**Abstract.** The NCAR Whole Atmosphere Community Climate Model with thermosphere and ionosphere eXtension (WACCM-X) v2.1 has been developed to include the neutral and ion-molecule chemistry and dynamics of three metals (Mg, Na, and Fe), which are injected into the upper mesosphere/lower thermosphere by meteoric ablation. Here we focus on the self-consistent electrodynamical transport of metallic ions in both the E and F regions. The model with full ion transport significantly improves the simulation of global distribution and seasonal variations of Mg<sup>+</sup>. Near the magnetic equator, the diurnal variation in upward and downward transport of Mg<sup>+</sup> is generally consistent with the “ionosphere fountain effect”. The thermospheric distribution of Fe is shown to be closely coupled to the transport of Fe<sup>+</sup>. The effect of ion mass on ion transport is also examined: the lighter ions (Mg<sup>+</sup> and Na<sup>+</sup>) are transported above 150 km more easily than the heavy Fe<sup>+</sup>. We also examine the impact of the transport of major molecular ions, NO<sup>+</sup> and O<sub>2</sub><sup>+</sup>, on the distribution of metallic ions.

## 10 1 Introduction

The presence of layers of meteor-ablated metal atoms between 80 and 105 km has been known for decades (Plane et al., 2015). More recently, there have been a growing number of observations of the thermospheric metal layers up to 200 km. For example: Chu et al. (2011) reported neutral Fe layer observations up to 155 km at McMurdo, Antarctica (77.8°S, 166.7°E); Gao et al. (2015) found that several observations of Na layers reached up to 170 km, using a large-aperture astronomical telescope at Lijiang, China (26.7°N, 100.0°E); and Friedman et al. (2013) investigated a descending thermospheric K layer up to ~155 km at Arecibo, Puerto Rico (18.35°N, 66.75°W). These high altitude thermospheric neutral metal layers are challenging to explain, since ablation occurs predominantly below these altitudes, which raises interesting questions regarding their formation mechanisms. Neutral metal atoms and their corresponding atomic ions are tightly coupled through ionization (via photoionization or charge transfer with ambient ions e.g. NO<sup>+</sup> and O<sub>2</sub><sup>+</sup>), and neutralization (via dielectronic recombination with

20 electrons, or dissociative electron recombination if they have formed a molecular ion) (Plane et al., 2015). Thus, the vertical  
and horizontal transport of metallic ions is a key process for controlling the behavior of neutral atoms in the thermosphere  
(E and F regions). Interestingly, the reported occurrence of thermospheric metal layers appears to show great geographical  
variability, underlining the importance of global ion transport. In addition, metallic ions play a central role in the formation of  
thin, concentrated layers of ions in the E-region (sporadic E layers, or Es), which affect radio transmission (e.g., Narcisi, 1968;  
25 Layzer, 1972; Plane et al., 2015; Yu et al., 2021).

Thus far, a number of modeling studies have attempted to simulate the transport of metal ions in the thermosphere and, more  
recently, the role of metallic ions in the formation of the thermospheric metal layers. For example, Carter and Forbes (1999)  
developed a two-dimensional (2-D) model to examine both global and local transport of  $\text{Fe}^+$  ions; Chu and Yu (2017) used a  
thermosphere-ionosphere  $\text{Fe}/\text{Fe}^+$  model to investigate the formation of thermospheric Fe layers observed by lidar at McMurdo,  
30 Antarctica; and Cai et al. (2019) conducted a 2-D simulation of  $\text{Na}/\text{Na}^+$  in the E and F regions to explore the formation of  
thermospheric sodium layers observed at the Andes Lidar Observatory (30.25°S, 70.74°W). Recently, Huba et al. (2019) have  
included the global transport of metallic ions ( $\text{Mg}^+$  and  $\text{Fe}^+$ ) into the SAMI3 model of the E and F regions, and concluded  
from a two-day model run that ions are redistributed by the combined effects of the neutral wind and electric field. However,  
no previous studies appear to have examined the full transport of metal ions in a self-consistent global chemical-dynamical  
35 model, incorporating the full life cycle of thermospheric metal atom and metal ion chemistry and the injection of these metals  
from meteoric ablation.

This paper describes the development of a new global model of three metal species (magnesium, iron, and sodium) in the E  
and F regions, to gain a detailed understanding of the effects of multi-scale atmospheric motions from the lower atmosphere and  
solar activity on the thermospheric metal layers. The main contribution reported here is to incorporate a self-consistent solution  
40 of full global transport of  $\text{Mg}^+$ ,  $\text{Fe}^+$  and  $\text{Na}^+$  in both the E and F regions, within the chemistry-climate WACCM-X 2.1 model,  
in addition to a detailed description of the neutral and ion-molecule chemistry of these metals and the meteoric ablation source  
required to model the metal atom layers around 90 km. This is described in Section 2. Section 3 presents the findings of the  
model simulation, focusing on the seasonal and the diurnal variation of ions and the affects of ion electro-dynamical transport.  
The final section includes a brief summary and a discussion of future directions with the model.

## 45 2 Model Description and Ion Transport

### 2.1 Model Description

WACCM-X is developed in the present study to include the full life cycle of meteoric metals combined with interactive chem-  
istry, dynamics, deposition and ion transport in the ionosphere. WACCM-X is an atmospheric component of the Community  
Earth System Model (CESM, version 2.1.3; Hurrell et al., 2013) developed by the National Center for Atmospheric Research.  
50 The key chemistry and dynamical features are based on CAM4 and WACCM4 and are described in detail in Marsh et al.  
(2013b), and Neale et al. (2013). Validated metal chemistry modules for magnesium (Langowski et al., 2015), sodium (Marsh  
et al., 2013a), and iron (Feng et al., 2013) with updated rate coefficients from Plane et al. (2015), Bones et al. (2016) and Viehl

et al. (2016), are added. The transport of the neutral and ionized metallic species by eddy/molecular diffusion and winds is treated in the same way as most active chemical species (for example, O<sub>3</sub>, CO<sub>2</sub> etc.).

