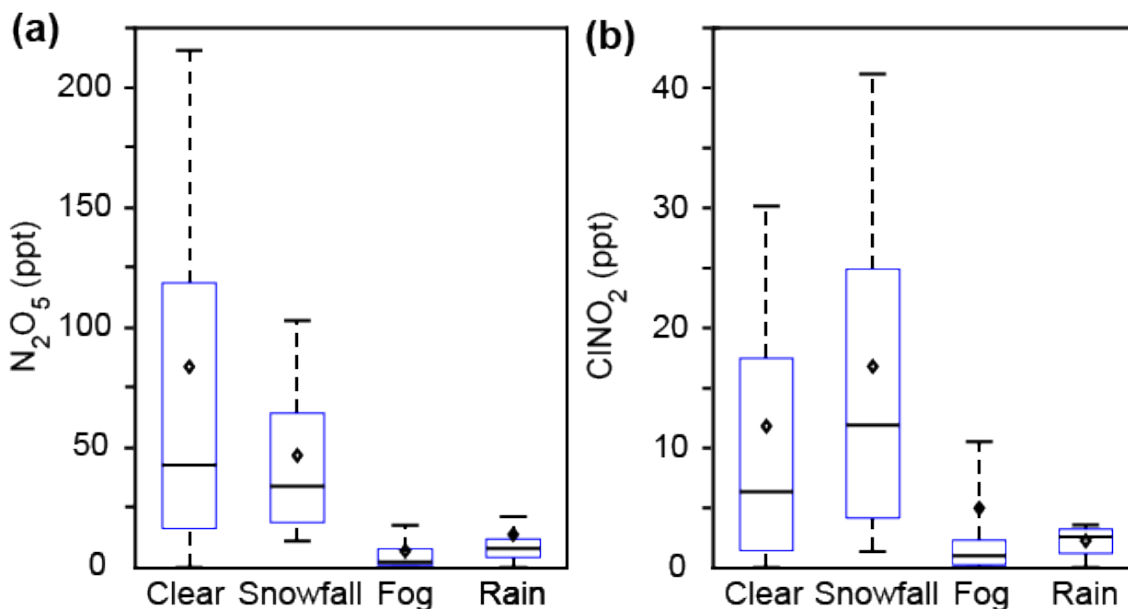

Table 1, with additional data ($\text{PM}_{2.5}$ Cl^- and NO_3^- , temperature, relative humidity, and friction velocity) for these time periods provided in Table S1. Here we discuss observations during these weather events across the entire campaign; example case studies are discussed in Section 3.2. The average nighttime N_2O_5 mole ratios ($\pm 95\%$ confidence interval) were 84 ± 5 ppt, 47 ± 2 ppt, 14 ± 2 ppt, and 7.1 ± 0.6 ppt during clear, snowfall, rain, and fog conditions, respectively (**Fig. 2**). In comparison to clear conditions, average N_2O_5 mole ratios were 37 ± 5 ppt (1.8 times), 70 ± 5 ppt (6.0 times), and 77 ± 5 ppt (12 times) lower during snowfall, rain, and fog, respectively. The decrease in N_2O_5 abundance during fog suggests N_2O_5 uptake by fog droplets, and is consistent with previous observations (Brown et al., 2016; Osthoff et al., 2006; Sommariva et al., 2009; Wood et al., 2005). More recently, a study by Osthoff et al. (2018) noted decreased ClNO_2 abundance during drizzle/rain and fog during Jul.-Aug. in coastal British Columbia. However, clear conditions are generally the focus of previous N_2O_5 and ClNO_2 studies (Chang et al., 2011; Simpson et al., 2015).

Table 1: Mean ($\pm 95\%$ confidence interval) mole ratios of N_2O_5 and ClNO_2 , $\text{PM}_{2.5}$ Cl^- and NO_3^- concentrations, temperatures, and relative humidity during each type of weather event (clear, snow, fog, and rain) and ground cover (bare and snow-covered ground) measured across the entire campaign, between 18:00-08:00 EST. The numbers of 30 min periods (n) and percentages of nighttime periods classified as each weather condition are included in parenthesis. Note that bare and snow-covered ground co-existed with the weather conditions, as discussed in Section 3.4. 95% confidence intervals are reported to describe the variabilities in 30 min averaged values of the parameters for the various weather and ground cover conditions.

Weather or Ground Cover Condition	N_2O_5 (ppt)	ClNO_2 (ppt)	$[\text{Cl}^-]$ ($\mu\text{g m}^{-3}$)	$[\text{NO}_3^-]$ ($\mu\text{g m}^{-3}$)	Temperature (K)	Relative Humidity (%)
Clear (n=726, 72%)	84 ± 5	11.8 ± 0.7	0.257 ± 0.007	0.95 ± 0.04	270.8 ± 0.3	75.0 ± 0.5
Snowfall (n=157, 16%)	47 ± 2	16.8 ± 0.7	0.258 ± 0.006	0.81 ± 0.03	265.8 ± 0.2	83.0 ± 0.3
Fog (n=58, 6%)	7.1 ± 0.6	5.0 ± 0.6	0.456 ± 0.008	1.38 ± 0.04	276.7 ± 0.2	93.7 ± 0.3
Rain (n=63, 6%)	14 ± 2	2.27 ± 0.06	0.22 ± 0.01	0.126 ± 0.007	282.1 ± 0.2	90.2 ± 0.4

Snow-covered ground (20 d, 57%)	70±5	14.9±0.8	0.30±0.01	1.03±0.04	268.4±0.3	80.0±0.5
Bare ground (15 d, 43%)	68±4	7.0±0.5	0.21±0.01	0.67±0.03	274.8±0.3	75.8±0.6

245

250 **Figure 2:** Box plots showing 30 min averaged mole ratios of (a) N_2O_5 and (b) $ClNO_2$ during clear
 conditions and weather events (snowfall, fog, and rain) from the entire campaign, January 20 - February
 24. Bars represent the 10th, 50th, and 90th percentiles, boxes represent the 25th and 75th percentiles, and
 diamonds represent the means. Only nighttime data between 18:00 and 08:00 EST are included. Data
 during all weather events (snowfall, fog, rain) are significantly different ($p < 0.05$, t-test) from clear
 255 conditions.

The average $ClNO_2$ mole ratios were 16.8 ± 0.7 ppt during snowfall, 11.8 ± 0.7 ppt in clear
 conditions, 5.0 ± 0.6 ppt during fog, and 2.27 ± 0.06 ppt when raining (Fig. 2). In comparison to clear
 conditions, average $ClNO_2$ mole ratios were 6.8 ± 0.9 ppt (2.4 times) and 9.5 ± 0.7 ppt (5.2 times) lower
 during fog and rain, respectively. Lower average abundances of $ClNO_2$ during fog and rainfall, compared
 260 to clear conditions, are consistent with previous observations (Osthoff et al., 2018) and were likely due

to scavenging either of ClNO₂ directly or its precursors (R2). In contrast, average ClNO₂ mole ratios were 5±1 ppt (1.4 times) higher during snowfall than clear conditions. This result is surprising, considering that its precursor, N₂O₅, showed lower mole ratios, on average, during snowfall in comparison to clear conditions. We hypothesize that snowpack ClNO₂ production contributes to this observation, which is discussed in *Sect. 3.3-3.4*. Particle-phase chloride and nitrate concentrations were not statistically significantly different between clear and snowfall conditions (p=0.96 and 0.08, respectively), nor were aerosol number or surface area concentrations (p=0.06 and 0.31, respectively), as discussed in *Sect. 3.5*. The effects of temperature and relative humidity are discussed in *Sect. 3.5*.

