24 **Abstract.** Cloud and precipitation processes are still a main source of uncertainties in numerical weather prediction and climate
25 change projections. The Priority Program “Polarimetric Radar Observations meet Atmospheric Modelling (PROM)“, funded
26 by the German Research Foundation (Deutsche Forschungsgemeinschaft, DFG), is guided by the hypothesis that many
27 uncertainties relate to the lack of observations suitable to challenge the representation of cloud and precipitation processes in
28 atmospheric models. Such observations can, however, ~~nowadays at present~~ be provided e.g. by the recently installed dual-
29 polarization C-band weather radar network of the German national meteorological service in synergy with cloud radars and
30 other instruments at German supersites and similar national networks increasingly available worldwide. While polarimetric
31 radars potentially provide valuable in-cloud information e.g. on hydrometeor type, quantity, and microphysical cloud and
32 precipitation processes, and atmospheric models employ increasingly complex microphysical modules, considerable
33 knowledge gaps still exist in the interpretation of the observations and in the optimal microphysics model process formulations.

34 PROM is a coordinated interdisciplinary effort to ~~intensify-increase~~ the use of polarimetric radar observations in data
35 assimilation, which requires a thorough evaluation and improvement of parameterizations of moist processes in atmospheric
36 models. As an overview article of the inter-journal special issue “Fusion of radar polarimetry and numerical atmospheric
37 modelling towards an improved understanding of cloud and precipitation processes”, this article outlines the knowledge
38 achieved in PROM during the past two years and gives perspectives for the next four years.

39 **1 Introduction and Objectives of the priority program**

40 ~~A-Among~~ the main sources of uncertainty in the models used in numerical weather prediction (NWP) and climate change
41 projections are the parameterizations of cloud and precipitation processes (Bauer et al., 2015). A major part of these
42 uncertainties can be attributed to missing observations suitable to challenge the representation of cloud and precipitation
43 processes employed in atmospheric models. A wealth of new information on precipitation microphysics and generating
44 processes can be gained from observations from polarimetric weather radars and their synergistic analysis at different
45 frequencies. The dual-polarization upgrade of the United States National Weather Service (NWS) S-Band Weather
46 Surveillance Radar 1988 Doppler (WSR-88D) network was completed in 2013. Germany finished upgrading its C-band
47 network to polarimetry in 2015 in parallel with other European countries. The synergistic exploitation of polarimetric
48 precipitation radars together with measurements from cloud radars and other instrumentation available at supersites and
49 research institutions enables for the first time a thorough evaluation and potential improvement of current microphysical
50 parameterizations based on detailed multi-frequency remote-sensing observations. Data assimilation merges observations and
51 models for state estimation as a prerequisite for prediction and can be seen as a smart interpolation between observations while
52 exploiting the physical consistency of atmospheric models as mathematical constraints.

53 Considerable knowledge gaps still exist, however, both in radar polarimetry and atmospheric models, which still impede the
54 full exploitation of the triangle between radar polarimetry, atmospheric models, and data assimilation and call for a coordinated
55 interdisciplinary effort. The German Research Foundation (Deutsche Forschungsgemeinschaft, DFG) responded to this call
56 and established the Priority Program “Polarimetric Radar Observations meet Atmospheric Modelling (PROM)”; its first 3-
57 year funding period began in 2019, which will be followed by a second funding period starting in 2022. PROM exploits the
58 synergy of polarimetric radar observations and state-of-the-art atmospheric models to better understand moist processes in the
59 atmosphere, and to improve their representation in climate- and weather prediction models. The overarching goal is to extend
60 our scientific understanding at the verges of the three disciplines, radar polarimetry – atmospheric models – data assimilation,
61 for better predictions of precipitating cloud systems. To approach this goal the initiators of PROM at the Universities of Bonn
62 and Leipzig in Germany identified the following five objectives (see also Trömel et al., 2018):

Formatiert: Schriftart: Nicht Fett

63 1) Exploitation of radar polarimetry for quantitative process detection in precipitating clouds and for model evaluation
64 including a quantitative analysis of polarimetric fingerprints and microphysical retrievals,

65 2) **i**mprovement of cloud and precipitation schemes in atmospheric models based on process fingerprints detectable in
66 polarimetric observations,

67 3) **m**onitoring of the energy budget evolution due to phase changes in the cloudy, precipitating atmosphere for a better
68 understanding of its dynamics,

69 4) **a**nalyzing precipitation system by assimilation of polarimetric radar observations into atmospheric models for weather
70 forecasting, and

71 5) **r**adar-based detection of the initiation of convection for the improvement of thunderstorm prediction.