55 A detailed description of WACCM-X 2.0 is provided by Liu et al. (2018a) and a brief summary is given here. The model has some key features and improvements since WACCM-X 1.0 (Liu et al., 2010), including a self-consistent electrodynamics module, F-region O<sup>+</sup> transport, a solver for electron and ion temperatures, and reduction in the damping coefficient of atmospheric tides (Liu et al., 2018b). The model top is set at  $4.1 \times 10^{-10}$  hPa ( $\sim 500$  to  $\sim 700$  km, depending on solar activity), with a vertical resolution of a quarter of a scale-height in the mesosphere and thermosphere. The horizontal resolution is 1.9° in  
60 latitude and 2.5° in longitude, and all model results used in the paper are from one-year free-running simulations perpetual year 2000AD under solar medium conditions (constant F107=124 and Kp=2.17) with an output frequency of 1 hr. The O<sup>+</sup> transport method is described in detail by Liu et al. (2018a).

## 2.2 Ion Transport Equation

Since meteoric ablation, deposition, transport by the neutral winds, eddy and molecular diffusion, chemical production, and  
65 loss are already contained in the metal chemistry modules, the metal ion transport is calculated separately, in a similar way to the treatment of O<sup>+</sup> transport described by Liu et al. (2018a). The continuity equation of metal ion transport can be simplified as:

$$\frac{\partial n_i}{\partial t} = -\nabla \cdot (n_i \mathbf{V}_i) \quad (1)$$

where  $n_i$  represents the number density of metal ions, and  $\mathbf{V}_i$  is the ion transport velocity. The ion transport velocity is adapted  
70 from the derivation described by Carter and Forbes (1999) and Chu and Yu (2017), extended to a 3-D global model:

$$\mathbf{V}_i = \frac{\xi}{1+\xi^2} \frac{\mathbf{V}_n \times \mathbf{B}}{B} + \frac{1}{1+\xi^2} \frac{(\mathbf{V}_n \cdot \mathbf{B}) \mathbf{B}}{B^2} + \frac{\xi}{1+\xi^2} \frac{\mathbf{E}}{B} + \frac{1}{1+\xi^2} \frac{\mathbf{E} \times \mathbf{B}}{B^2} + \mathbf{V}_{ambi} \quad (2)$$

where  $\mathbf{E}$  and  $\mathbf{B}$  are the electric field and the Earth's magnetic field, respectively.  $\mathbf{V}_n$  is the neutral wind, and  $\xi = \frac{\nu_{in}}{\omega_i}$  is the ratio of ion-neutral collision frequency (in the laboratory frame-of-reference (Banks and Kockarts (1973)) to the ion gyro-frequency.  
75  $\mathbf{V}_{ambi}$  is the ion velocity due to ambipolar diffusion, given by Schunk and Nagy (2000, equations (5.54) and (5.70)), where we treat the metallic ions as minor ions and O<sup>+</sup> as a major ion species in the F region. The first two terms are related to contributions by the neutral winds, with the first term being the  $\mathbf{V} \times \mathbf{B}$  drift i.e. the Lorentz force. The third and fourth terms are due to the electric field. A Flux-Corrected Transport (FCT) algorithm (Boris et al., 1993) is applied to compute the vertical transport velocity; this algorithm is designed for solving steep density gradients.

80 As mentioned above, charge transfer from molecular ions such as NO<sup>+</sup> and O<sub>2</sub><sup>+</sup> to metal atoms provides a major sources of metallic ions. However, due to the short lifetime of these two molecular ions ( $\sim 5$  mins in the daytime), they were assumed to be in chemical equilibrium in WACCM-X 2.0. In this study, the transport of molecular ions NO<sup>+</sup> and O<sub>2</sub><sup>+</sup> is now considered along with the metal ions. Simulation results with and without the molecular ion transport are compared to determine the impact on the metal ion distribution.

