9 **Abstract**

10 Nitrate is an increasingly important component of fine particulate matter (PM<sub>2.5</sub>)  
11 in Chinese cities. The production of nitrate is not only related to the abundance of its  
12 precursor, but also supported by atmospheric photochemical oxidants. The control of  
13 nitrogen oxides (NO<sub>x</sub>) emissions may thereby lead to nonlinear changes of nitrate  
14 concentrations, raising a new challenge to the current emission control actions in  
15 China. This paper uses comprehensive measurements and a regional meteorology-  
16 chemistry model with optimized mechanisms to establish the nonlinear responses  
17 between particulate nitrate and NO<sub>x</sub> emission controls in the megalopolises of China.  
18 Nitrate is an essential component of PM<sub>2.5</sub> in eastern China, accounting for 9.4–15.5%  
19 and 11.5–32.1% of the PM<sub>2.5</sub> mass for the warm and cold seasons. The hypothetical  
20 NO<sub>x</sub> emission reduction scenarios (–10%~–80%) during summer-autumn result in  
21 almost linearly lower PM<sub>2.5</sub> by –2.65% in Beijing-Tianjin-Hebei (BTH) and –2.79%  
22 in Yangtze River Delta (YRD) per 10% cut of NO<sub>x</sub> emissions, whereas they increase  
23 the oxidant levels and lead to a rather complicated response of PM components in  
24 winter. Wintertime nitrate is found to increase by 4.28% in BTH and 4.60% in YRD,  
25 with higher dinitrogen pentoxide (N<sub>2</sub>O<sub>5</sub>) intermediate products produced from

26 increased ozone introduced by lower NO<sub>x</sub> emissions. An inflexion point appears at  
27 40–50% NO<sub>x</sub> emission reduction, and a further cut in NO<sub>x</sub> emission is predicted to  
28 cause –8.74% reduction of nitrate for BTH and –10.59% for YRD per 10% cut of  
29 NO<sub>x</sub> emissions. In addition, the 2012–2016 NO<sub>x</sub> control strategy actually leads to no  
30 change or even increase of nitrate in some areas (8.82% in BTH and 14.41% in YRD)  
31 during winter. This paper helps understand the nonlinear aerosol and photochemistry  
32 feedbacks, and defines the effectiveness of proposed mitigations for the increasingly  
33 serious nitrate pollution in China.  
34

## 35 1 Introduction

36 Secondary inorganic aerosols (SIA), including sulfate ( $\text{SO}_4^{2-}$ ), nitrate ( $\text{NO}_3^-$ ) and  
37 ammonium ( $\text{NH}_4^+$ ) account for 30–60% of the total fine particulate matter ( $\text{PM}_{2.5}$ )  
38 mass during haze events in China (Huang et al., 2014a; Zhao et al., 2013). Since the  
39 enactment of the Air Pollution Action Plan in 2013, the Chinese government has  
40 taken drastic measures to reduce the emissions of sulfur dioxide ( $\text{SO}_2$ ), nitrogen  
41 oxides ( $\text{NO}_x$ ) and primary  $\text{PM}_{2.5}$ , leading to significant decreases in sulfate and  
42 overall  $\text{PM}_{2.5}$  concentrations in cities (Silver et al., 2018; Li et al., 2021a; Wang et al.,  
43 2017). Meanwhile, the nitrogen/sulfur (N/S) ratio in  $\text{PM}_{2.5}$  increased significantly and  
44 nitrate had been the main component of  $\text{PM}_{2.5}$  (16–45%) during haze episodes,  
45 despite a more than 20% reduction in the concentrations of its precursor  $\text{NO}_x$  (Shao et  
46 al., 2018; Wen et al., 2018; Zhai et al., 2019). The increasingly serious nitrate  
47 pollution has emerged to be the new emphasis of air pollution controls in China.

48 Nitrate formation involves complex multiphase chemical reactions. In the  
49 daytime, nitrogen dioxide ( $\text{NO}_2$ ) reacts with hydroxyl radical (OH) to produce nitric  
50 acid ( $\text{HNO}_3$ ). With excess ammonium ( $\text{NH}_3$ ), low temperature and insufficient  
51 sulphuric acid, this reaction can proceed quickly and produce high ammonium nitrate  
52 (Seinfeld and Pandis, 2006). In the nighttime, however, high-concentration  $\text{NO}_2$  reacts  
53 with ozone ( $\text{O}_3$ ) to produce the nitrate radical ( $\text{NO}_3$ ) and dinitrogen pentoxide ( $\text{N}_2\text{O}_5$ ).  
54 The heterogeneous hydrolysis of  $\text{N}_2\text{O}_5$  on wet particles is the main pathway for  
55 nocturnal nitrate formation (56–97%) (He et al., 2018; Pathak et al., 2011; Xue et al.,  
56 2014).

57 Nitrate chemistry is not only related to the abundance of its precursor  $\text{NO}_x$ , but  
58 also supported by atmospheric oxidants (OH and  $\text{O}_3$ ) produced from the  
59 photochemical reactions of  $\text{NO}_x$  and volatile organic compounds (VOCs) (Meng et al.,

60 1997). Using a box model, some studies have determined that the relationship  
61 between particulate nitrate and  $\text{NO}_x$  emissions is nonlinear depending on the ozone  
62 chemical sensitivity regime (Pun and Seigneur, 2001; Nguyen and Dabdub, 2002).  
63 Pun and Seigneur (2001) showed that the daytime  $\text{HNO}_3$  production was more  
64 sensitive to the concentration of atmospheric oxidants, and that in the VOC-limited  
65 regime the decrease of  $\text{HNO}_3$  production due to the  $\text{NO}_x$  emission control might be  
66 offset by the increase of OH. Nguyen and Dabdub (2002) calculated a detailed  
67 isopleth between nitrate and  $\text{NO}_x$  emission; they found that the reduction of  $\text{NO}_x$   
68 emission resulted in a decrease of nitrate in the  $\text{NO}_x$ -limited regime, and an increase  
69 of nitrate under extreme conditions in the VOC-limited regime. Despite that, the  
70 single-site box model results could not distinguish the regional differences among  
71 chemical regimes; the basic hypotheses in box models to predict nitrate production,  
72 e.g., stagnant atmosphere or fixed  $\text{NO}_2/\text{NO}_y$  ratio, are also unreasonable in the real  
73 atmosphere.