72 In the first funding period, **each of the** 14 projects (see <https://www2.meteo.uni-bonn.de/spp2115>) distributed over Germany
73 contribute to at least one of these objectives. In most projects, a radar meteorologist works together with a modeller in order
74 to successfully combine expert knowledge from both research fields. This overview article of the ACP/AMT/GMD inter-
75 journal special issue entitled “Fusion of radar polarimetry and numerical atmospheric modelling towards an improved
76 understanding of cloud and precipitation processes” outlines methodologies developed and results achieved from a selection
77 of the projects during the past two years, and provides overall perspectives for the next four years. The paper is organized as
78 follows: Section 2 explains prevailing challenges in the representation of clouds in atmospheric models, while Sect. 3 provides
79 methodologies to extend our insight in the microphysics of clouds and precipitation by exploiting radar polarimetry. Section 4
80 addresses the fusion of numerical modelling and radar polarimetry via model evaluation either in radar observation space using
81 observation operators or using microphysical retrievals. First conclusions for improved model parameterizations and for a
82 better representation of model uncertainty in radar data assimilation are drawn. Section 5 provides a summary and perspectives
83 for the following years.

84 **2 Representation of clouds in atmospheric models**

85 The representation of cloud and precipitation processes in atmospheric models is a central challenge for NWP and climate
86 projections (e.g., Bauer et al., 2015; Forster et al., 2021), which also impacts offline hydrological models by modulating the
87 distribution of incoming solar radiation and precipitation and affecting the simulated hydrological processes such as
88 evapotranspiration, runoff, and groundwater depths (e.g., Shrestha, 2021). While the primitive equations provide a solid
89 theoretical basis for atmospheric model dynamics, the key diabatic processes that drive energetics and thus circulation, are
90 poorly resolved.– Important diabatic processes are linked to cloud and precipitation microphysics acting at scales of
91 micrometres and turbulent processes ranging from several to hundreds of meters. While significant progress has been achieved
92 by high-resolution modelling at the coarser end of this range (e.g., Heinze et al., 2017; Stevens et al., 2020), the intricate and
93 complex microphysical processes still require parameterizations in any dynamic atmospheric model down to and including the
94 scale of direct numerical simulations (e.g., Mellado et al., 2009).

95 A key uncertainty in weather prediction and climate modelling results from the still-rudimentary representation of moist
96 processes and from the diabatic heating/cooling the models induce due to latent heat and their interaction with radiation. The
97 generation and interpretation of past and future climate states additionally has to consider changes in microphysical processes
98 due to anthropogenic aerosol acting, e.g., as cloud condensation nuclei and ice nucleating particles. For short-term weather
99 prediction, the location and evolution of convective events with lifetimes of hours or less are particularly challenging, while
100 relatively slow moving and frontal systems with lifetimes of days show reasonable predictability (Alifieri et al., 2012).