## 85 3 Results and Discussion

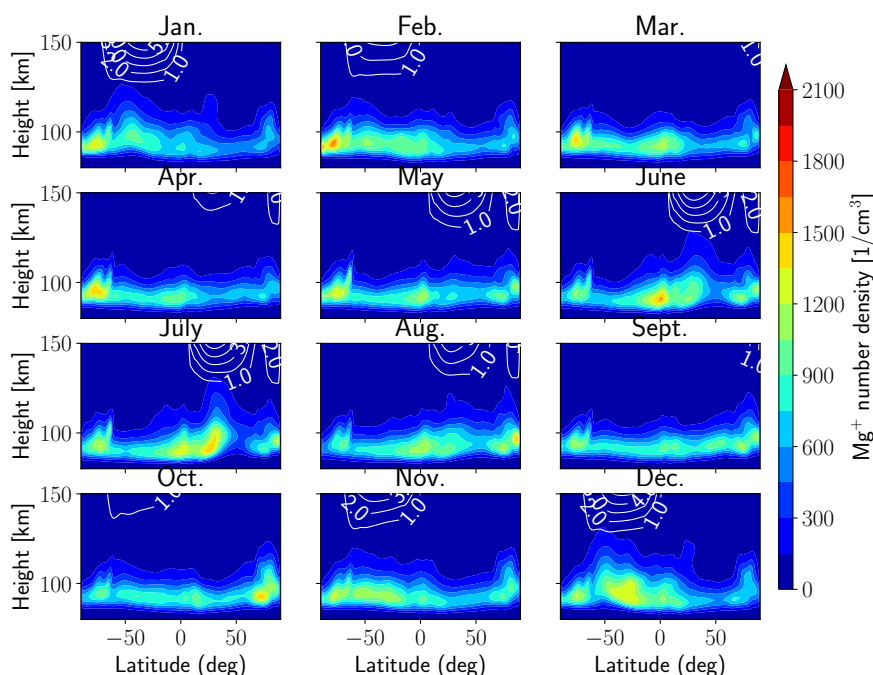

$\text{Na}^+$ ,  $\text{Fe}^+$  and  $\text{Mg}^+$  undergo similar transport forces in the E and F regions, apart from the effect of their mass differences. Because  $\text{Mg}^+$  is the only one of these ions for which near-global observations are available (Langowski et al., 2015), we focus here on the results for  $\text{Mg}^+$ . However, we also explore  $\text{Fe}/\text{Fe}^+$  ion-neutral coupling in the formation of thermospheric metal layers, since Fe is the most abundance and widely studied thermospheric metal species. In addition, the  $\text{Mg}^+/\text{Fe}^+$  and  $\text{Mg}^+/\text{Na}^+$  ratios are employed to examine the effect of metal ion mass difference, because  $\text{Fe}^+$  is more than twice as heavy as  $\text{Mg}^+$  (56 versus 24 amu), while the masses of  $\text{Na}^+$  and  $\text{Mg}^+$  are very similar (23 versus 24 amu).

### 3.1 Seasonal variation of $\text{Mg}^+$ simulated by WACCM-X

Figure 1 shows the monthly mean density of  $\text{Mg}^+$  as a function of latitude and altitude, where the monthly mean data is zonally averaged. An obvious seasonal signal is exhibited with clear latitudinal dependence, which is generally consistent with the SCIAMACHY measurements (Figure 6 in Langowski et al. (2015)). At middle latitudes ( $\sim 40^\circ \pm 10^\circ$ ), the peak altitude of  $\text{Mg}^+$  is  $\sim 10$  km higher in the summer hemisphere, which is very similar to the observations (Langowski et al., 2015). This appears to be caused by the field-aligned transport of the ions driven by the summer to winter neutral wind (second term in Eq. 2), with monthly mean upward drift velocity of  $\sim 5$  m/s at a height of 150 km in the summer hemisphere (contour line in Figure 1; the seasonal variation of the neutral meridional wind is not shown). Since the metallic ions are the main reservoir for neutral metal atoms in the lower thermosphere (Plane et al., 2015), this is in good agreement with the summer maximum occurrence trends of thermospheric neutral sodium layers observed by mid-latitude lidars (Wang et al., 2012; Dou et al., 2013; Xun et al., 2020). In contrast to the SCIAMACHY measurements, which shows a minimum at the equator, the WACCM-X simulation shows a maximum in peak altitude and number density at the equator. Note that the SCIAMACHY observations are made at a particular local time of around 10:00 LT, whereas the WACCM-X data in Figure 1 is a diurnal and zonal average. To address this, we also present the simulation results at the same local time (10:00 LT) in Figure 2, and they are in better agreement with SCIAMACHY observations. Another noteworthy feature is that this simulation shows the pronounced maximum in peak altitude and density at  $\sim 45^\circ$  (N/S) at 10 LT, in accord with the SCIAMACHY observations, which is absent in the previous models.

Figure 3 (a-d) presents the global geographical distribution of  $\text{Mg}^+$  column densities at the equinoxes and solstices, and at 00 UTC. The white dashed line depicts the dip equator. Despite the high accumulation of column density at the poles, the  $\text{Mg}^+$  column density exhibits relatively high distributions at lower and middle latitudes in the summer hemisphere (Figure 3 (b) and (d)). This is in good agreement with the conclusion of a summertime maximum shown in Figure 1. Interestingly, the geographic distributions in all four seasons show stronger convergences along the magnetic equator, which might be related to the modulation of the equatorial fountain effect.

In Figure 3 (e) we show the seasonal variation of zonal-averaged  $\text{Mg}^+$  column density at different latitudes. The modelled  $\text{Mg}^+$  column exhibits a maximum in the summer hemisphere at middle and high latitudes, which is in general agreement with the results derived from the SCIAMACHY measurements and WACCM-Mg model results (Figure 9 and Figure 16 in

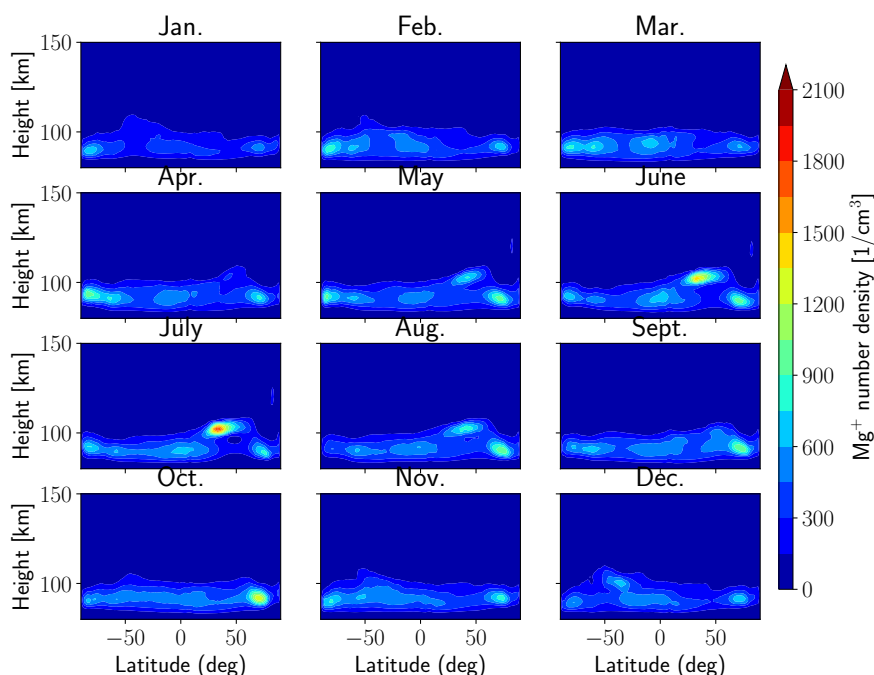

**Figure 1.** Monthly and zonal mean of the  $\text{Mg}^+$  number density (color contours) and the upward drift velocity (in m/s) due to field-aligned transport driven by neutral-ion collision (line contours) as a function of latitude and altitude in different months.