74 As an important precursor for both fine particles and ozone, the strict control of  
75  $\text{NO}_x$  emission has started in China since the 12<sup>th</sup> Five-Year Plan (Zheng et al., 2018).  
76 A confounding factor is that, for most cities in China, the production of  $\text{O}_3$  is usually  
77 limited by  $\text{VOC}_s$  (Liu et al., 2010). The control of  $\text{NO}_x$  emission has therefore  
78 resulted in an increase of  $\text{O}_3$  concentrations in recent years (Li et al., 2021a; Li et al.,  
79 2019a; Kalsoom et al., 2021), implying complex impacts on nitrate formation. Some  
80 simulations thought that the  $\text{NO}_x$  emission increase in 2005–2012 resulted in an  
81 increase of nitrate by  $3.4\% \text{ yr}^{-1}$  in eastern China (Geng et al., 2017; Wang et al.,  
82 2013), and the following  $\text{NO}_x$  emission control resulted in a decrease of nitrate by 3–  
83 14% (Wang et al., 2014). Recent evidence from field observations (Fu et al., 2020)  
84 and numerical simulations (Dong et al., 2014) suggested that the  $\text{NO}_x$  emission

85 reduction in China could result in an increase of nitrate in winter through increased  
86 photochemical oxidants and nocturnal  $\text{N}_2\text{O}_5$  chemistry, but a decrease in other seasons.  
87 In the next 5–10 years,  $\text{SO}_2$  emissions might level off in China, while  $\text{NO}_x$  emissions  
88 will become stringently controlled to ensure further air quality improvements (Zheng  
89 et al., 2018). Accurately understanding the nonlinear aerosol and photochemistry  
90 feedbacks is crucial to resolve the emerging nitrate pollution and to establish  
91 reasonable air pollution control strategies in China.

92 To address this issue, we use comprehensive measurements and a regional  
93 meteorology-chemistry model combined with hypothetical  $\text{NO}_x$  emission scenarios to  
94 establish the nonlinear response relationships between particulate nitrate and  $\text{NO}_x$   
95 emission controls in the megalopolises of China. The model configurations, numerical  
96 designs and observational data are presented in Sect. 2. Sect. 3 discusses the results.  
97 Finally, a summary is presented in Sect. 4.

## 98 **2 Materials and Methods**

### 99 **2.1 Model setup and experimental designs**

100 This study uses the Weather Research and Forecasting-Chemistry (WRF-Chem)  
101 model version 4.1 developed by Grell et al. (2002) to simulate the meteorology and  
102 atmospheric chemistry. The mesoscale meteorology and air quality simulations of  
103 WRF-Chem have been improved in terms of incorporating the satellite-derived land  
104 surface parameters (Li et al., 2014; Li et al., 2017), and optimizing the SIA formation  
105 pathways enhanced by mineral aerosols (Li et al., 2019b; Huang et al., 2014b).

106 The modeling domain covers two main megalopolises of China and its adjacent  
107 areas—the Beijing-Tianjin-Hebei (BTH) region and the Yangtze River Delta (YRD)  
108 region (Fig. 1). The modeling framework is configured with  $81 \times 86$  grid cells at 25 km  
109 horizontal resolution. The model is run with an 84-hour model cycle, with the first 12

110 hours discarded as spin-up time and model outputs of each model cycle to provide  
111 chemical initial conditions for the subsequent overlapping 84-hour simulation. The 6-  
112 hour,  $1^\circ \times 1^\circ$  National Centers for Environmental Prediction Final (NCEP/FNL)  
113 analysis fields are regularly input for the model initial and lateral boundary  
114 meteorological conditions.

115 The model physical configurations include the YSU boundary layer scheme  
116 (Noh et al., 2003), the RRTMG radiation scheme (Iacono et al., 2008), the Noah land  
117 surface scheme (Ek et al., 2003) and the Lin microphysics scheme (Lin et al., 1983).  
118 We have further updated the land cover type and vegetation data in WRF mesoscale  
119 model with the latest land surface parameters derived from Moderate Resolution  
120 Imaging Spectroradiometer (Li et al., 2014; Li et al., 2017).

121 The atmospheric chemistry is simulated using the Carbon Bond Mechanism  
122 version Z (CBMZ) (Zaveri and Peters, 1999) gas-phase chemistry module coupled  
123 with a four-bin sectional Model for Simulating Aerosol Interactions and Chemistry  
124 (MOSAIC) (Zaveri et al., 2008). The aqueous-phase chemistry is based on the  
125 Carnegie Mellon University (CMU) scheme including 50 species and more than 100  
126 reactions (Fahey and Pandis, 2001). Formation of SIA in the model accounts for the  
127 gas-phases oxidation of  $\text{SO}_2$  and  $\text{NO}_2$ , and aqueous-phase oxidation of  $\text{SO}_2$  by  
128 hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) and  $\text{O}_3$  in cloud. We have also optimized the SIA  
129 formation pathways by including the aqueous  $\text{SO}_2$  oxidation catalyzed by mineral  
130 ions and heterogeneous uptake of  $\text{SO}_2$ ,  $\text{NO}_2$ ,  $\text{NO}_3$ ,  $\text{N}_2\text{O}_5$  and  $\text{HNO}_3$  on mineral  
131 aerosols in the MOSAIC aerosol module (Li et al., 2019b; Huang et al., 2014b).

132 Anthropogenic emissions are adopted from the 2016 Multi-resolution Emission  
133 Inventory for China (MEIC) and the 2010 MIX-Asia emission inventory for regions  
134 outside of mainland China developed by Tsinghua University (<http://meicmodel.org>).

135 Biogenic emissions are calculated online using the Model of Emissions of Gases and  
136 Aerosols from Nature (Guenther et al., 2006).