3.2 Effects of rain, snow, and fog (case study nights)

To further examine the behavior of N₂O₅ and ClNO₂ mole ratios in response to snowfall, rain, and fog, we present four nocturnal case study periods that were representative of the four different weather conditions (clear, snowfall, fog, and rain) observed during the campaign (**Fig. 3**). Case study nights were chosen to capture a sustained weather event (e.g. >7 h of clear conditions, snowfall, fog, or rainfall). Additionally, ground cover and friction velocity were matched as closely as possible for case study nights to the campaign-wide averages during different types of weather events. Additional data specific to the case studies is provided in the supplemental material (**Table S2, Fig. S4-S6**). The clear case night of Jan 31-Feb 01 had no precipitation or fog, an average u^* of 0.16±0.01 m s⁻¹ (campaign average u^* was 0.150±0.004 m s⁻¹ during nighttime clear conditions), and bare ground. N₂O₅ mole ratios were fairly stable around 200 ppt (average 200±16 ppt, range 75-274 ppt) throughout the night, with ClNO₂ mole ratios increasing steadily between 18:00-07:30 from 1.5 ppt to 45 ppt (average 23±5 ppt, range 0.6-4.5 ppt) (**Fig. 3a**).

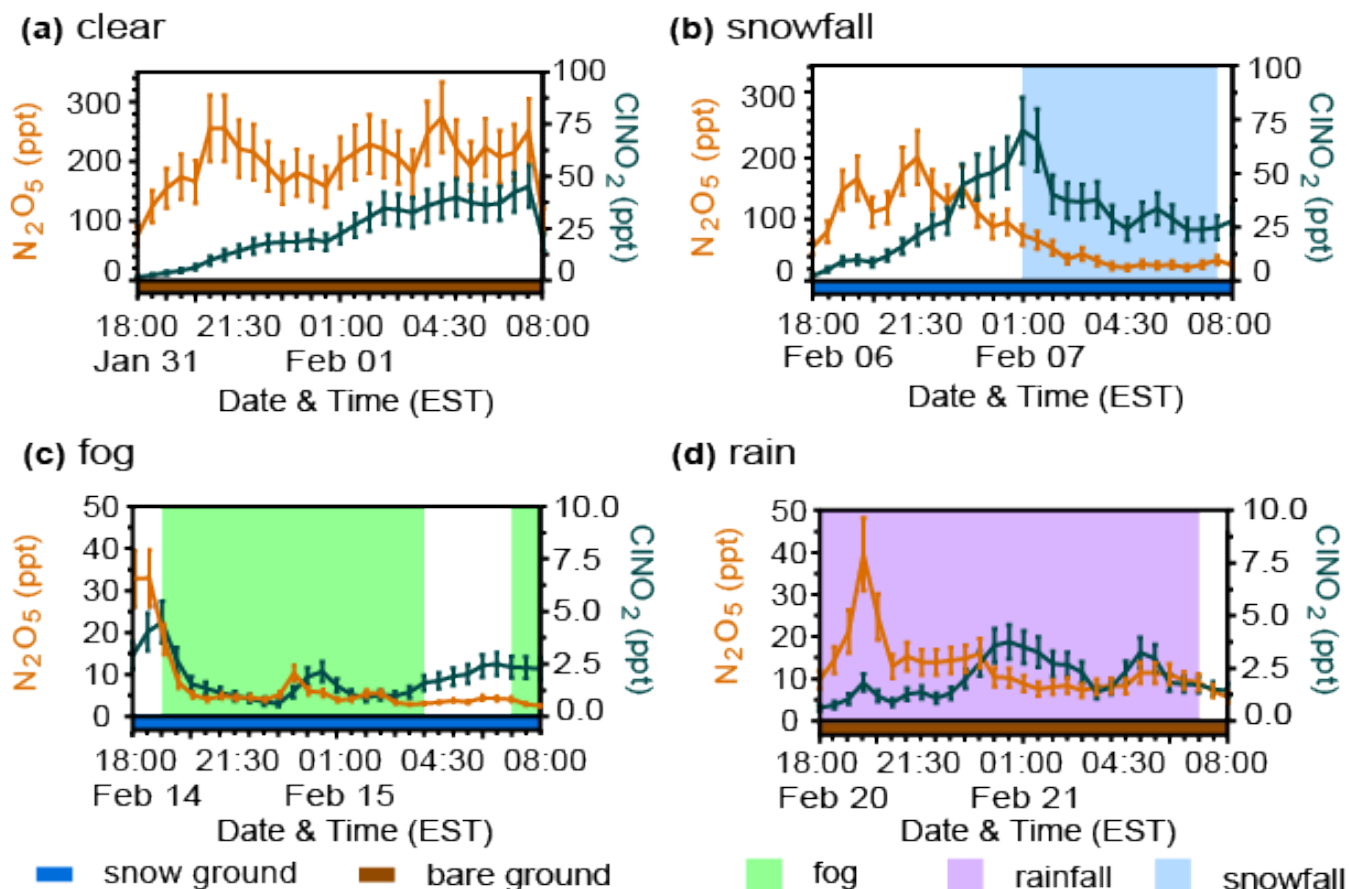

Figure 3: Four example case study periods are shown, corresponding to (a) clear conditions, (b) snowfall, (c) fog, and (d) rainfall. The 30-min averaged abundances of N_2O_5 (orange) and $ClNO_2$ (dark blue) are displayed for each case. Error bars represent propagated uncertainties. The shading below the x-axis represents ground cover – snow (blue) or bare ground (brown).