101 Atmospheric modelling in Germany has recently seen substantial advances both in terms of cloud-resolving simulations in
102 NWP mode and in the implementation of ice and mixed-phase precipitation formation processes. Traditionally, different model
103 systems were used for NWP and climate modelling, which were also both heavily used in academic research. The modelling
104 system for long-term climate integrations is the ECHAM model (Stevens et al., 2013). Since it was created by modifying
105 global forecast models developed by ECMWF (European Centre for Medium-Range Weather Forecasts), its name is a
106 combination of ECMWF and Hamburg, the place of development of its parameterization package. The COSMO model,
107 however, was operated at horizontal resolutions down to 2.8 km and used for NWP and reanalysis studies. Research with the
108 ECHAM (the acronym is a combination of ECMWF (European Centre for Medium-Range Weather Forecasts) and Hamburg)
109 model family originating from the NWP model of the ECMWF focused on long-term climate integrations at horizontal
110 resolutions on the order of 100 km (Stevens et al., 2013), and the COSMO model operated at horizontal resolutions down to
111 2.8 km was used for NWP and reanalysis studies. Both model families are currently being replaced by the ICOSahedral
112 Nonhydrostatic (ICON) modelling framework (Zängl et al., 2015) jointly developed by the Max-Planck Institute for
113 Meteorology and the German national meteorological service (Deutscher Wetterdienst, DWD). Its climate version (the ICON
114 general circulation model, ICON GCM) inherited its physics package from the ECHAM model, and the NWP version
115 incorporated the one from the COSMO model. A third version largely based on the COSMO physics package was developed
116 for higher resolutions (Dipankar et al., 2015) and employs a large-eddy turbulence scheme (ICON-LEM). The latter is able to
117 operate on large domains (Heinze et al., 2017; Stevens et al., 2020) and includes aerosol-cloud interactions (Costa-Surós et al.,
118 2020). In PROM primarily the three ICON model variants (ICON-LEM, ICON-NWP, and ICON-A/GCM) are used.

119 In most atmospheric models, cloud and precipitation microphysical processes are represented by bulk microphysical schemes
120 that distinguish between different hydrometeor classes and include their specific masses as prognostic variables while their
121 size distributions are parameterized (the ICON model considered here uses the scheme by Seifert and Beheng, 2006).
122 Computationally much more demanding are so-called spectral-bin microphysics schemes (Khain et al., 2015), which evolve
123 cloud- and precipitation particle size distributions discretized into size-interval bins. An example is the Hebrew University
124 Cloud Model (HUCM) created by Khain et al. (2005) that treats both liquid and much more intricate (since ice may occur in
125 various shapes and densities) ice crystal distributions. The model is employed by some of the PROM projects in addition to
126 the liquid-only bin-microphysics model by Simmel et al. (2015) extended to the ice phase based on the scheme by Hashino

127 and Tripoli (2007). For the simulation of the evolution of specific air volumes a Lagrangian particle model (McSnow; Brdar
128 and Seifert, 2018) is used in PROM, that models ice and mixed-phase microphysical processes such as depositional growth,
129 aggregation, riming, secondary ice generation, and melting closer to the real processes than bulk formulations. Microphysical
130 processes including radiation-particle interactions obviously depend on particle shape; thus, the evolution of shapes in particle
131 models – and their signatures in radar observations – is instrumental for a full understanding and adequate representation of
132 the microphysical processes in models. Advanced microphysical parameterizations such as spectral-bin or Lagrangian particle
133 schemes are relevant for cloud-resolving models and exploited in PROM for the development and improvement of bulk
134 parameterizations. Scientific questions about global climate require long model integrations and thus coarse spatial resolutions
135 due to computing time constraints. At these resolutions (usually of order of 100 x 100 km² in the horizontal), fractional
136 cloudiness needs to be considered when the grid-box mean relative humidity is below 100%, which requires parameterizations
137 of subgrid-scale variability in relative humidity. Here, PROM builds on assumptions employed in the global ICON model
138 (ICON GCM) to predict fractional cloudiness (e.g., Quaas, 2012).

139 **3 Observational insights from polarimetric radar observations and challenges**