Langowski et al. (2015)), and the SBUV nadir measurements (Figure 9 in Joiner and Aikin (1996)). The partial column density above 110 km still shows a similar seasonal variation, which is probably due to thermospheric ion transport (not shown).

### 120 3.2 Diurnal variation of $\text{Mg}^+$ simulated by WACCM-X

To investigate the diurnal variation of metallic ions in the model, we present the  $\text{Mg}^+$  number density (on a log scale) as a function of latitude and altitude at the December Solstice and  $0^\circ$  longitude; the panels show universal times (i.e. local times) of 00, 06, 12 and 18 UT (Figure 4 (a-d)). The white dotted line denotes the  $F_2$ -layer height of the peak electron density ( $hmF_2$ ). This shows that the strongest diurnal variations are found in equatorial and high latitudes. Here we focus on the “fountain effect” on ion transport, where the equatorial ions are first lofted to higher altitudes via  $E \times B$  motion, and then drift down along the magnetic field lines (Kelley, 2009).  $\text{Mg}^+$  is expected to be lofted to high altitudes ( $\sim 400$  km) by the  $E \times B$  drift above the magnetic equator during the day, because of the daytime eastward electric fields (Huba et al., 2019). Figure 4 (e) shows the diurnal variation of  $\text{Mg}^+$  number density near the dip equator ( $12^\circ\text{N}$ ,  $0^\circ$ ) as a function of local time; the upward drift of  $\text{Mg}^+$  peaks at around 20 LT, and the  $\text{Mg}^+$  then drifts down towards the main layer at midnight ( $\sim 02$  LT). Note that the reduction of  $\text{Mg}^+$  at the equator at 06 LT confirms that the ion density at the equator is largely dependent on local time (Figure 4 (b) and

125  
130

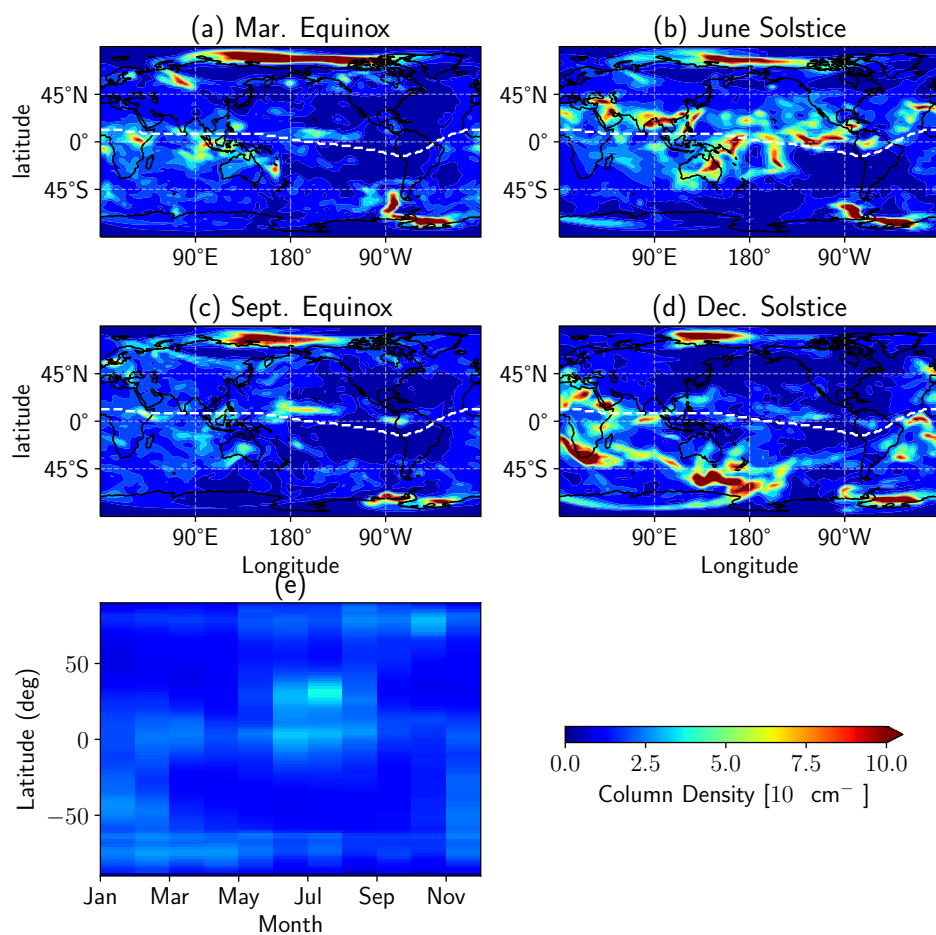

**Figure 2.** Monthly mean  $\text{Mg}^+$  number density obtained by averaging data at 10 LT for all longitudes as a function of latitude and altitude in different months.