To discuss changes in gas-phase concentrations during precipitation and fog, we apply the concept of solution equilibrium to the surface layer of a drop (i.e. a rain or fog droplet) in terms of a local equilibrium between the analyte in the gas-phase and the analyte dissolved in the surface layer (Pruppacher and Klett, 1997). This equilibrium can then be described using Henry's law and Henry's law constants (K_H). For N_2O_5 , fast, irreversible hydrolysis is assumed, equivalent to an infinite effective K_H (Jacob, 1986; Sander, 2015). For $ClNO_2$, the $K_H=4.5 \times 10^{-4} \text{ mol m}^{-3} \text{ Pa}^{-1}$ at standard temperature (Frenzel et al., 1998; Sander, 2015), showing little variation between ~ 278 and 294 K . Converting the K_H for $ClNO_2$ to its dimensionless Henry solubility (also called the air-water partitioning coefficient, K_{AW}), as

295 in Sander (2015), gives a unitless ratio between the aqueous and gas phases of >1 at temperatures above freezing. This means, at equilibrium, ClNO_2 is expected to be more abundant in the aqueous-phase than in the gas-phase. The fast irreversible hydrolysis assumed for N_2O_5 makes it more water soluble than ClNO_2 ; therefore, scavenging by liquid droplets is expected for both gas-phase N_2O_5 and ClNO_2 , but to a greater extent for N_2O_5 . Here, we examine the fog and rainfall case studies to characterize the effects of
300 scavenging by aqueous droplets on N_2O_5 and ClNO_2 abundance. Variations in N_2O_5 and ClNO_2 over the course of the nights are likely due to variability in fog/rainfall that were not resolved by the time resolution of the reported weather conditions, which also do not reflect precipitation rates or fog concentrations that would be expected to vary through the nights. For the fog case night of Feb 14-15, fog was present from 19:00-04:00 and 07:00-08:00 (**Fig. 3c**). This case had an average u^* of $0.18 \pm 0.02 \text{ m s}^{-1}$ (campaign average
305 u^* was $0.162 \pm 0.007 \text{ m s}^{-1}$ during nighttime fog) and snow-covered ground. N_2O_5 mole ratios decreased rapidly from the maximum of 32 ppt at 18:00 and fell to a local minimum of 2.3 ppt at 22:30; it then remained low in abundance (<10 ppt) for the rest of the night, reaching its true minimum of 1.1 ppt at 03:30. ClNO_2 mole ratios reached the maximum of 4.5 ppt at 19:00 and then decreased coincident with the appearance of fog and remained low in abundance (<3 ppt) for the rest of the night, reaching its
310 minimum of 0.6 ppt at 23:00. Considering the first hour after the fog onset (19:00-20:00), N_2O_5 mole ratios decreased from 16.6 ppt to 3.4 ppt (decrease of 13.2 ppt or 80%) and ClNO_2 mole ratios decreased from 4.5 ppt to 1.6 ppt (decrease of 2.9 ppt or 64%).

Similarly, the rainfall case night of Feb 20-21 was characterized by rainfall from 18:00-07:00 and bare ground (**Fig. 3d**). While sonic anemometer data were unavailable on this night, elevated wind speeds
315 of $2.2\text{-}8.9 \text{ m s}^{-1}$ (average= $5.0 \pm 0.5 \text{ m s}^{-1}$) (**Fig. S4** and **Table S2**) are consistent with increased turbulence, with u^* likely greater than 0.25 m s^{-1} for the duration of the night (**Fig. S5**). N_2O_5 mole ratios decreased rapidly from the maximum of 40 ppt at 19:30, stabilized at ~ 15 ppt from 20:30-00:00, and then decreased again to ~ 10 ppt until 08:00. ClNO_2 mole ratios reached the maximum of 3.7 ppt at 00:30, with a second local maximum of 3.0 ppt at 05:30; ClNO_2 abundance was <2 ppt before 23:30 and after 06:00. The
320 observations during the fog and rainfall case studies reinforce the trends observed for the campaign averages (**Fig. 2-3**) and illustrate the importance of scavenging by liquid droplets.

The snowfall case night of Feb 06-07 was characterized by snowfall from 01:00-07:30 (**Fig. 3b**), an average u^* of $0.06 \pm 0.01 \text{ m s}^{-1}$ (campaign average u^* was $0.129 \pm 0.004 \text{ m s}^{-1}$ during nighttime snowfall), and snow-covered ground. N_2O_5 mole ratios reached the maximum of 201 ppt at 21:30 and then gradually
325 decreased throughout the rest of the night; it reached its minimum of 22 ppt at 04:00 and then remained low in abundance (22-34 ppt). ClNO_2 mole ratios reached the maximum of 70 ppt at 01:00, the same time that snowfall began, and then decreased steadily to the minimum of 24 ppt at 04:30, after which it also remained low in abundance (24-34 ppt). Considering the first hour after snowfall onset (01:00-02:00), N_2O_5 mole ratios decreased from 74.8 ppt to 53.6 ppt (decrease of 21.2 ppt or 28%) and ClNO_2 mole
330 ratios decreased from 69.8 ppt to 40.3 ppt (decrease of 29.5 ppt or 42%).

The observations during the snowfall case are also consistent with campaign-wide observations (**Fig. 2-3**). In comparison to the clear case, the snowfall case night shows that N_2O_5 mole ratios were generally lower during snowfall (by 2.1 times, on average), whereas ClNO_2 mole ratios were typically higher during snowfall (by 1.4 times, on average). Even though the clear case study had the highest mole
335 ratios of N_2O_5 , the snowfall case study had the highest mole ratios of ClNO_2 (**Fig. 3** and **Table S2**). The clear and snowfall case studies differed in both ground cover and air turbulence, with lower friction velocity (average= $0.06 \pm 0.01 \text{ m s}^{-1}$) and snow-covered ground observed during the snowfall case and intermediate friction velocity (average= $0.16 \pm 0.01 \text{ m s}^{-1}$) and bare ground observed during the clear case study. Additional effects on the abundances of N_2O_5 and ClNO_2 are further investigated in the following
340 sections.

3.3 Effects of turbulence

Turbulent mixing (quantified here using friction velocity, u^* , **E1**) affects abundances of surface-level trace gases (Stull, 1988). Stronger turbulent mixing promotes vertical transport, and weaker turbulent mixing keeps trace gases near the ground (Stull, 1988). Turbulence regimes were divided within
345 the context of our study to allow subsequent analysis by binning with sufficient data in each bin. Here, lower turbulence refers to $u^* < 0.1 \text{ m s}^{-1}$, higher turbulence is $u^* > 0.25 \text{ m s}^{-1}$, and mid-turbulence refers to $0.1 < u^* < 0.25 \text{ m s}^{-1}$. Lower turbulence occurred 39% of the time, mid-turbulence occurred 42% of the time, and higher turbulence occurred 14% of the time (**Fig. S3**). For context, typical u^* values range

from near 0 m s^{-1} during calm conditions to 1 m s^{-1} during strong winds; moderate wind values often have u^* values near 0.5 m s^{-1} (Stull, 2017). Lower friction velocity, in general, was observed during our study, which focuses on nighttime measurements during winter. We investigate the effects of atmospheric turbulence on the abundances of ClNO_2 and N_2O_5 by comparing lower ($u^* < 0.1 \text{ m s}^{-1}$) and higher turbulence ($u^* > 0.25 \text{ m s}^{-1}$) periods across 30 min averaged periods for a full diel cycle during the entire campaign (**Fig. 4**). Periods of snowfall, fog, and rainfall were included in this analysis due to the relationships which exist between weather events and friction velocity; for example, snowfall occurred most often during lower turbulence conditions, while rainfall occurred most often during higher turbulence conditions, the effects of which are further discussed in *Sect. 3.5*.