140 DWD operates 17 state-of-the-art polarimetric Doppler C-band weather radars which provide a 3-D sampling of precipitating
141 particles above Germany every five minutes. Together with their Doppler information, radars are the backbone for precipitation
142 and nowcasting products for all meteorological services. Although precipitation monitoring is still the most widespread
143 application of weather radars, their upgrade to polarimetry worldwide not only improves precipitation estimates; their
144 observations are also increasingly exploited for the evaluation and improvement of the representation of cloud- and
145 precipitation processes in atmospheric models (e.g., Gao et al., 2011; Jung et al., 2012; You et al., 2020; Wang et al., 2020).
146 Additional observations from cloud radars nowadays available at so-called supersites (in Germany e.g., the Jülich Observatory
147 for Cloud Evolution – Core Facility; JOYCE-CF; Löhnert et al., 2015; <http://www.cpex-lab.de>), universities, and research
148 facilities (e.g. the Leipzig Aerosol and Cloud Remote Observations System; LACROS; Bühl et al., 2013) open opportunities
149 to inform and improve atmospheric models. The use of shorter wavelengths of cloud radars shifts the sensitivity of the
150 observations towards smaller particles and partly increases the magnitude of the received polarimetric signals (e.g. K_{DP} – the
151 differential phase shift between horizontal and vertical polarization per distance called specific differential phase – scales with
152 λ^{-1}), which allows for more detailed studies of ice and cloud microphysics. Polarimetric and multi-frequency radar observations
153 allow for a more granular look at microphysical processes and provide a great data base for model evaluation, the improvement
154 of microphysical parameterizations, and data assimilation, and thus have the potential to significantly improve both weather
155 forecasts and climate predictions.

3.1 Multi-frequency and spectral polarimetry for ice and cloud microphysics

The PROM-project *Understanding Ice Microphysical Processes by combining multi-frequency and spectral Radar polarimetry and super-particle modelling (IMPRINT)* improves ice microphysical process understanding by using spectral multi-frequency and radar polarimetric observations in combination with Monte-Carlo Lagrangian super-particle modeling (Brdar and Seifert, 2018). Mid-latitude stratiform clouds, which occur frequently during winter time over JOYCE-CF, are the main focus. Radar polarimetric variables are well known to be particularly sensitive to the presence of asymmetric ice particles (e.g. Kumjian, 2013). Only recently, also polarimetric cloud radars operating at Ka or W-band are routinely available (Oue et al., 2018; Myagkov et al., 2016; Bühl et al., 2016; Matrosov et al., 2012). Some polarimetric variables are wavelength dependent (K_{DP} is inversely proportional to the wavelength), which provides enhanced sensitivity to ice particle concentration at higher frequencies. Multi-frequency approaches are complementary to radar polarimetry as they are sensitive to larger ice particles. Most commonly, the dual wavelength ratio (DWR), defined as the logarithmic difference of the effective reflectivity Z_e at two frequencies, is used. When ice particles transition from Rayleigh into non-Rayleigh scattering from one wavelength to a higher one, the DWR increases, which allows to infer the characteristic size of the underlying size distribution. The use of three radar frequencies (e.g. X, Ka, W) extends the discernable size range; e.g. the DWR of the Ka-W combination saturates for very large particles (Kneifel et al., 2015; Ori et al., 2021). The information content can be further extended when also the Doppler spectral information is explored. The different fall velocities allow for the separation of different hydrometeors; the high differential reflectivity (Z_{DR}) signal originating from small, slow falling ice crystals can be distinguished from the also low Z_{DR} signal of faster falling snow aggregates, which usually dominate the total Z_{DR} . Only few studies used so far spectral polarimetric observations for ice and snow microphysical studies (Luke et al., 2021; Oue et al., 2018; Pfitzenmayer et al., 2018; Spek et al., 2008). The observations collected during the first multi-months winter campaign carried out at JOYCE-CF as part of the IMPRINT project provide for the first time the opportunity to investigate both, polarimetry and multi-frequency observations in the Doppler spectra space. An example is the analysis of the dendritic growth layer (DGL) illustrated in Fig. 1 for a snowfall event observed on 22nd January 2019 at JOYCE-CF. Especially in the upper half of the cloud, the Z_{DR} is enhanced while K_{DP} values are low (Fig. 1b-c). Starting at the $-15\text{ }^\circ\text{C}$ isotherm, the Z_{DR} sharply decreases and shows an anti-correlation with the enhanced DWR (Fig. 1a) and K_{DP} values. These polarimetric signatures have been reported by previous studies (e.g., Moisseev et al., 2015 among others), and also the DWR increase below the $-15\text{ }^\circ\text{C}$ level resembles the examples shown in Oue et al. (2018). Oue et al. (2018) concluded in agreement with findings in Moisseev et al. (2015), that an increasing concentration of asymmetric aggregates are partly responsible for the enhanced K_{DP} values because the number of small ice particles will decrease due to aggregation. The spectrally-resolved Z_{DR} (sZ_{DR} , Fig. 1e), however, reveals that high Z_{DR} -producing, slowly falling ice particles are still present down to the $-5\text{ }^\circ\text{C}$ level. The spectrally resolved DWR (Fig. 1d) shows that the particles falling from above into the DGL are already partly aggregated. At $-17\text{ }^\circ\text{C}$, the spectra are much wider and a new spectral mode appears which is linked to the rapid sZ_{DR} increase (Fig. 1e). The new ice particle mode increases in Doppler velocity and $sDWR$ until 20 dB are reached. Unlike Z_{DR} , the K_{DP} (Fig. 1c and