137 A series of WRF-Chem simulations are designed as summarized in Table 1. In  
138 the baseline simulation (denoted as the B0 scenario), the anthropogenic emissions in  
139 China remain unchanged at the usual levels. Simulation N0 is the same as the base  
140 case B0, but it only considers the  $\text{NO}_2+\text{OH}$  gas-phase oxidation pathway for the  
141 production of nitrate aerosol. The B0 and N0 simulations are designed to distinguish  
142 the formation mechanisms for the high concentrations of nitrate aerosols during the  
143 warm and cold seasons. A group of sensitivity scenarios (C1~C8) are designed with  
144 the perturbed anthropogenic  $\text{NO}_x$  emissions in China cut by 10%, 20%...and 80%,  
145 respectively. The differences between B0 and C1~C8 simulations are calculated to  
146 illustrate the responses of particulate pollution in China's megacities to the  $\text{NO}_x$   
147 emission reduction scenarios. Another simulation (E1) is designed with the  
148 anthropogenic emission of  $\text{NO}_x$  in China set to the 2012 level to show the impacts of  
149 2012–2016  $\text{NO}_x$  control strategy on particulate pollution.

150 For all simulation scenarios, two month-long periods during the Campaign on  
151 Air Pollution and Urban Meteorology in Yangtze River Delta (CAPUM-YRD)—  
152 August 15 to September 16 (Period I) and November 24 to December 26 (Period II) in  
153 2016, are simulated to represent the warm and cold seasons, respectively (Shu et al.,  
154 2019). The complete simulation consists of thirteen 84-hour model cycles with the  
155 first 6 days as spin-up for chemistry and the remaining model outputs for analysis.

## 156 **2.2 Weather and air pollutants data**

157 Surface meteorological observations at 186 land-based automatic stations in  
158 China (Fig. 1) are collected for model meteorological validation, including hourly

159 data of 2 m air temperature, 2 m relative humidity and 10 m wind speed. These data  
160 are archived at the U. S. National Climatic Data Center (NCDC) (Smith et al., 2011).

161 Air pollutants data at the national air quality monitoring network and regional  
162 supersites of China (Fig. 1) are used for model chemical validation. Six routine air  
163 pollutants including particulate matter with aerodynamic diameter less than 10  $\mu\text{m}$   
164 ( $\text{PM}_{10}$ ),  $\text{PM}_{2.5}$ ,  $\text{SO}_2$ ,  $\text{NO}_2$ , carbon monoxide (CO) and  $\text{O}_3$  are monitored and reported  
165 hourly by Chinese National Environmental Monitoring Center (CNEMC) network  
166 (available at <http://websearch.mep.gov.cn/>). This nationwide monitoring network  
167 includes 1597 sites covering 454 cities in mainland China, as shown in Fig. 1.

168 Additionally, four comprehensive atmospheric environment supersites in YRD  
169 including Dianshanhu (DSH; 31.1°N, 121.0°E), Pudong (PD; 31.2° N, 121.5°E),  
170 Nanjing (NJ; 32.1°N, 118.8°E) and Hangzhou (HZ; 30.3°N, 120.2°E) measured the  
171 mass concentrations of  $\text{PM}_{2.5}$ , water-soluble ions (sulfate, nitrate, ammonium, sodium,  
172 chloride, potassium, calcium and magnesium), carbonaceous aerosols (elemental  
173 carbon (EC) and organic carbon (OC)) and gaseous pollutants ( $\text{SO}_2$ ,  $\text{NO}_2$ , CO and  $\text{O}_3$ )  
174 during the CAPUM-YRD campaign. Details for the methods and data at the four  
175 supersites are described in Shu et al. (2019).

## 176 **3 Results and discussions**

### 177 **3.1 Model weather and chemical validation**

178 Model evaluations indicate that the WRF-Chem model is able to simulate the  
179 weather and atmospheric pollution characteristics in China. The simulated magnitudes  
180 of surface temperature by WRF-Chem in general agree with actual observations, with  
181 a correlation efficient ( $R$ ) of 0.89 and 0.94, and a normalized mean bias (NMB) of  
182  $-0.55\%$  and  $-0.80\%$  respectively in Period I and Period II (Table 2). Underestimation  
183 of relative humidity ( $-5.65\%$  in Period I and  $-6.56\%$  in Period II) is common in the

184 WRF simulation and is attributed to the influence of the boundary layer  
185 parameterization on the weather forecast (Bhati and Mohan, 2018; Gomez-Navarro et  
186 al., 2015). Clear overestimation of wind speed (23.72% in Period I and 40.64% in  
187 Period II) might be because of the unresolved topography in WRF (Jimenez et al.,  
188 2013; Li et al., 2014).

189 The predicted concentrations of routine air pollutants also faithfully captures the  
190 spatial and seasonal patterns of observed surface PM<sub>2.5</sub>, SO<sub>2</sub>, NO<sub>2</sub> and O<sub>3</sub> levels in  
191 both seasons (Fig. 2). Both simulations and observations display high air pollutant  
192 concentrations in the vicinity of North China Plain (NCP) and eastern China, but with  
193 higher O<sub>3</sub> levels in the warm seasons and oppositely higher PM<sub>2.5</sub> and other gaseous  
194 pollutants in winter. The model statistical evaluations show a MB of -3.66, -1.14, 4.7  
195 and 18.32 μg m<sup>-3</sup>, and NMB of -9.92, -6.46, 16.47 and 7.72% for PM<sub>2.5</sub>, SO<sub>2</sub>, NO<sub>2</sub>  
196 and O<sub>3</sub> in Period I, and a relatively larger MB of -27.31, -11.65, 1.27 and -39.01 μg  
197 m<sup>-3</sup>, and NMB of -29.82, -28.11, 2.40 and -31.05% in Period II, respectively (Table  
198 3). The uncertainty in emissions data, the absence of secondary organic aerosol in  
199 MOSAIC aerosol chemistry or the simulated wind errors may be responsible for the  
200 larger atmospheric chemical biases in winter, which has been extensively discussed in  
201 some studies (Zhao et al., 2016; Li et al., 2021a).