Figure 4. Campaign-wide diel patterns of 30 min averaged (a) N_2O_5 and (b) ClNO_2 , binned by lower ($u^* < 0.1 \text{ m s}^{-1}$) and higher ($u^* > 0.25 \text{ m s}^{-1}$) friction velocities. Shading represents one standard deviation. Asterisks represent statistically significant (t-test) differences at the $p < 0.05$ level between the lower and higher friction velocity bins for each 30 min period from January 20-February 24 (excluding February 20-21 when the sonic anemometer was not operational). The number of 30 min time periods, from 18:00-08:00, is reported as n. Lower turbulence occurred 39% of the time ($n=391$) and higher turbulence occurred 14% ($n=137$) of the time; sonic anemometer data were unavailable for 5% ($n=53$) of nighttime periods.

Significantly higher ($p < 0.05$, t-test) N_2O_5 mole ratios were observed under higher turbulence conditions at 02:00, 03:30, 04:00, 06:00, and 07:30, and 08:00 (**Fig. 4a**). These statistically significant

time points correspond to, on average, 5.9 times higher N_2O_5 mole ratios during higher turbulence conditions, in comparison to lower turbulence conditions. Considering the entire period of 02:00-08:00, N_2O_5 mole ratios were 4.0 times higher, on average, during higher turbulence conditions in comparison to lower turbulence conditions. Before 02:00, no statistically significant differences were observed in N_2O_5 abundance between higher and lower turbulence conditions, suggesting that titration of NO_3 (N_2O_5 precursor, **R3**) by NO was not significant during these time periods. Considering the nighttime period as a whole (18:00-08:00), N_2O_5 mole ratios were higher by 24 ± 4 ppt (1.6-fold) during higher turbulence, in comparison to lower turbulence conditions. For context in relation to the various weather conditions, higher turbulence ($u^* > 0.25 \text{ m s}^{-1}$) was present for 13%, 9%, 19%, and 17% of the time during clear, snowfall, fog, and rainfall conditions, respectively (**Fig. S3**).

NO_3 , a reactant necessary to produce N_2O_5 (**R3**), is sensitive to changes in NO and O_3 levels; in particular, titration of NO_3 by NO (**R7**) is an important loss process at night and results in lower N_2O_5 production (Asaf et al., 2010). Therefore, when NO is emitted and confined near the ground in the stable nocturnal boundary layer, NO_3 has a short near-surface lifetime, thereby limiting N_2O_5 levels (Brown et al., 2007; Wang et al., 2006). Such stable conditions are associated with nocturnal temperature inversions, which can be observed during wintertime in the mid-latitudes (Leblanc and Hauchecorne, 1997). As expressed by kinematic heat flux less than 0 K m s^{-1} , a nocturnal temperature inversion was observed every night of the study (**Fig. S7**). As expected during more stable conditions, reduced N_2O_5 mole ratios were observed during nighttime lower turbulence ($u^* < 0.1 \text{ m s}^{-1}$) compared to higher turbulence ($u^* > 0.25 \text{ m s}^{-1}$) periods (average N_2O_5 mole ratios of 40 ± 2 ppt and 64 ± 3 ppt, respectively).

Vehicle NO_x emissions from the nearby roadway location $\sim 80 \text{ m}$ away (McNamara et al., 2021) are suggested to control the magnitude of the nighttime titration effect at the field site, as few time periods overnight were statistically different in O_3 mole ratios between the lower and higher turbulence conditions, on average (**Fig. S8**). However, despite 39% of the nighttime periods being characterized by lower turbulence ($u^* < 0.1 \text{ m s}^{-1}$) (**Fig. S3**), N_2O_5 mole ratios during the full campaign ranged from 0.15-702 ppt (mean 44 ± 4 ppt) during nighttime, resulting in the observed ClNO_2 production even under lower turbulence conditions. We explored the loss of NO_3 to reaction with VOCs (e.g. **R6**) using a box numerical model (*Sect. S1*, **Fig. S14**). These modeling results show that during the four case nights, which

had varying temperatures, friction velocities, and ground cover (**Fig. 3, Table S2**), NO_3 is simulated to be lost primarily through formation of ClNO_2 and HNO_3 (**Fig. S14**), rather than reaction with VOCs.

In contrast to its precursor N_2O_5 , ClNO_2 shows significantly higher ($p < 0.05$, t-test) average mole ratios under lower turbulence ($u^* < 0.1 \text{ m s}^{-1}$) conditions at 21:30, 22:00, 23:00, and 07:00 (**Fig. 4b**). These statistically significant time periods correspond to an average 6.3 times higher ClNO_2 mole ratio during lower turbulence conditions, in comparison to higher turbulence conditions. Considering the entire period of 21:30-07:30, ClNO_2 mole ratios were 3.6 times higher, on average, during lower turbulence conditions in comparison to higher turbulence conditions. Considering the nighttime period as a whole (18:00-08:00), ClNO_2 mole ratios were higher by 7 ± 1 ppt (2.6-fold) during lower turbulence, in comparison to higher turbulence conditions.

In summary, average N_2O_5 mole ratios were significantly higher ($p < 0.05$) at six different 30 min time periods, corresponding to 5.9 times higher N_2O_5 mole ratios during higher turbulence conditions, in comparison to lower turbulence conditions. The reduced N_2O_5 mole ratios observed under lower turbulence conditions are likely due to the short lifetime of NO_3 (N_2O_5 precursor, R3) when vehicle NO_x is emitted into the stable boundary layer, as observed in previous studies (Brown et al., 2007; Wang et al., 2006). However, average ClNO_2 mole ratios were significantly higher ($p < 0.05$) during four different 30 min time periods, corresponding to 6.3 times higher ClNO_2 mole ratios during lower turbulence conditions, in comparison to higher turbulence conditions. This points to a likely surface source of ClNO_2 upon surface deposition of N_2O_5 . Therefore, in Section 3.4, we investigated the influence of ground cover (Section 3.4).

3.4 Effects of ground cover

There were no statistically significant ($p < 0.05$, t-test) differences in the average abundances of N_2O_5 over the diel period for snow-covered vs bare ground (**Fig. 5a**). This is consistent with measurements of similar net negative (deposition) fluxes of N_2O_5 over both snow-covered and bare ground (McNamara et al., 2021). The nighttime average mole ratios of N_2O_5 were 70 ± 5 ppt and 68 ± 4 ppt over snow-covered and bare ground, respectively. In contrast, **Figure 5b** shows significantly higher ($p < 0.05$, t-test) average ClNO_2 mole ratios observed over snow-covered ground at 19:30-22:00, 23:00-

00:00, 01:00-01:30, 03:00, and 07:30. These statistically significant time points correspond to, on
425 average, 3.5 times higher ClNO₂ mole ratios over snow-covered ground, in comparison to bare ground.
Considering the entire period of 19:30-07:30, ClNO₂ mole ratios were 2.8 times higher, on average, over
snow covered ground in comparison to bare ground. This is consistent with measurements of typical net
positive (production) fluxes of ClNO₂ over snow-covered ground, and with field-based chamber
experiments showing that ClNO₂ can be produced from the reaction of N₂O₅ on the saline snowpack
430 (McNamara et al., 2021). The nighttime average mole ratios of ClNO₂ were 14.9±0.8 ppt and 7.0±0.5 ppt
over snow-covered and bare ground, respectively.