Formatiert: Nicht Hochgestellt/ Tiefgestellt

f) remains at values between $1 \text{ and } 2 \text{ } \frac{\text{m}^2}{\text{deg km}^3}$ down to the $-5 \text{ } ^\circ\text{C}$ level. A possible explanation of the bimodal spectra - increased sZ_{DR} and K_{DP} might be secondary ice processes such as collisional fragmentation (Field et al., 2017). The few existing laboratory studies indicate that the number of fragments rapidly increases at $-20 \text{ } ^\circ\text{C}$, reaching a maximum at $-17 \text{ } ^\circ\text{C}$ and decreasing again towards $-10 \text{ } ^\circ\text{C}$ (Takahashi et al., 1995; Takahashi, 2014). This temperature dependence fits well to the observed radar signatures in the DGL, although the laboratory studies only considered collisions of solid ice spheres. As we can exclude strongly rimed particles in the snowfall case shown in Fig. 1, fragile dendritic structures growing on the surface of aggregates might be responsible, which precipitate into the DGL and might easily break into smaller pieces during particle collisions (Fig. 1d). Monte-Carlo Lagrangian super-particle model (Brdar and Seifert, 2018) simulations were recently extended in IMPRINT by a habit prediction scheme and a parameterization of ice collisional fragmentation following Phillips et al. (2017). The role of ice fragmentation and other ice microphysical processes is currently investigated with a radar observation operator for explaining the observed radar signatures of intense aggregation shown in Fig. 1.

The PROM-project *Investigation of the initiation of convection and the evolution of precipitation using simulations and polarimetric radar observations at C- and Ka-band (IcePolCKa)* combines observations of the C-band Polarization Diversity Doppler Radar (POLDIRAD) at the German Aerospace Center (DLR), Oberpfaffenhofen, with those of the Ka-band, Millimeter-wave cloud RADar of the Munich Aerosol Cloud Scanner (miraMACS) at Ludwig-Maximilians-Universität (LMU), Munich. While IMPRINT combines triple-frequency zenith-pointing observations with spectral cloud radar polarimetry, IcePolCKa explores the life cycle of convective precipitation with spatially separated weather and cloud radars- in order to quantify ice crystal properties in precipitation formation. The project focuses on ice particle growth and its role in precipitation formation within convective cells. Coordinated Range-Height-Indicator (RHI, varying elevation at constant azimuth) scans along the 23 km long cross-section between both radars allow to observe- DWR (Fig. 2a) and Z_{DR} (Fig. 2b) fingerprints of individual convective cells. While the deviation from Rayleigh scattering with increasing ice crystal size at the cloud radar wavelength ~~is used to~~allows distinguishing regions dominated by aggregation from regions with depositional growth, the slanted perspective of the weather radar helps to narrow down the aspect ratio of ice crystals. Although the DWR technique to infer ice crystal size is ~~well established~~well established (e.g. Kneifel et al., 2015), assumptions about the unknown ice crystal shape are necessary. Here, simultaneous polarimetric measurements, like Z_{DR} , help to narrow down ~~estimates of~~ the average asphericity of ice crystals and reduce ambiguities in retrieving ice crystal size and ice water content. IcePolCKa develops an algorithm, which uses Z_H , Z_{DR} and DWR measurements from the two radars to retrieve IWC, the mean particle diameter D_m , and the aspect ratio of ice crystals using a least-squares fit between measurements and T-matrix scattering simulations. The model of horizontally aligned spheroids in combination with an effective medium approximation following Hogan et al (2012) is used to find the simplest ice particle model which explains the multi-wavelength polarimetric measurements. The approach allows ~~to study~~studying the covariance of DWR and Z_{DR} while varying particle density, mean particle diameter D_m , and aspect ratio. More sophisticated models, such as discrete dipole approximation (DDA) simulations of specific ice crystals, would require the knowledge of the aspect ratio, and make it hard to identify ice shape collections along these free variables. The