202 As the most important component of PM<sub>2.5</sub>, reasonable representation of SIA is  
203 imperative to PM<sub>2.5</sub> simulation. Evaluations with measurements of PM<sub>2.5</sub> components  
204 at the four supersites of eastern China show that the model performs reasonably in  
205 simulating the seasonal variations and proportions of aerosol species in PM<sub>2.5</sub>, but it is  
206 biased low by 10–40% in simulating the magnitudes of SIA concentrations (Fig. 3).  
207 The model underestimation is -1.8, -2.2 and -2.2 μg m<sup>-3</sup> for sulfate, nitrate and  
208 ammonium, respectively, in Period I, and -2.6, -4.3 and -3.4 μg m<sup>-3</sup> in Period II. The

209 model also captures the large change of S/N ratios from the warm to cold seasons, that  
210 vary from 2.4 in Period I to 0.6 in Period II. Our previous work (Li et al., 2019) has  
211 confirmed that the optimized aqueous and heterogeneous SIA formation pathways in  
212 WRF-Chem significantly reduce the model biases by 41.38% for sulfate and 44.55%  
213 for nitrate during the CAPUM-YRD campaign of 2016. Recent studies highlighted  
214 that the remaining SIA simulation biases may be attributed to the missing aqueous  
215 oxidation of SO<sub>2</sub> by NO<sub>2</sub> on alkaline aerosols under humid conditions (Wang et al.,  
216 2016; Cheng et al., 2016).

### 217 **3.2 Air pollution and aerosol composition characteristics**

218 Chemical composition analyses of major gaseous and particulate air pollutants  
219 suggest large seasonal variations of air pollution characteristics in China (Fig. 2).  
220 Mainly emitted from combustion sources, atmospheric pollutants accumulate in the  
221 densely industrialized and populated megalopolises of China, with a hotspot along  
222 Beijing, Hebei, Shandong and their adjacent cities frequently exceeding China's  
223 National Ambient Air Quality Standards. The average concentrations of PM<sub>2.5</sub>, SO<sub>2</sub>,  
224 NO<sub>2</sub> and daily-maximum O<sub>3</sub> in China's routine air quality monitoring network are  
225 36.88, 17.65, 28.53 and 237.45 μg m<sup>-3</sup> for Period I, and 91.59, 41.45, 53.01 and  
226 125.62 μg m<sup>-3</sup> for Period II. The PM<sub>2.5</sub>, SO<sub>2</sub> and NO<sub>2</sub> concentrations show obvious  
227 increases by 148.35%, 134.84% and 85.80% during winter. The maximum PM<sub>2.5</sub>  
228 concentration recorded in the winter period could be more than 600 μg m<sup>-3</sup>, which is  
229 the highest value ever recorded in 2016 and leads to the "orange" air quality alert.

230 The further analyses of PM<sub>2.5</sub> mass concentrations, major PM<sub>2.5</sub> components and  
231 gases at the four supersites in YRD are presented in Fig. 4–5. Organic matter (OM) is  
232 obtained by multiplying the OC concentrations by a factor of 1.6, accounting for the  
233 hydrogen and oxygen in organic compounds. The measured SIA concentrations

234 exhibit high levels, with average values of  $18.8 \mu\text{g m}^{-3}$  for Period I and  $37.1 \mu\text{g m}^{-3}$   
235 for Period II. The three SIA components together account for 48.6% and 56.9% of the  
236 total  $\text{PM}_{2.5}$  mass concentrations, and become the dominant components of  $\text{PM}_{2.5}$  in  
237 the two periods. The ratios of sulfate, nitrate and ammonium in total  $\text{PM}_{2.5}$  range from  
238 13.5–28.9%, 9.4–15.5% and 9.4–14.9% at the four supersites for Period I, and 9.2–  
239 20.3%, 11.5–32.1% and 7.0–19.8% for Period II, respectively. The higher proportion  
240 of nitrate in  $\text{PM}_{2.5}$  than that of sulfate during winter, with a sulfur/nitrogen (S/N) ratio  
241 of 0.64, is in accordance with recent observations during other winter haze periods in  
242 China (Shao et al., 2018; Zhang et al., 2018; Zhang et al., 2019). They emphasized  
243 that since the enactment of Clean Air Action Plan in 2013, the  $\text{PM}_{2.5}$  components had  
244 changed clearly with decreasing contributions from coal combustion.

245 The high proportions of sulfate and nitrate in  $\text{PM}_{2.5}$  could be related to the high  
246 oxidation rates of  $\text{SO}_2$  and  $\text{NO}_2$ . The observed average values of sulfur oxidation ratio  
247 ( $\text{SOR} = [\text{SO}_4^{2-}] / ([\text{SO}_4^{2-}] + [\text{SO}_2])$ ) and nitrogen oxidation ratio ( $\text{NOR} = [\text{NO}_3^-] / ([\text{NO}_3^-]$   
248  $]+ [\text{NO}_2])$ ) are 0.41 and 0.13 in Period I, and 0.33 and 0.21 in Period II, indicating  
249 enhanced secondary oxidation formation. Figure 6 illustrates the contributions of each  
250 formation pathway for the high concentrations of nitrate calculated from B0 and E0  
251 simulations. It is shown that on a daily basis the gas-phase oxidation production of  
252  $\text{HNO}_3$  and its subsequent partitioning to the aerosol phase is the principal formation  
253 route for particulate nitrate, with the average contributions of 60.19% for BTH and  
254 91.71% for YRD in Period I and 75.14% for BTH and 85.94% for YRD in Period II,  
255 heterogeneous hydrolysis of  $\text{N}_2\text{O}_5$  and other reactive nitrogen gases contributed to the  
256 remaining nitrate particularly in BTH with high aerosol loading. These results are in  
257 line with previous assessments (Alexander et al., 2009; Wen et al., 2018; Sun et al.,

258 2018), which reported that the global tropospheric nitrate burden is dominated by  
259 nitrate formation via  $\text{NO}_2+\text{OH}$  (76%), followed by  $\text{N}_2\text{O}_5$  hydrolysis (18%).