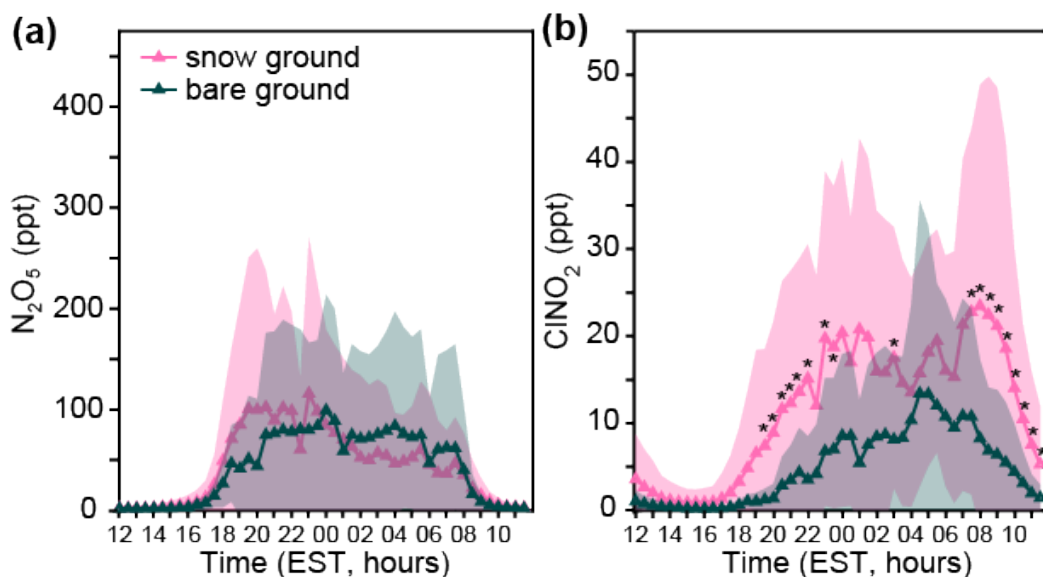

Figure 5. Diel patterns of 30 min averaged mole ratios of (a) N₂O₅ and (b) ClNO₂ binned by snow-
covered and bare ground conditions from January 20 to February 24. Shading represents one standard
435 deviation. Asterisks represent statistically significant (t-test) differences at the $p < 0.05$ level between
snow-covered and bare ground for each 30 min time period. The ground was snow-covered 57% [20 d]
of the study and was bare for 43% [15 d] of the study.

To summarize, there were no statistically significant ($p < 0.05$) differences in average N₂O₅ mole
ratios over the diel period for snow-covered versus bare ground. Yet, significantly higher ($p < 0.05$)
440 average ClNO₂ mole ratios were observed over snow-covered ground for 11 (of 28) nighttime 30 min
time periods, corresponding to 3.5 times higher ClNO₂ mole ratios over snow-covered ground, in
comparison to bare ground. During the same field campaign, net positive (production) fluxes of ClNO₂
were measured over snow-covered ground, and field-based chamber experiments showed that ClNO₂ can

be produced from the reaction of N_2O_5 on the saline snowpack (McNamara et al., 2021). The observed
445 enhancement of ClNO_2 over snow-covered ground results herein suggests that snowpack ClNO_2
production was a frequent and significant occurrence across the field campaign (e.g. enough to influence
the campaign-wide average results). We investigate the effects of other parameters (e.g. $\text{PM}_{2.5}$, Cl^- , NO_3^- ,
temperature, relative humidity, O_3 concentration, aerosol surface area, and pressure) in Section 3.5.

3.5 Competing effects of environmental conditions

450 Many of the environmental conditions discussed (precipitation/fog, turbulence regimes, and snow-
covered/bare ground) occur simultaneously, and as a result, are difficult to discuss in isolation. Higher
mole ratios of N_2O_5 were observed under higher turbulence conditions ($u^* > 0.25 \text{ m s}^{-1}$) (Section 3.3),
which occurred most frequently (67%) over bare ground (**Fig. S3**). In contrast, higher mole ratios of
 ClNO_2 were observed under lower turbulence conditions ($u^* < 0.25 \text{ m s}^{-1}$) (Section 3.3), which occurred
455 most frequently (73%) over snow-covered ground (**Fig. S3**). For select nights when vertical profile
experiments were conducted by McNamara et al. (2021) during the same campaign, no statistically
significant difference ($p = 0.48$) was observed for N_2O_5 deposition fluxes over bare ground versus snow-
covered ground. Lower turbulence ($u^* < 0.1 \text{ m s}^{-1}$) and snow-covered ground were observed
simultaneously for 24%, 48%, 26%, and 2% of the time during clear, snowfall, fog, and rainfall
460 conditions, respectively (**Fig. S3**). The prevalence of lower turbulence and snow-covered ground during
snowfall likely also contributes to the result that mole ratios of ClNO_2 were highest on average during
snowfall (**Fig. 2**). These trends are consistent with snowpack ClNO_2 production, as also evidenced by the
positive (upward) ClNO_2 fluxes observed over snow-covered ground and negative (downward) ClNO_2
fluxes observed over bare ground, during separate vertical profile experiments during the same campaign
465 McNamara et al. (2021).

Given that multiple environmental factors that control N_2O_5 and ClNO_2 mole ratios are changing
across the various weather conditions, we used a box numerical model, described in Section S1, to explore
the variations in N_2O_5 and ClNO_2 abundances that can be attributed to changes in temperature, pressure,
 O_3 mole ratios, and aerosol surface area across the four case study nights. This numerical model does not
470 consider the impacts of fog, rainfall, snowfall, ground cover, turbulence, or advection. Note that no

relationship was observed between wind direction or wind speed and mole ratios of N_2O_5 or ClNO_2 (**Fig. S13**), suggesting limited advection influence. Further, under the low wind speed conditions of the campaign (nighttime median = 1.0 m s^{-1}), the gas mole ratios are expected to be higher in response to decreased atmospheric dispersion of gases and emissions/deposition from nearby sources/sinks.

475 Therefore, we mainly attribute differences between calculated and measured N_2O_5 and ClNO_2 abundances primarily to the effects of non-parameterized meteorological processes (e.g., wet deposition and fog droplet scavenging). The model results (**Fig. 6, S14-16**) are discussed in detail in Section S2. Importantly, we conclude that variations in temperature, pressure, O_3 mole ratios, and aerosol surface area between the different case studies are insufficient to explain the significant differences in N_2O_5 and ClNO_2 mole ratios

480 observed between these case study nights and point to the importance of other processes, including scavenging, discussed in this manuscript.