(e)). The phase of  $\text{Mg}^+$  diurnal variation shows a high correlation with variations in the electron density (the change of  $\text{hmF}_2$ ). Instead of being redistributed along the magnetic field lines to the subtropical region by the “classical” fountain effect (e.g., Pi et al., 2009), the  $\text{Mg}^+$  shows a more complex downward trajectory, i.e., the ions are not transported symmetrically to both sides of the geomagnetic equator, which is closer to the scenario proposed by Cai et al. (2019).

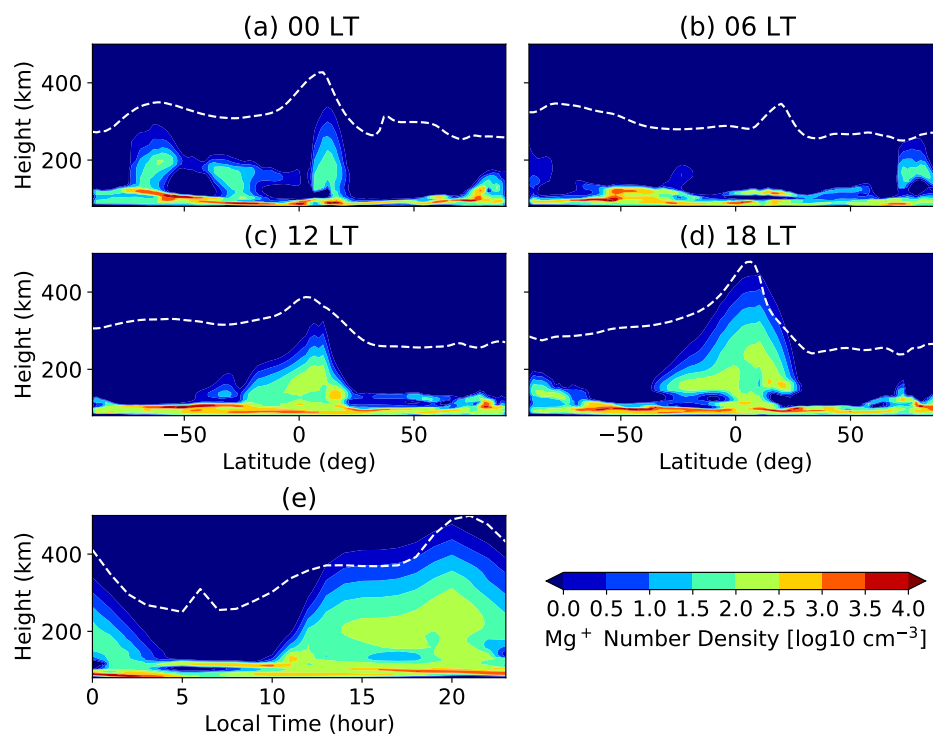

### 135 3.3 Fe and $\text{Fe}^+$ vertical profile comparison

In order to demonstrate the effect of electro-dynamical transport on the metals, a standard simulation without metal ion transport was performed (termed the control run). Figure 5 shows the  $\text{Fe}^+$  and Fe vertical profiles for the ion transport run (solid lines), and control run (dotted/dashed lines) at the equinoxes and solstices. Three geographic latitudes at a longitude of  $180^\circ$  are chosen for comparison:  $0^\circ$  for the magnetic equator,  $20^\circ\text{S}$  for the subtropical region corresponding to the fountain effect downward drift, and  $45^\circ\text{S}$  for the middle latitude corresponding to the summertime peak altitude. Without the ion transport (the control run), both Fe and  $\text{Fe}^+$  exhibit roughly Gaussian-shaped layers with peak heights between 90 and 100 km (dotted/dashed lines).  
140 When ion transport is turned on, the vertical profiles of  $\text{Fe}^+$  vary depending on latitude and season. For instance,  $\text{Fe}^+$  near the equator is always transported to a higher altitude (blue lines), consistent with the fountain effect in the dip equator region.

**Figure 3.** (a-d) Global geographical distribution of the  $Mg^+$  column density during the equinoxes and solstices, at 00 UTC. (e) Seasonal variation of the zonal mean  $Mg^+$  column density as a function of month and latitude. The white dashed lines indicates the position of the dip equator.