### 260 **3.3 Nonlinear responses of $\text{PM}_{2.5}$ to $\text{NO}_x$ emissions and their policy implication**

#### 261 **3.3.1 $\text{PM}_{2.5}$ - $\text{NO}_x$ and $\text{O}_3$ - $\text{NO}_x$ responses in the warm and cold seasons**

262  $\text{NO}_x$  is key in atmospheric chemistry and serves as an important precursor for  
263 both ozone and secondary aerosols. We conduct a series of simulations with perturbed  
264  $\text{NO}_x$  emissions ( $-10\%$ – $-80\%$ ) to assess the responses of  $\text{PM}_{2.5}$  mass concentrations to  
265  $\text{NO}_x$  emissions in two megalopolises of China (Fig. 7). The WRF-Chem simulation  
266 results show that the responses of surface  $\text{PM}_{2.5}$  concentrations to  $\text{NO}_x$  emissions vary  
267 in different seasons and display strong nonlinear in winter. To better quantify their  
268 effectiveness, we define the  $\text{NO}_x$  emission control efficiency ( $\beta$ ), denoting the  
269 percentage change of  $\text{PM}_{2.5}$  or its components concentrations in response to  
270 successive 10% cut of  $\text{NO}_x$  emission. In Period I (Aug–Sep), the  $\text{PM}_{2.5}$ - $\text{NO}_x$  responses  
271 are closer to a linear function, reflecting a stronger sensitivity to  $\text{NO}_x$  emission  
272 changes in the warm season. The surface  $\text{PM}_{2.5}$  concentrations decrease almost  
273 linearly as we gradually reduce  $\text{NO}_x$  emissions in China, with the  $\beta$  values of  $-2.65\%$   
274 in BTH and  $-2.79\%$  in YRD. However, the  $\text{PM}_{2.5}$ - $\text{NO}_x$  emission responses in Period  
275 II (Nov–Dec) display strong nonlinearity and are analogous to a bell-shaped  
276 distribution for both regions. The  $\text{NO}_x$  emission reduction within the first 50% would  
277 even increase surface mean  $\text{PM}_{2.5}$  concentrations by  $+1.33\%$  in BTH, and this  $\beta$  value  
278 increases to  $+1.42\%$  in YRD with the first 40%  $\text{NO}_x$  emission reduction.  
279 Subsequently, the  $\text{PM}_{2.5}$  responses shift towards a similar linear pattern, with a  $\beta$   
280 value of  $-3.47\%$  in BTH and  $-3.89\%$  in YRD.

281 The distinct forms of  $\text{PM}_{2.5}$ - $\text{NO}_x$  emission responses in the warm and cold  
282 seasons are determined by the changing features of SIA concentrations in response to

283 NO<sub>x</sub> controls (Fig. 8–9) under the seasonal ozone chemical sensitivity regimes. The  
284 photochemical indicator of  $\Delta[\text{O}_3]_{\text{NO}_x}/\Delta[\text{O}_3]_{\text{VOC}_s}$  with a critical value of 1.0 is used to  
285 investigate the season-varying ozone sensitivity in China, which is calculated as the  
286 ratio of ozone concentration changes under 20% NO<sub>x</sub> emission reduction to that under  
287 20% VOC<sub>s</sub> emission reduction (Fig. S1). The results indicate a strong VOC-limited  
288 ozone chemistry across China during winter, while either VOC-limited regime over a  
289 large portion of NCP and eastern China or NO<sub>x</sub>-limited regime in northern and  
290 western China during summer-autumn, as also indicated from previous studies (Xie et  
291 al., 2014; Dong et al., 2014; Liu et al., 2010). We find larger O<sub>3</sub> and OH productions  
292 under lower NO<sub>x</sub> emission conditions in both seasons, particularly in Period II (Nov–  
293 Dec) with an increase rate of 28.51% and 36.92% in BTH and 34.36% and 33.6% in  
294 YRD per 10% cut of NO<sub>x</sub> emission than the base case (Fig. 8–9(b, d)). The SIA  
295 formation chemistry is highly limited by atmospheric oxidants produced from the  
296 NO<sub>x</sub>-VOC<sub>s</sub>-O<sub>3</sub> photochemical cycles. The nonlinear O<sub>3</sub>-NO<sub>x</sub> responses indicate a  
297 rather complicated aerosol and photochemistry feedback in megacities.

### 298 3.3.2 Nonlinear responses of particulate nitrate to NO<sub>x</sub> emissions

299 The SIA formation chemistry is basically driven by atmospheric oxidants levels,  
300 and a reduction of NO<sub>x</sub> emission may have counter-intuitive effects on SIA  
301 components by controlling atmospheric oxidants levels. The calculated SIA  
302 components for each emission scenario in both months show that sulfate has minor  
303 changes with reducing NO<sub>x</sub> emissions but nitrate and ammonium aerosols can be  
304 substantially decreased/increased (Fig. 8–9).

305 Response of sulfate to the NO<sub>x</sub> emissions is more predictable and determined by  
306 the changes of atmospheric oxidant levels since that the conversion of SO<sub>2</sub> to sulfate  
307 is mainly driven by OH in the gas-phase and by dissolved H<sub>2</sub>O<sub>2</sub> or O<sub>3</sub> in the presence

308 of fog or cloud. In Period I (Aug–Sep), the sulfate-NO<sub>x</sub> response follows a bell-  
309 shaped distribution as that of O<sub>3</sub>-NO<sub>x</sub> response curve, with a fitted curve in Eq. 1. The  
310 surface sulfate concentrations has minor changes by −6.69%~+2.33% in BTH and by  
311 −9.55%~+3.47% in YRD under the −10~−80% NO<sub>x</sub> emission reduction scenarios.

$$312 \quad [\text{SO}_4^{2-}] = -2.45\Delta E_{\text{NO}_x}^2 - 2.15\Delta E_{\text{NO}_x} + 5.90 \text{ in BTH} \quad (\text{Eq. 1})$$

$$313 \quad [\text{SO}_4^{2-}] = -2.26\Delta E_{\text{NO}_x}^2 - 1.31\Delta E_{\text{NO}_x} + 6.65 \text{ in YRD}$$

314 where [SO<sub>4</sub><sup>2-</sup>] is the surface mean concentration of sulfate (μg m<sup>-3</sup>); ΔE<sub>NO<sub>x</sub></sub> is the  
315 percentage change of NO<sub>x</sub> emission (%).

316 As expected, the production of nitrate reflects a strong sensitivity to NO<sub>x</sub> and it  
317 decreases linearly with the NO<sub>x</sub> emission control, with a β value of −10.89% in BTH  
318 and −11.39% in YRD, which further leads to a decrease of ammonium concentrations  
319 by −4.10% in BTH and −4.73% in YRD. The formation of nitrate involves the  
320 NO<sub>2</sub>+OH→HNO<sub>3</sub> gas-phase oxidation and the heterogeneous hydrolysis of N<sub>2</sub>O<sub>5</sub>.  
321 The strong sensibility of particulate nitrate in response to NO<sub>x</sub> decrease can be  
322 explained by its synchronously suppressive production of intermediate products  
323 HNO<sub>3</sub> and N<sub>2</sub>O<sub>5</sub>. For example, when the NO<sub>x</sub> emission is cut by 20%, the surface  
324 NO<sub>2</sub> concentration in BTH drops by 21.96% but O<sub>3</sub> increases slightly by 2.56% due to  
325 greater VOC availability in warm season, leading to substantial reductions in the  
326 surface HNO<sub>3</sub> (−16.72%) and N<sub>2</sub>O<sub>5</sub> (−8.94%) concentrations.