For the clear snowfall, fog, and rainfall case study nights, simulated N_2O_5 mole ratios averaged 150 ppt, 190 ppt, 140 ppt, and 380 ppt, respectively, during the last 4 h of the simulation (hours 10-14, 04:00-08:00 EST, to account for model spin-up and stabilization) (**Fig. 6**). In comparison, the maximum

485 observed N_2O_5 mole ratios were 274 ppt, 34.2 ppt, 2.7 ppt, and 11.4 ppt from 04:00-08:00 EST during the clear, snowfall, fog, and rainfall cases respectively (**Fig. 6**). While plausible scenarios of $[\text{NO}_2]$ and N_2O_5 uptake could simulate the observed N_2O_5 mole ratios (**Fig. S15**), the model scenario corresponding to previous work in wintertime Ann Arbor, MI (McNamara et al., 2020) underpredicts the average N_2O_5 mole ratio (229 ppt) by 42%. However, in contrast, the model drastically over-predicted N_2O_5 mole ratios

490 for both the fog case (by ~50 times) and rainfall case (by ~30 times), and also over-predicted N_2O_5 mole ratios during the snowfall case (by ~5 times). As discussed in Section S2, realistic model conditions could not simulate the observed N_2O_5 mole ratios for the fog, rainfall, and snowfall cases. This supports scavenging as a missing N_2O_5 sink, with this being most significant during fog and rainfall, and potentially also contributing during snowfall.

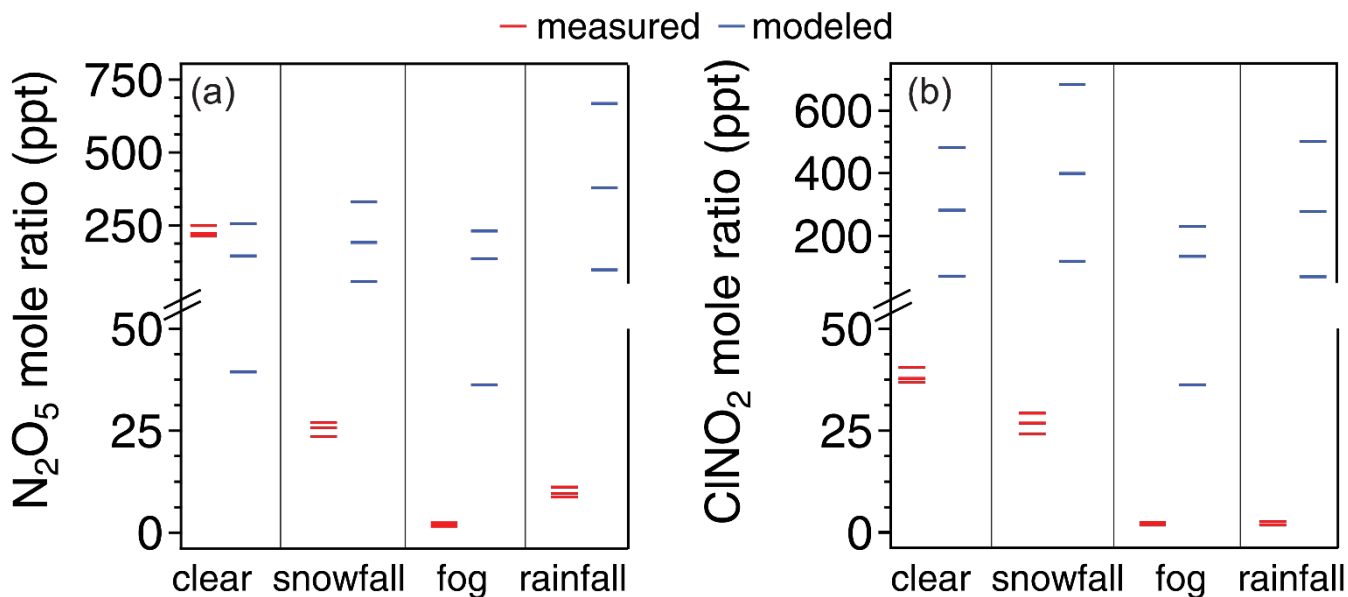

Figure 6: A comparison of measured (red) vs modeled (blue) mole ratios of N_2O_5 (a) and ClNO_2 (b) for each case study night. For measured values, the minimum, average, and maximum mole ratios from 04:00 – 08:00 EST of each case study (Fig. 3) are shown. For modeled values, the average mole ratios from the last 4 h of each 14 h simulation are shown; model inputs for the case studies are described in *Sect. S1*. Here, we hold the $\gamma^*\phi$ product (N_2O_5 uptake \times ClNO_2 yield) constant at 0.0037, and show the model outputs when $[\text{NO}_2] = 9.4$ ppb, 31 ppb, and 59 ppb, respectively; $[\text{NO}_2] = 9.4$ ppb produced the lowest modeled values of N_2O_5 and ClNO_2 , and $[\text{NO}_2] = 59$ ppb produced the highest modeled values of N_2O_5 and ClNO_2 . For context, McNamara et al. (2020) previously reported a modeled median $[\text{NO}_2]$ of 31 ppb and $\gamma^*\phi$ product constant of 0.0037 for wintertime Ann Arbor, MI.

Considering the entire SNACK field campaign, temperature was statistically significantly different between clear conditions and snowfall, fog, and rainfall, respectively ($p < 0.05$, t-test) (**Fig. 7c**). The average nighttime temperatures were 265.8 ± 0.2 K, 270.8 ± 0.3 K, 276.7 ± 0.2 K, and 282.1 ± 0.2 K during snowfall, clear conditions, fog, and rainfall, respectively. Since lower temperatures favor N_2O_5 production in its thermal equilibrium (**R3**) (Asaf et al., 2010; Wagner et al., 2013), and because snowfall conditions had the lowest average temperature (**Fig. 7c**), we would expect N_2O_5 to be highest in abundance during snowfall if other processes did not dominate. In contrast, the measurements showed the highest average N_2O_5 mole ratios during clear conditions (**Fig. 2**), highlighting the importance of other effects, including wet scavenging. Further, as shown in the case study model simulations, discussed above, that did not consider scavenging, simulated N_2O_5 mole ratios were highest during the rainfall case

due to lower aerosol surface area concentrations, and second highest during the snowfall case because of the temperature effect (**Fig. 7**). Therefore, we conclude that temperature alone cannot explain the significant differences in N_2O_5 mole ratios between the clear, fog, rainfall, and snowfall conditions.

520 Relative humidity was also statistically significantly different between clear conditions and snowfall, fog, and rainfall, respectively ($p < 0.05$) across the SNACK field campaign (**Fig. 7d**). The average nighttime RH values were $75.0 \pm 0.5\%$, $83.0 \pm 0.3\%$, $90.2 \pm 0.4\%$, and $93.7 \pm 0.3\%$ during clear conditions, snowfall, rainfall, and fog, respectively. Higher RH typically increases N_2O_5 partitioning from the gas to aqueous phases (e.g. Osthoff et al., 2006; Sommariva et al., 2009; Wood et al., 2005). Indeed, 525 the pattern of N_2O_5 abundance was anticorrelated with RH (**Fig. 2** and **Fig. 7d**). This reinforces that N_2O_5 heterogeneous uptake is strongly RH dependent (Bertram et al., 2009; Davis et al., 2008; Evans and Jacob, 2005; Griffiths and Cox, 2009; Hallquist et al., 2003), with enhanced uptake and removal occurring when RH and aerosol liquid water content are high.