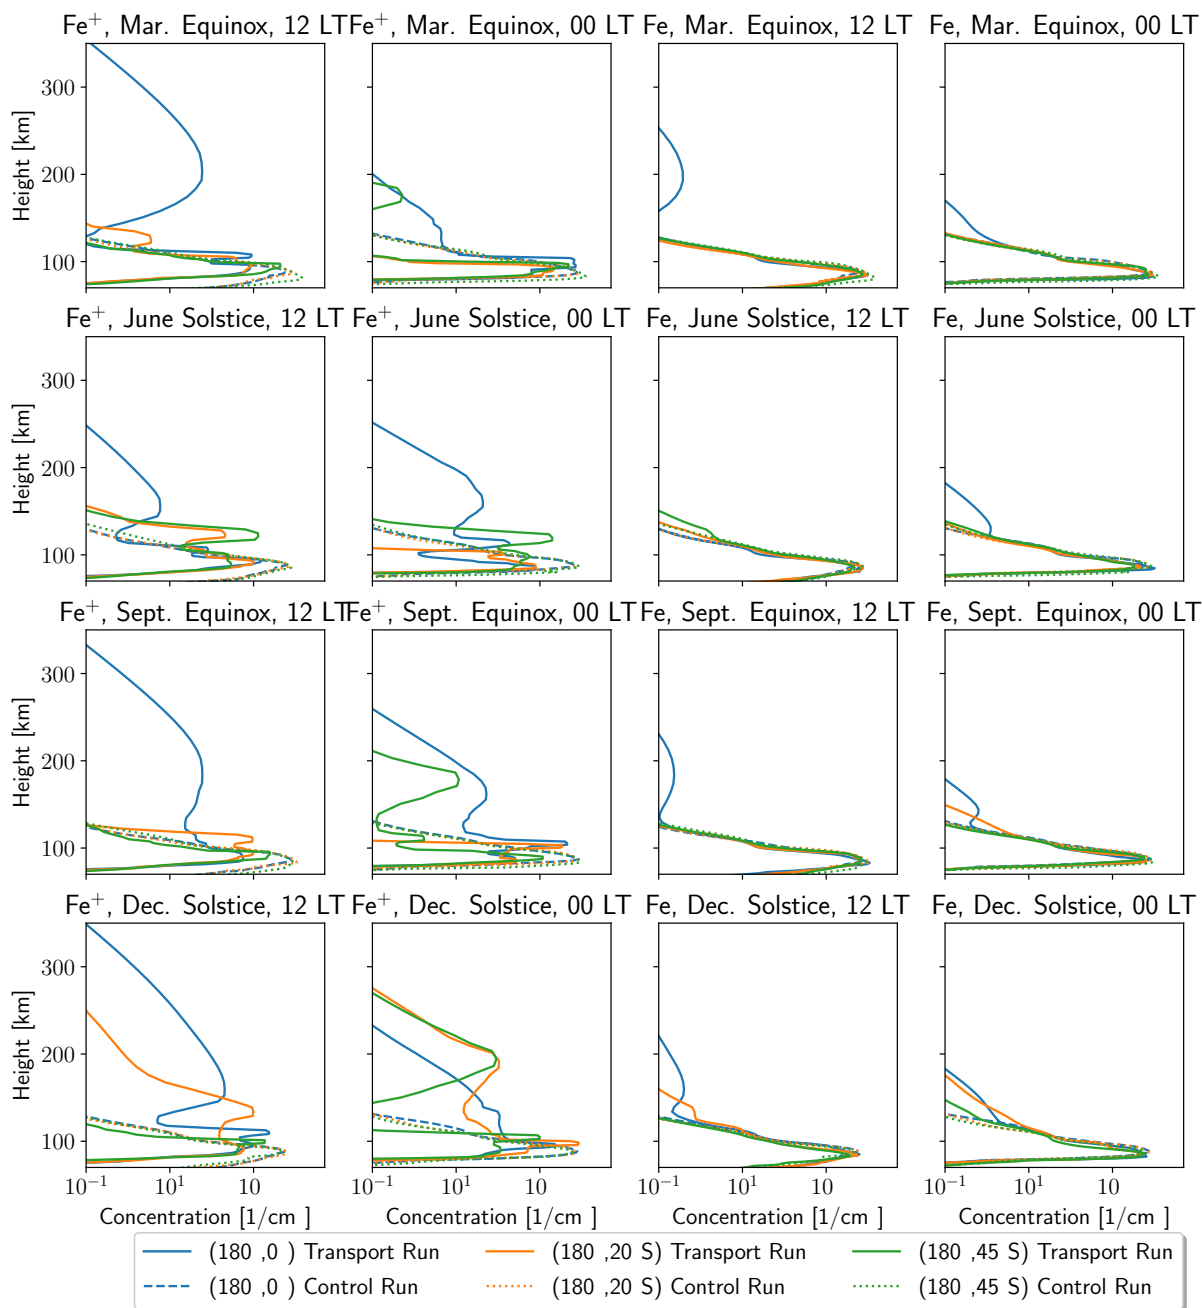

**Figure 4.** (a-d) Mg<sup>+</sup> density as a function of latitude and altitude at the December Solstice and longitude 0°, at four universal times (local times): 00, 06, 12, 18 UT. (e) Mg<sup>+</sup> density over (12°N, 0°) as a function of local time and altitude. The white dashed lines denote hmF<sub>2</sub>.

However, ions at subtropical (20°S) and middle (45°S) latitudes exhibit quite different transport motions. At middle latitudes, at midday the distribution is similar to that in the control run, but at midnight Fe<sup>+</sup> is transported to a high level (~1 cm<sup>-3</sup> at 200-300 km) except at the June Solstice (green lines). In contrast, the ions at subtropical latitude (orange line) are transported upward to a small extent at midday, but transported downward to a lower height (~1 cm<sup>-3</sup> at ~100 km) at March Equinox and June Solstice at midnight, which is in reasonable agreement with the downward drift of the fountain effect along the magnetic field lines at midnight.

Since the neutral atoms are not directly transported by the electromagnetic field, they are influenced by ions through the recombination between ions and electrons. The last two panels in Figure 5 illustrate the Fe atom distributions. In general, the upward transport of Fe<sup>+</sup> does not significantly contribute to changes of Fe (at densities > 1 cm<sup>-3</sup>), so that the vertical distribution of Fe in the transport run is similar to that in the control run. However, there is an obvious increase in high-altitude Fe (i.e. above ~140 km) in the equatorial region (blue line), corresponding to the upward transport of ions; and at the December solstice around midnight, the Fe number density above 150 km is much higher than that in the control run at all southern latitudes.

**Figure 5.** Comparison of the vertical profiles of the  $\text{Fe}^+$  (left two panels) and  $\text{Fe}$  (right two panels) number densities, for the control run (dotted/dashed lines) and run with ion transport (solid lines) over selected geographic latitudes, at the equinoxes and solstices and midday (12 LT) and midnight (00 LT).