327 In Period II (Nov–Dec), we find opposite results with bell-shaped distributions  
328 for nitrate-NO<sub>x</sub> response (Eq. 2) and ammonium-NO<sub>x</sub> response (Eq. 3), and linearly  
329 increasing sulfate concentrations (β=+1.34% in BTH and +2.29% in YRD) in the  
330 VOC-poor environment, leading to small PM<sub>2.5</sub> changes in winter. Such nonlinear  
331 nitrate-NO<sub>x</sub> emission responses can be explained by the derived excess oxidants as we  
332 gradually reduce NO<sub>x</sub> emissions in each scenario. It is noted that in winter the nitrate-

333 NO<sub>x</sub> response is determined by the production of N<sub>2</sub>O<sub>5</sub> intermediate product, which is  
334 more sensitive to the concentration of atmospheric oxidants under low NO<sub>x</sub> emission  
335 reduction conditions. The significant increase of surface O<sub>3</sub> in each NO<sub>x</sub> emission  
336 scenario leads to an enhancement of N<sub>2</sub>O<sub>5</sub> level from 10% to more than 100%, which  
337 is produced from the  $NO_2 \xrightarrow{O_3} NO_3 \xrightarrow{NO_2} N_2O_5$  chemical reaction and is a crucial intermediate  
338 product for nitrate formation. In spite of the HNO<sub>3</sub> concentration remaining nearly  
339 unchanged or decreasing slightly by less than 5% in response to NO<sub>x</sub> control, nitrate  
340 is found to increase ( $\beta=+4.28\%$  in BTH and  $+4.60\%$  in YRD) with higher N<sub>2</sub>O<sub>5</sub>  
341 produced from the increased ozone introduced by attenuated titration. An inflexion  
342 point appears at the 40–50% NO<sub>x</sub> emission reduction scenario, and a further reduction  
343 in NO<sub>x</sub> emission is predicted to cause  $-8.74\%$  and  $-6.18\%$  reductions of particulate  
344 nitrate and ammonium for BTH, and  $-10.59\%$  and  $-8.17\%$  for YRD.

345  $[NO_3^-] = -34.54\Delta E_{NO_x}^2 - 30.66\Delta E_{NO_x} + 10.52$  in BTH (Eq. 2)

346  $[NO_3^-] = -36.53\Delta E_{NO_x}^2 - 26.94\Delta E_{NO_x} + 9.70$  in YRD

347  $[NH_4^+] = -9.12\Delta E_{NO_x}^2 - 8.73\Delta E_{NO_x} + 5.40$  in BTH (Eq. 3)

348  $[NH_4^+] = -10.55\Delta E_{NO_x}^2 - 8.36\Delta E_{NO_x} + 4.58$  in YRD

349 where  $[NO_3^-]$  and  $[NH_4^+]$  are the surface mean concentrations ( $\mu\text{g m}^{-3}$ ) of nitrate  
350 and ammonium, respectively.

351 These results reveal that the increase in atmospheric oxidants in response to NO<sub>x</sub>  
352 control can offset the decreasing precursor concentrations and further enhance the  
353 formation of secondary nitrate, as recently found during the COVID-19 pandemic  
354 (Huang et al., 2020; Li et al., 2021b). Our results provide insights for developing  
355 mitigation strategies for the ubiquitous secondary aerosols in winter haze of China.

### 356 **3.3.3 Impacts of 2012–2016 NO<sub>x</sub> control strategy on particulate pollution**

357 During the 12<sup>th</sup> Five-Year Plan period (2011–2015), a series of end-of-pipe  
358 pollutant controls (e.g., Selective Catalytic Reduction techniques) were carried out for  
359 power, industry and transportation sectors. These measures effectively controlled the  
360 national NO<sub>x</sub> emissions by 22.8% from 2012 to 2016 (MEIC v1.3) in China. To  
361 quantify the effects of recent NO<sub>x</sub> control measures on the levels of photochemical  
362 oxidants and particulate nitrate, we conduct an additional simulation with NO<sub>x</sub>  
363 emissions set to the levels of 2012 in E1.

364 The model simulations (Fig. 10) suggest that reducing China's NO<sub>x</sub> emissions  
365 alone from 2012 to 2016 leads to an average  $-24.93\%$ ~ $-8.62\%$  decrease of NO<sub>x</sub>  
366 concentrations in the surface layer. As previously pointed out, the 2012–2016 NO<sub>x</sub>  
367 emission control measures lead to increased O<sub>3</sub> and OH levels in winter, which offset  
368 the effectiveness of NO<sub>x</sub> emission reduction in alleviating winter nitrate. No obvious  
369 declines in the winter nitrate levels are observed and even increase in some areas  
370 ( $+8.82\%$  in BTH and  $14.41\%$  in YRD; Fig. S2–S3). As shown, the largest PM<sub>2.5</sub>  
371 responses shift towards the southern Hebei and central China provinces, where the  
372 wintertime PM<sub>2.5</sub> concentrations are particularly high in this region. The substantial  
373 emission changes from 2012 to 2016 lower the PM<sub>2.5</sub> air pollution by up to  $-1.84\%$  in  
374 BTH and  $-3.52\%$  in YRD for Period I and oppositely increase PM<sub>2.5</sub> by  $2.36\%$  in  
375 BTH and  $4.67\%$  in YRD for Period II. The past NO<sub>x</sub> emission control strategy leads  
376 to increased atmospheric oxidant levels and deteriorate particulate pollution in winter  
377 due to the nonlinear photochemistry and aerosol chemical feedbacks, without regard  
378 to the other control measures. This conclusion is also supported by evidence from the  
379 recent field observations (Fu et al., 2020).