The box model overestimated ClNO_2 mole ratios for the clear case (by ~ 6 times), despite lower 530 simulated N_2O_5 mole ratios compared to modeled values (by $\sim 42\%$) (**Fig. 6**), as discussed in the Section S2. Since the chosen values for $[\text{NO}_2]$, N_2O_5 uptake, and ClNO_2 yield corresponded to previous work in wintertime Ann Arbor, MI (McNamara et al., 2020), this points to the variability and need to better constrain N_2O_5 uptake and ClNO_2 yield, as highlighted previously by McDuffie et al. (2018). However, realistic model conditions could be chosen to simulate the observed clear case N_2O_5 and ClNO_2 mole ratios (**Fig. S15 and S16**). In contrast to the clear case, realistic $[\text{NO}_2]$, N_2O_5 uptake, and ClNO_2 yield 535 values could not be chosen to simulate the observed ClNO_2 mole ratios, similar to the result for N_2O_5 mole ratios, discussed above. Average simulated ClNO_2 mole ratios were 400 ppt, 140 ppt, and 280 ppt for the snowfall, fog, and rainfall cases, respectively, during the last 4 h of the simulation (**Fig. 6**). In comparison, the maximum observed ClNO_2 mole ratios were 33.6 ppt, 2.5 ppt, and 3.2 ppt from 04:00- 540 08:00 EST of the snowfall, fog, and rainfall cases, respectively (**Fig. 6**). Further, the model drastically overpredicted ClNO_2 mole ratios during the fog case (by ~ 50 times, similar to the N_2O_5 mole ratio overprediction) and rainfall case (by ~ 90 times, as compared to ~ 30 times over-prediction of N_2O_5 mole ratios), but also over-predicted ClNO_2 mole ratios during the snowfall case (by ~ 12 times, as compared to ~ 5 times for N_2O_5 mole ratios). The similar overprediction of N_2O_5 and ClNO_2 during fog supports fog

545 droplet scavenging of N_2O_5 , in particular, as a missing sink in the model. The higher overprediction of ClNO_2 mole ratios, compared to N_2O_5 , during the rainfall case, in particular, suggests that ClNO_2 , in addition to N_2O_5 , likely undergoes scavenging/wet deposition.

We also investigated N_2O_5 and ClNO_2 levels in the context of observed $\text{PM}_{2.5} \text{Cl}^-$ and NO_3^- concentrations. The averages for these parameters are given for clear conditions and each type of weather event in **Table 1**, with additional data provided in **Table S2**. As shown by Bertram and Thornton (2009), both N_2O_5 uptake and the product yield of ClNO_2 are expected to increase with increasing particulate chloride concentrations. The effects of increased particulate chloride are two-fold, with less N_2O_5 expected to remain in the gas-phase due to the increased uptake, and a higher ClNO_2 abundance expected because of the higher product yield. $\text{PM}_{2.5} \text{Cl}^-$ concentrations were not statistically significantly different 555 between snowfall and clear conditions ($p=0.96$, t-test), between snowfall and rainfall ($p=0.11$), or between clear and rainfall conditions ($p=0.10$) (**Fig. 7a**).

$\text{PM}_{2.5} \text{Cl}^-$ concentrations were statistically significantly higher during fog, in comparison to clear conditions ($p<0.05$), with the average concentration during fog higher by $0.20\pm 0.01 \mu\text{g m}^{-3}$ (1.8 times) on average. Although total submicron aerosol number concentrations were not statistically significantly 560 different between clear and fog conditions ($p=0.88$), submicron aerosol surface area concentrations were significantly higher ($p<0.05$) during fog compared to clear conditions, by $52\pm 7 \mu\text{m}^2 \text{cm}^{-3}$ (1.3 times) with respect to campaign averages (**Fig. S11-S12**). N_2O_5 uptake is expected to increase with increasing aerosol surface area concentration (Bertram and Thornton, 2009), but despite elevated $\text{PM}_{2.5} \text{Cl}^-$ and aerosol surface area concentrations during fog, average ClNO_2 abundance was lower during fog in comparison 565 to clear conditions (**Fig. 2**). We expect that, during fog, elevated RH (**Fig. 7d**) has a greater impact on ClNO_2 abundance than $\text{PM}_{2.5} \text{Cl}^-$ concentration or aerosol surface area concentration. Production of particle-phase chloride, presumed to be from uptake of gas-phase HCl , has been observed previously during fog/haze events in highly polluted urban India (Gunthe et al., 2021) and near an incinerator (Johnson et al., 1987). However, for this study in Kalamazoo, MI, road salting seems more plausible as 570 the dominant source of increased $\text{PM}_{2.5} \text{Cl}^-$ during wintertime fog.

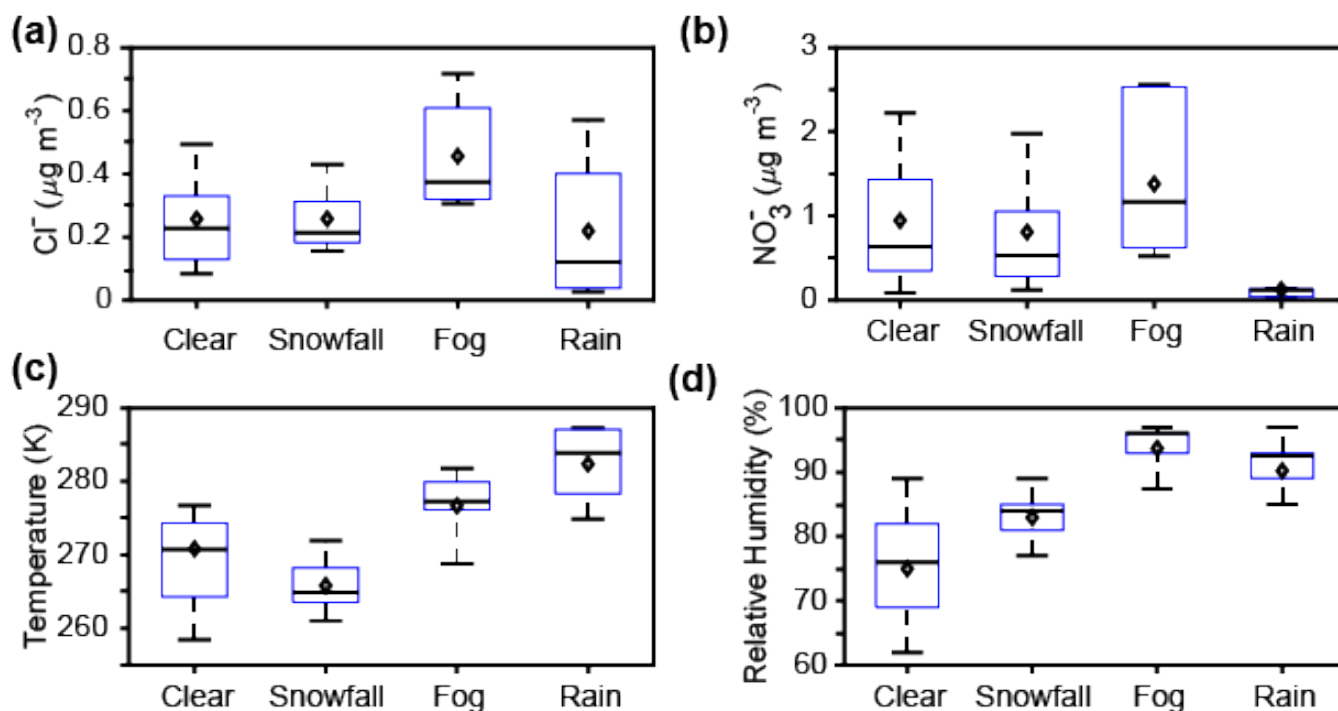

Figure 7. Box plots showing 30 min averaged PM_{2.5} (a) chloride and (b) nitrate concentrations, (c) air temperatures and (d) relative humidity values during clear conditions and weather events (snowfall, fog, and rain). Bars represent the 10th, 50th, and 90th percentiles, boxes represent the 25th and 75th percentiles, and diamonds represent the means. Only nighttime data, between 18:00 and 08:00 EST, are included.