### 3.4 Effect of metal ion mass on transport

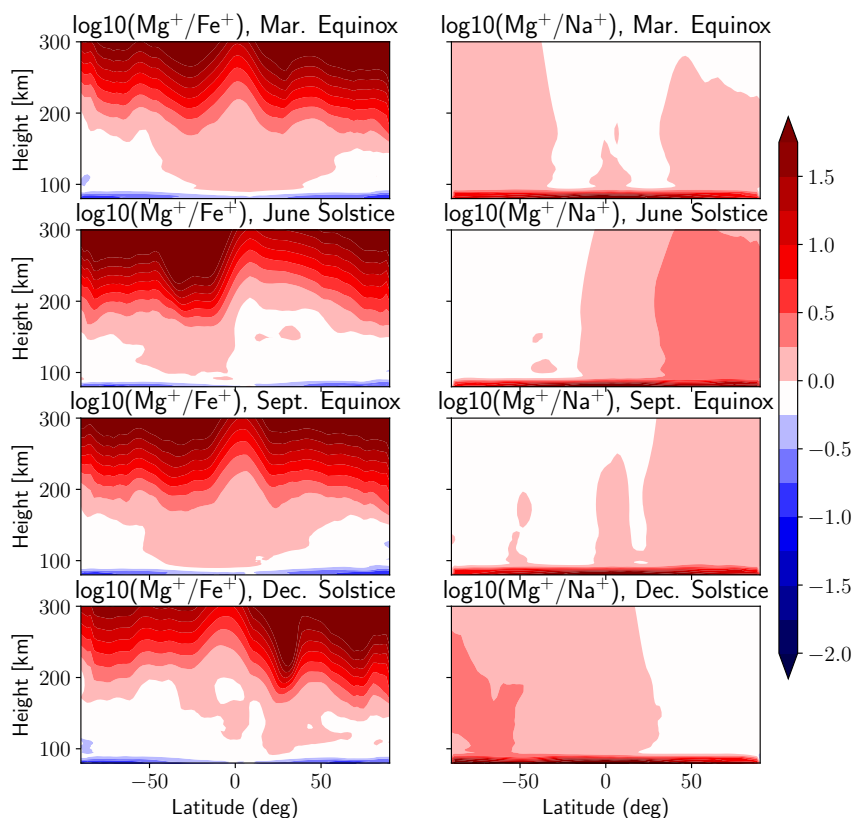

Figure 6 compares the  $\text{Mg}^+/\text{Fe}^+$  ratio (left panel) and the  $\text{Mg}^+/\text{Na}^+$  ratio (right panel) as a function of height and latitude at the equinoxes and solstices. Note that changes in the ratios below 100 km are due to differences in the ion-molecule chemistries of the metals (Plane et al., 2015), which is not the focus here. There are several advantages in choosing these three metallic ions. First,  $\text{Fe}^+$  is more than twice as heavy as  $\text{Mg}^+$ . Second,  $\text{Fe}^+$  is much heavier, and  $\text{Mg}^+$  is slightly lighter, than the mean mass of air molecules in the E region. Third,  $\text{Na}^+$  has a comparable mass with  $\text{Mg}^+$ . As expected, the lighter ions are transported above 150 km more easily than the heavy  $\text{Fe}^+$ , so that the  $\text{Mg}^+/\text{Fe}^+$  ratio increases from  $\sim 1$  at 120 km to  $>2$  above 150 km and to  $>30$  above 300 km. By the same token, the  $\text{Mg}^+/\text{Na}^+$  ratio shows very little change above 120 km.

The zonally-averaged  $\text{Fe}^+/\text{Mg}^+$  ratio below 200 km simulated by WACCM-X also accords with the limited available observations (Dymond et al., 2003; Kumar and Hanson, 1980), which showed that the average  $\text{Fe}^+/\text{Mg}^+$  ratio is around 1.5:1. The present study also simulates the extreme variability of the  $\text{Fe}^+/\text{Mg}^+$  ratio above 300 km (as low as 1:50 in Kumar and Hanson (1980)). However, the unexpectedly large  $\text{Fe}^+/\text{Mg}^+$  ratio ( $\sim 10\text{--}50$ ) reported by Dymond et al. (2003) is only captured at a few points about 150 km in our model (not shown). Interestingly, the striking differences between distinct TIFe and diffuse TINa reported by Chu et al. (2020) is thought to be related to mass separation. There is no question that more observations are needed to confirm and validate these findings.

### 3.5 Effect of $\text{NO}^+$ and $\text{O}_2^+$ transport

Figure 7 and 8 compares the distribution of metal ions from two simulations, one with the transport of all ions (hereafter TA), and the other with  $\text{NO}^+$  and  $\text{O}_2^+$  in chemical equilibrium (hereafter CE). Note that the simulation results presented herein investigate the potential impacts of the transport of two major molecular ions on the distribution of metallic ions and do not provide a comprehensive review of all possible effects.

Figure 7 shows the monthly mean density of  $\text{Mg}^+$  as a function of latitude and altitude in June for the TA (Figures 7a) and CE (Figures 7b) simulations, along with their difference (Figures 7c), where the monthly mean data is zonally averaged. In general, there is a good correspondence between the two simulations in terms of the latitude-altitudinal distribution of the monthly mean  $\text{Mg}^+$  density. As seen in Figure 7c, the peak density in CE simulation is generally a little higher than that in the TA simulation, especially in the high latitudes of the southern hemisphere. Figure 8 compares the diurnal variation of  $\text{Mg}^+$  in the two simulations. Both cases simulate the significant “fountain effect”, which was discussed in Section 3.2. With the transport of major molecular ions, the peak height of the metal layer after midnight is higher. As discussed by Plane et al. (2015), charge transfer of neutral metal atoms with  $\text{NO}^+$  and  $\text{O}_2^+$  is the major sources of metallic ions in the E region. Due to the very short lifetimes of  $\text{NO}^+$  and  $\text{O}_2^+$  during daytime, the transport of these molecular ions between model grid-boxes has little effect on the metallic ions. In contrast, the reduced densities of the molecular ions (and electrons) at night means that their increased lifetimes become comparable to transport lifetimes. Additional metallic ions are therefore produced via charge transfer with the downward transport of  $\text{NO}^+$  and  $\text{O}_2^+$  at night in the TA simulation.