#### 380 **4 Conclusions**

381       Recent air pollution actions have significantly lowered the PM<sub>2.5</sub> levels in China  
382 via controlling emissions of SO<sub>2</sub> and NO<sub>x</sub>, but raised a new question of how effective  
383 NO<sub>x</sub> emission controls can be on the mitigation of emerging nitrate and ozone air  
384 pollution. We use comprehensive measurements and a regional meteorology-  
385 chemistry model with optimized mechanisms to establish the nonlinear responses  
386 between particulate nitrate and NO<sub>x</sub> emission controls in the megalopolises of China.

387       Nitrate is an essential component of PM<sub>2.5</sub> in eastern China, accounting for 9.4–  
388 15.5% and 11.5–32.1% of the total PM<sub>2.5</sub> mass for the warm and cold seasons,  
389 respectively. We find that the efficiency of PM<sub>2.5</sub> reduction is highly sensitive to NO<sub>x</sub>  
390 emission and it varies in different seasons depending on the ozone chemical regimes.  
391 The reduction of NO<sub>x</sub> emissions during summer-autumn results in almost linearly  
392 lower PM<sub>2.5</sub> by –2.65% in BTH and –2.79% in YRD per 10% cut of NO<sub>x</sub> emissions,  
393 whereas it increases the atmospheric oxidant levels (28.51% and 36.92% for O<sub>3</sub> and  
394 OH in BTH and 34.36% and 33.6% in YRD) and leads to a rather complicated  
395 response of the PM components in winter. Nitrate is found to increase ( $\beta$ =+4.28% in  
396 BTH and +4.60% in YRD) in winter with higher N<sub>2</sub>O<sub>5</sub> intermediate produced from  
397 the increased ozone introduced by attenuated titration, despite the nearly unchanged  
398 or slightly decreased HNO<sub>3</sub> concentrations in response to NO<sub>x</sub> control. An inflexion  
399 point appears at 40–50% NO<sub>x</sub> emission reduction, and a further reduction of NO<sub>x</sub>  
400 emission is predicted to cause –8.74% reductions of particulate nitrate for BTH and  
401 –10.59% for YRD. In addition, the 2012–2016 NO<sub>x</sub> emission control strategy leads to  
402 –24.93%–8.62% decrease of surface NO<sub>x</sub>, and no change or even increase of  
403 wintertime nitrate in BTH (+8.82%) and YRD (14.41%).

404 Our results emphasize that future  $PM_{2.5}$  pollution mitigation strategies should  
405 also focus on reducing the key oxidants involved in secondary aerosol production.  
406  $VOC_s$ , which is not a direct precursor for SIA, is effective in SIA controls due to their  
407 influence on atmospheric oxidation cycles (Tsimpidi et al., 2008; Womack et al., 2019;  
408 Nguyen and Dabdub, 2002). Womack et al. (2019) evaluated the impacts of  
409 traditional ozone mitigation strategies on ammonium nitrate production in the Salt  
410 Lake Valley, USA. They found that the ammonium nitrate aerosol pollution is  
411 responsive to  $VOC_s$  control and not initially responsive to  $NO_x$  control. Tsimpidi et al.  
412 (2008) also showed that the reduction of  $VOC_s$  emissions caused a marginal increase  
413 of  $PM_{2.5}$  during summer in eastern United States, whereas it resulted in a decrease of  
414 oxidant levels and 5–20% reduction of both inorganic and organic  $PM_{2.5}$  components  
415 during winter. Larger and synchronized  $NO_x$  and  $VOC_s$  emissions reductions are  
416 required to overcome the adverse effects of nonlinear photochemistry and aerosol  
417 chemical feedbacks.

418 Atmospheric  $NH_3$  also acts as a critical neutralizing species for SIA production  
419 and efficient haze mitigation (Liu et al., 2019). Atmospheric chemistry modeling  
420 indicated that controlling  $NH_3$  emission would significantly reduce the population-  
421 weighted  $PM_{2.5}$  concentration by 6.2–21% with 60–100%  $NH_3$  reductions in January,  
422 implying the need to consider  $NH_3$  emission controls when designing the  $PM_{2.5}$   
423 pollution mitigation strategies (Wen et al., 2021). China's anthropogenic emissions are  
424 estimated to decrease by 62% for  $SO_2$  and 17% for  $NO_x$  over 2010–2017, while  
425  $NH_3$  emissions slightly increased by 1% (Zheng et al., 2018). The recent “Three-year  
426 Action Plan Fighting for a Blue Sky” calls for agricultural  $NH_3$  emission controls but  
427 without a specific reduction target. Such emission changes would emphasize the need  
428 to jointly consider multi-pollutants emissions controls for mitigating SIA air pollution.

429 **Author contribution**

430 Mengmeng Li developed the model code, designed the numerical experiments,  
431 and wrote the original draft. Zihan Zhang carried out the numerical experiments. Shu  
432 Li and Bingliang Zhuang validated and analyzed the model results. Tijian Wang and  
433 Min Xie reviewed and revised the manuscript.

434 **Competing interests**

435 The authors declare that they have no conflict of interest.

669

670 **Table 1.** The emission scenarios in WRF-Chem numerical experiments

Simulation scenarios	Descriptions
B0	Base simulation under the 2016 emission conditions.
N0	Same as B0, but only consider the gas-phase oxidation pathway for the production of nitrate aerosol.
$C_N$ ( $N=1/2/\dots/8$ )	Same as B0, but anthropogenic $\text{NO}_x$ emissions are reduced by 10%, 20%...80%, respectively, relative to the usual levels in 2016.
E1	Same as B0, but anthropogenic $\text{NO}_x$ emissions are replaced using the MEIC inventory in 2012.