Formatiert: Hochgestellt

Formatiert: Nicht Hochgestellt/ Tiefgestellt

223 multi-wavelength polarimetric- measurements are also used as a benchmark for convective precipitation formation in NWP
224 models, where cloud microphysics introduce substantial uncertainty (e.g. Morrison et al., 2020; ~~Xue et al., 2017~~). In IMPRINT
225 simulated microphysical processes in NWP models will be compared to- fingerprints in radar observations: A nested WRF
226 setup covering the overlap area of both radars is used to simulate convective events with microphysical schemes of varying
227 complexity while the Cloud-resolving model Radar SIMulator (CR-SIM; Oue et al., 2020), produces synthetic radar
228 observations, such as DWR (Fig. 2c) and Z_{DR} (Fig. 2d). Fig. 2 illustrates that the Predicted Particle Properties (P3) scheme
229 (Morrison and Milbrandt, 2015) is able to produce DWR features of similar magnitude and variability compared to the
230 observations, while a realistic ice particle asphericity is still missing. IcePolCKa compiled over 30 convective days of
231 polarimetric measurements and simulations with 5 different schemes over a 2-year period., which is currently used to analyse
232 how well these different microphysical schemes reproduce the polarimetric observations. A cell-tracking algorithm (TINT;
233 Fridlind et al., 2019) facilitates the comparison on a cell object basis.— Comparison of macrophysical cloud characteristics,
234 such as echo top height or maximum cell reflectivity, show that the model simulates too few weak and ~~small-scales~~small-scale
235 convective cells, independent of the microphysics scheme. In ongoing studies, the P3 scheme seems to better represent radar
236 signatures within the ice phase, while a spectral bin scheme tends to better simulate radar signatures within rain, where all
237 other schemes are not able to correctly reproduce observed Z_{DR} features.

238
239 The PROM-project *A seamless column of the precipitation process from mixed-phase clouds employing data from a*
240 *polarimetric C-band radar, a micro-rain radar and disdrometers (HydroColumn)* characterizes precipitation processes inside
241 a vertical atmospheric column by combining polarimetric Doppler weather radar observations with co-located measurements
242 from micro-rain radars, disdrometers and in-situ measurements, and by relating these observations to the large-scale
243 atmospheric thermodynamics derived from NWP models. To date, spectral analyses are mostly performed with cloud radars
244 operating at shorter wavelengths (see previous paragraphs or, e.g., Shupe et al., 2004; Verlinde et al., 2013; Kalesse et al.,
245 2016; Gehring et al., 2020; Li and Moisseev, 2020), but their implementation across the national C-band radar network offers
246 prospects for operational area-wide applications, e.g. the identification of dominant precipitation particle growth processes
247 such as aggregation or riming. While the operational DWD birdbath scan has so far been used primarily to monitor Z_{DR} (Frech
248 and Hubbert, 2020), *HydroColumn* now also uses-exploits the Doppler spectra measured at C-band during the operational
249 DWD-birdbath-scan, that is used for monitoring the differential reflectivity (Frech and Hubbert, 2020), for the analysis of
250 microphysical process information. Fig. 3 shows quasi-vertical profiles (QVPs; Trömel et al., 2014; Ryzhkov et al., 2016) of
251 polarimetric variables and Doppler spectra from birdbath scans for a stratiform precipitation event monitored with the
252 Hohenpeißenberg C-band research radar (47.8014N, 11.0097E) of DWD together with in-situ particle images obtained by the
253 Falcon research aircraft from DLR during the BLUESKY campaign (Voigt et al., 2021) within the *POLICE* project
254 (Sect.4.2.1). In-situ measurements have been performed with the Cloud, Aerosol and Precipitation Probe CAPS (Kleine et al.,
255 2018) integrated in a wing station on the Falcon flying within a horizontal distance of about 20 km from the radar site and
256 within about ± 15 min of the radar measurements. The dendritic growth layer (DGL; Ryzhkov and Zmic, 2019) centered around