N₂O₅ uptake results in particulate nitrate production; however, the efficiency of N₂O₅ uptake to particles decreases with increasing particulate nitrate concentrations (Bertram and Thornton, 2009). PM_{2.5} NO₃⁻ concentrations were not statistically significantly different between snowfall and clear conditions (p=0.08). PM_{2.5} NO₃⁻ concentrations during rain were statistically significantly lower, in comparison to clear conditions (p<0.05), with average concentrations lower by 0.82±0.04 μg m⁻³ (7.5 times) (Fig 6b). This is attributed to increased scavenging and wet deposition of nitrate during rainfall, compared to snowfall, which is consistent with previous observations and calculations of scavenging coefficients for nitrate during rainfall and snowfall in winter in New York (Sperber and Hameed, 1986).

Particles rich in nitrate have been observed previously in the droplet mode (0.8–0.9 μm) during fog events; these particles form following fog droplet evaporation after nitrate production from HNO₃ and N₂O₅ uptake (Dall’Osto et al., 2009; Ge et al., 2012). In contrast to rain and snowfall, PM_{2.5} NO₃⁻

concentrations were statistically significantly higher during fog, in comparison to clear conditions ($p < 0.05$), by $0.43 \pm 0.06 \mu\text{g m}^{-3}$ (160 ± 20 ppt; 1.5 times) (**Figs. 6b** and **S10**). The increase in $\text{PM}_{2.5} \text{NO}_3^-$ is likely, in part, the result of heterogeneous uptake and hydrolysis of N_2O_5 (Brown et al., 2004; Osthoff et al., 2006), consistent with our observation of the lower average N_2O_5 mole ratios during fog (**Fig. 2**). On average, N_2O_5 was 76 ± 5 ppt lower during fog compared to clear conditions (**Figs. 2** and **S10**). While this difference is not completely attributable to N_2O_5 uptake, it would correspond to a nitrate concentration of $0.21 \mu\text{g m}^{-3}$. In addition to N_2O_5 , gas-phase HNO_3 uptake likely also contributed to the increased $\text{PM}_{2.5} \text{NO}_3^-$ observed during fog. Due to its high solubility, HNO_3 is predicted to be efficiently scavenged by fog droplets (>90-100% removal) (Ervens, 2015). However, due to the limited HNO_3 data available (**Fig. S9**), a quantitative evaluation of HNO_3 contribution to nitrate production was not possible. It is likely that both N_2O_5 and HNO_3 uptake, followed by aqueous-phase nitrate formation, led to the increased $\text{PM}_{2.5} \text{NO}_3^-$ observed during fog.

600 **4 Conclusions**

We examined the impacts of precipitation (rain, snowfall) and fog, atmospheric turbulence, and ground cover (snow-covered vs bare) on near-surface (~ 1.5 m above ground) N_2O_5 and ClNO_2 observed during January to February 2018 in Kalamazoo, Michigan. While N_2O_5 was observed during all nights of the campaign, N_2O_5 mole ratios were lowest during periods of lower turbulence ($u^* < 0.1 \text{ m s}^{-1}$) due to titration of NO_3 and O_3 by NO in the stable nocturnal boundary layer. N_2O_5 mole ratios were not statistically significantly different over bare versus snow-covered ground. ClNO_2 mole ratios were highest during periods of lower turbulence and snow-covered ground. This is consistent with N_2O_5 depositing and reacting with the chloride-containing snowpack to produce ClNO_2 . Indeed, vertical gradient measurements during the same study showed N_2O_5 deposition and an average positive (production) ClNO_2 flux over snow-covered ground, and snow chamber experiments showed that synthesized N_2O_5 reacted with the local saline snow to produce ClNO_2 (McNamara et al., 2021). This finding is also consistent with the laboratory study by Lopez-Hilfiker et al. (2012), which showed that N_2O_5 can react on halide-doped ice surfaces to produce ClNO_2 . The contribution of the snowpack as a common ClNO_2

source across the field campaign has important implications for the vertical distribution of atmospheric
615 chlorine chemistry, which will be examined in a future manuscript through one-dimensional modeling
for comparison with chloride-containing aerosol particles that serve as a major ClNO₂ source.

On average, both N₂O₅ and ClNO₂ abundances were lowest during rainfall and fog due to
scavenging. While both species are water soluble, N₂O₅ undergoes more efficient scavenging by liquid
droplets, particularly fog, as expected based on its higher Henry's Law constant and uptake coefficient
620 (Fickert et al., 1998; Gržinić et al., 2017). N₂O₅ uptake by fog droplets likely contributed to observed
elevated PM_{2.5} NO₃⁻ during fog events. Little is known about N₂O₅ and ClNO₂ scavenging by
precipitation, supporting the need for further investigation of this process. Overall, our results show that
observational and modeling studies of only clear conditions miss important processes including
scavenging, fog nitrate production, and the snowpack as a ClNO₂ source. This is important as rainfall,
625 fog, and snowfall occurred during 28% of the nighttime periods, representing a significant portion that
contributes significantly to the variability observed during this winter study.

Acknowledgements

This study was supported by the US National Science Foundation Atmospheric Chemistry
program (AGS-1738588 and PLR-1417914), an Alfred P. Sloan Foundation Research Fellowship in
630 Chemistry, and the University of Michigan. J.E. acknowledges funding from the Swiss National Science
Foundation (155999). We thank Andrew Ault, Nicholas Ellsworth, and Matthew McNamara for

Data Availability

635 The CIMS and AIM-IC datasets are archived through PANGAEA: Kulju, Kathryn; Pratt, Kerri A
(2021): N₂O₅, ClNO₂, PM_{2.5} chloride, and PM_{2.5} nitrate in Kalamazoo, Michigan, USA during January-
February 2018. PANGAEA, 2021, <https://doi.org/10.1594/PANGAEA.933765>.

Author Contributions

KK wrote the manuscript, with feedback from all coauthors. KP designed the study, and SM and
640 JE conducted the measurements and calibrations. KK led data analysis and interpretation, with
contributions from SM, JE, QC, JDF, and KP. HK and KK completed the box modeling. JDF assisted
with the air turbulence measurements and analysis, in particular. SB coordinated logistics at the field site.

Competing Interests

The authors declare that they have no conflict of interest.