671

672 **Table 2.** Statistical evaluations of the model meteorological performance

Variable	Obs	Sim	$R^a$	MB <sup>a</sup>	NMB <sup>a</sup>	ME <sup>a</sup>	RMSE <sup>a</sup>
Period I (15 August to 16 September)							
Temperature (°C)	24.04	23.91	0.89	-0.13	-0.55%	1.98	2.63
Humidity (%)	70.89	66.88	0.78	-4.01	-5.65%	11.07	14.67
Wind speed ( $\text{m s}^{-1}$ )	2.46	3.04	0.50	0.58	23.72%	1.38	1.83
Period II (24 November to 26 December)							
Temperature (°C)	3.43	3.40	0.94	-0.03	-0.80%	2.18	2.83
Humidity (%)	69.85	65.27	0.63	-4.58	-6.56%	13.51	17.88
Wind speed ( $\text{m s}^{-1}$ )	2.61	3.66	0.55	1.06	40.64%	1.70	2.23

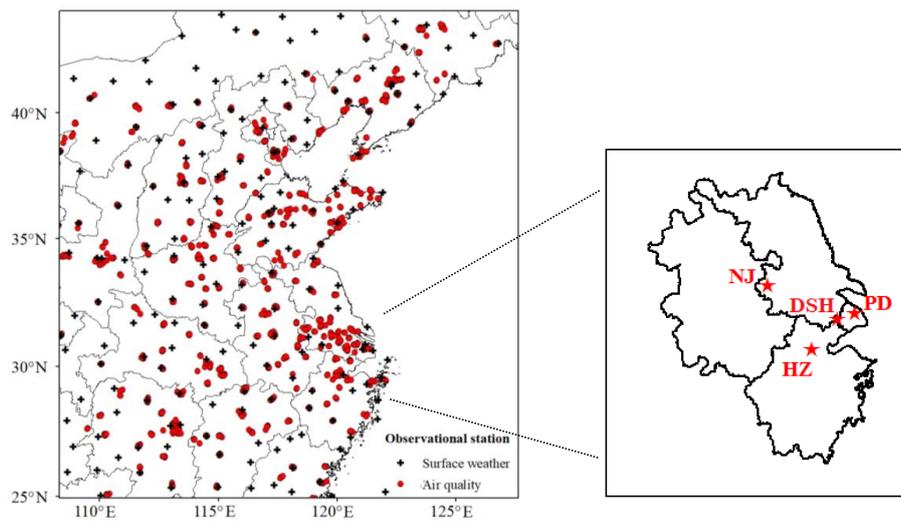

673 <sup>a</sup>  $R$ : correlation efficient; MB: mean bias; NMB: normalized mean bias; ME: mean  
 674 error; RMSE: root mean square error.

675

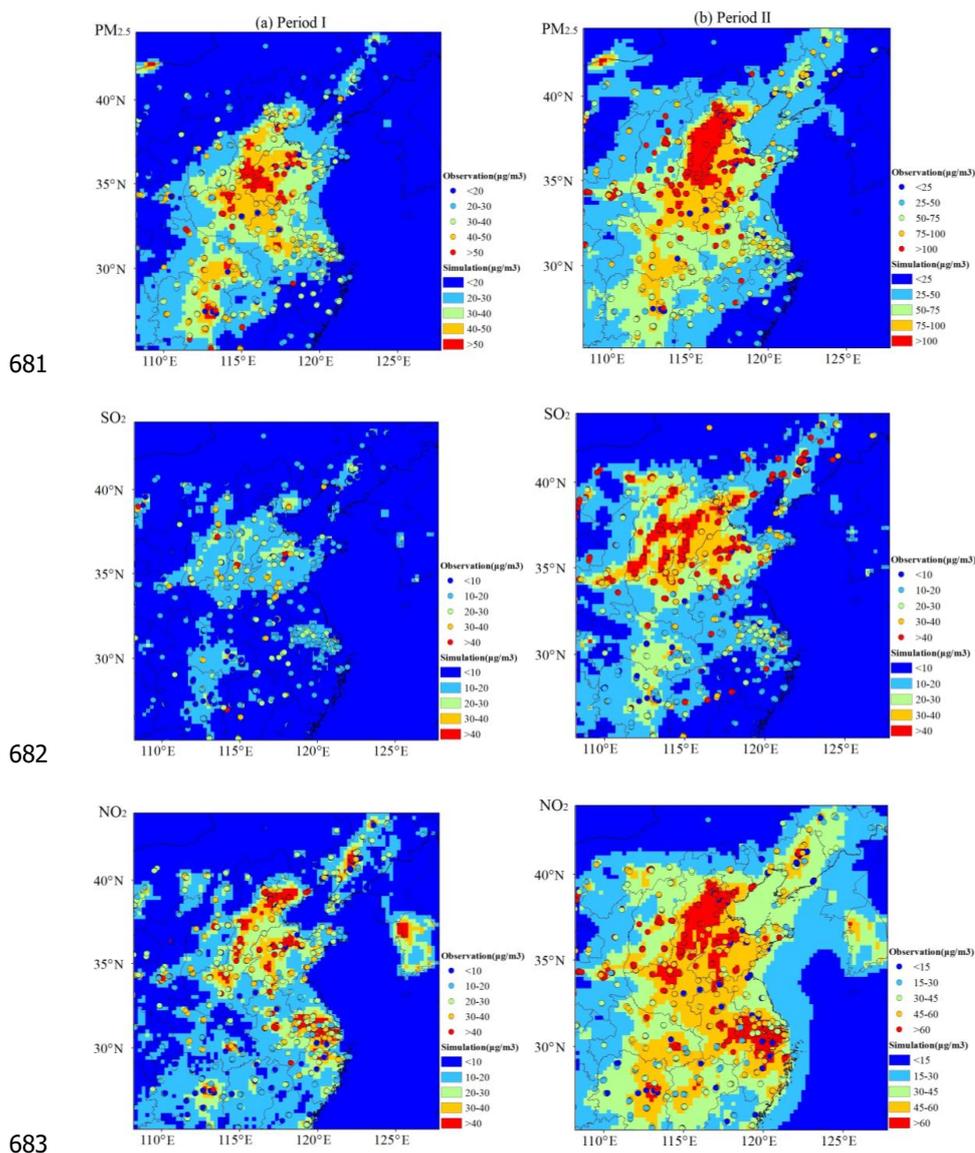

676 **Table 3.** Statistical evaluations of the model chemical performance

Variable	Obs	Sim	MB	NMB	Period I		Period II	
					Obs	Sim	MB	NMB
PM <sub>2.5</sub>	36.88	33.22	-3.66	-9.92%	91.59	64.28	-27.31	-29.82%
SO <sub>2</sub>	17.65	16.51	-1.14	-6.46%	41.45	29.80	-11.65	-28.11%
NO <sub>2</sub>	28.53	33.23	4.70	16.47%	53.01	54.28	1.27	2.40%
Daily-maximum O <sub>3</sub>	237.45	255.77	18.32	7.72%	125.62	86.61	-39.01	-31.05%