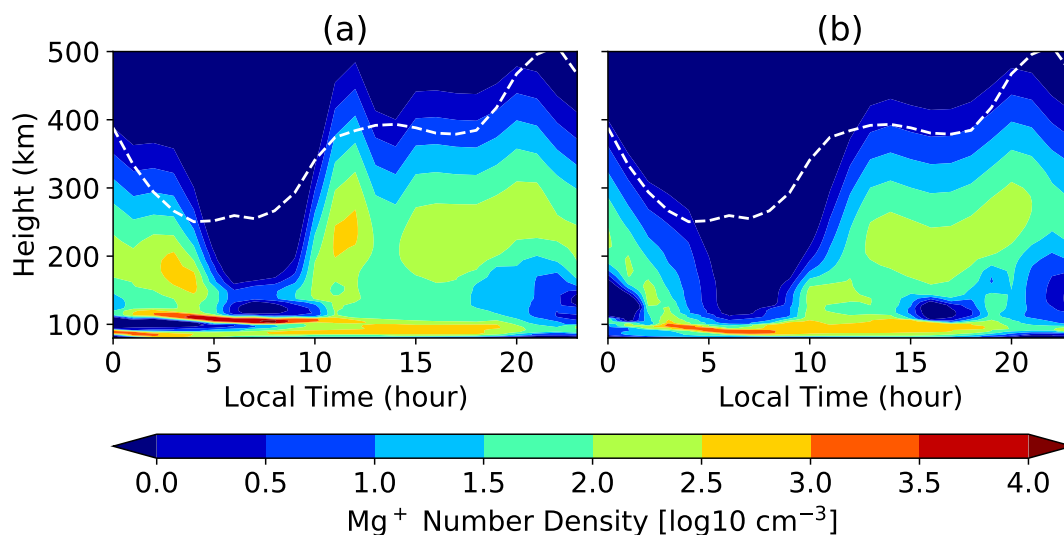

**Figure 6.** The zonally-averaged Mg<sup>+</sup>/Fe<sup>+</sup> ratio (left panel) and Mg<sup>+</sup>/Na<sup>+</sup> ratio (right panel) versus height and latitude at the equinoxes and solstices.

#### 4 Conclusions

- 190 The WACCM-X high altitude chemistry-climate model has been developed to incorporate the full life cycle of multiple meteoric metal ions and atoms (Mg, Na, and Fe, currently). A major advantage of WACCM-X is the self-consistent treatment of dynamics and electrodynamics allowing us to quantitatively investigate the global distribution of metal ions and the formation mechanisms of thermospheric metal layers. The present study explores, for the first time, the seasonal variations of thermospheric metal ions by including global metal ion transport in the E and F regions.
- 195 There are a number of interesting findings: (1) A clear seasonal cycle is found in the monthly averaged global distributions of Mg<sup>+</sup>, in good agreement with the SCIAMACHY measurements (Langowski et al., 2015). (2) Uplift of metal ions in the summer hemisphere at mid-latitudes ( $\sim 40^\circ \pm 10^\circ$ ), driven by the seasonal variation of meridional wind, appears to explain the

**Figure 7.** The monthly and zonal mean of the Mg<sup>+</sup> number density in June from (a) the TA simulation and (b) the CE simulation. (c) The difference between the TA and CE simulations.

**Figure 8.**  $\text{Mg}^+$  density over ( $12^\circ\text{N}$ ,  $0^\circ$ , near the dip equator) as a function of local time and altitude at June Solstice. The dashed lines denote hmF2. (a) for the TA simulation and (b) for the CE simulation.

summer maximum occurrence of thermospheric sodium layers observed by mid-latitude lidars (Wang et al., 2012; Dou et al., 2013; Xun et al., 2020). (3) Upward transport of metallic ions by  $E \times B$  forcing is generally consistent with the “fountain effect”. (4) The formation of thermospheric neutral metal layers is strongly influenced by the upward transport of ions, since metallic atoms and ions are coupled by relatively fast reactions in the lower thermosphere (Plane et al., 2015). (5) A pronounced mass separation of  $\text{Fe}^+$  with the two lighter ions,  $\text{Mg}^+$  and  $\text{Na}^+$ , is demonstrated above 150 km, with the ratio between the lighter ions ( $\text{Mg}^+$  and  $\text{Na}^+$ ) and heavier ions ( $\text{Fe}^+$ ) increasing with height by more than a factor of 2 above 150 km. More satellite observations of the  $\text{Mg}^+/\text{Fe}^+$  ratio are needed to test this prediction. (6) The role of  $\text{NO}^+$  and  $\text{O}_2^+$  transport in the distribution of metal ions in the model is examined by comparing the two simulation results. It is found that they have little effect on the monthly means of metal ions but affect the peak heights of metallic ions in the descending phase of the “fountain effect”.

Previous research has established that thermospheric neutral metal layers are modulated by dynamics (e.g. gravity waves, atmospheric tides) (e.g., Chu et al., 2011; Xue et al., 2013; Cai et al., 2017; Qiu et al., 2016; Chu et al., 2020). In the future, this new version of WACCM-X can be used to investigate the effect of lower atmospheric dynamical processes on the formation of thermospheric neutral metal layers, by using the “specified-dynamics” version of the model (SD-WACCM-X).

*Code and data availability.* As a part of CESM2, WACCM-X is available at <http://www.cesm.ucar.edu/models/cesm2/>.

*Author contributions.* JW, WF, HL, and JMCP designed the simulations and wrote the manuscript. XX and DRM contributed to the discussion and explanation of model simulations. All authors discussed the results and commented on the manuscript at all stages.

*Competing interests.* The authors declare that they have no conflict of interest.