257 -15 °C is characterized by Z_{DR} maxima of ~ 1 dB and K_{DP} of ~ 0.2 °deg km⁻¹, and a strong Z_H increase towards lower levels
258 (Fig. 3a). Particle images collected at temperatures below about -15 °C indicate mostly small irregular ice particles with the
259 number of larger particles increasing toward -15 °C (see levels L1 and L2 in Fig. 3c), and further down also reveal dendrites
260 and plates (L3, L4). In general, aggregation and riming become highly effective particle growth mechanisms at temperatures
261 around -7 °C (Libbrecht, 2005), and both processes result in a reduction of Z_{DR} (Fig. 3a). The vertically pointing Doppler
262 measurements can be used here to gain a deeper insight into the particle growth process. In this case study, the Doppler
263 measurements illustrated in Fig. 3b indicate typical ice-particle fall speeds increasing to about 2 m s⁻¹ just above the melting
264 layer and thus suggest a transition from predominantly aggregates to moderately rimed particles based on the relationship
265 between Doppler velocity and riming degree found by Kneifel and Moisseev (2020). This conclusion is supported- by the
266 corresponding in-situ images showing increasing riming of polycrystals and aggregates toward the melting layer (L6). The
267 analysis confirms the benefit of interpreting radar signatures from polarimetric weather radar observations in combination with
268 vertically pointing Doppler radar measurements, which was previously pointed out for higher-frequency cloud research radars
269 (Oue et al., 2018; Kumjian et al., 2020). This novel application of radar spectral analysis to vertically-pointing operational
270 weather radar scans may provide a more detailed view into intense precipitation events, such as hailstorms, where the use of
271 cloud radars is severely limited due to the strong attenuation at high radar frequencies.

272 3.2. Anthropogenic modifications of precipitation microphysics

273 The PROM-project *Polarimetry Influenced by CCN aNd INP in Cyprus and Chile (PICNICC)* seeks to improve our
274 understanding of aerosol effects on microphysical growth processes in mixed-phase clouds. *PICNICC* exploits unique remote-
275 sensing datasets from the LACROS suite (Radenz et al., 2021) extended with ground-based remote sensing instruments
276 installed at Leipzig University, Universidad de Magallanes (Punta Arenas), and Cyprus University of Technology (Limassol).
277 Thus, dual-frequency polarimetric radar observations from the polluted, aerosol-burden Northern and from the clean, pristine
278 Southern hemisphere can be contrasted for microphysical process studies as already performed in the project for stratiform
279 mixed-phase clouds to investigate inter-hemispheric contrasts in the efficiency of heterogeneous ice formation (Radenz et al.,
280 2021). The PICNICC project challenges the hypothesis that higher ice crystal concentrations favour aggregation, which is
281 expected to be more frequent for high aerosol loads and accordingly higher ice nucleating particle (INP) concentrations, while
282 riming should prevail when supercooled liquid layers are sustained due to a scarcity of INP. Evaluating this hypothesis requires
283 the distinction between aggregation and riming in mixed-phase cloud systems. Fig. 4 demonstrates for a deep mixed-phase
284 cloud system passing the low-aerosol site- in Punta Arenas (53°S, 71°W), Chile, on 30 August 2019, the capability of the
285 LACROS suite ~~when combined with a 94-GHz Doppler radar~~ to distinguish between aggregates and rimed particles when
286 combined with a 94-GHz Doppler radar. The pattern of the 94-GHz radar reflectivity factor (Z , Fig. 4a) underlines the complex
287 structure of the system. The height spectrogram of the vertical-pointing 94-GHz slanted linear depolarization ratio (SLDR,
288 Fig. 4 e) from 08:30 UTC exhibits regions of changing shape signatures and multi-modality in the cloud radar Doppler spectra,
289 where multiple hydrometeor populations coexist. The polarizability ratio ξ_e (Myagkov et al., 2016; ~~Fig. 4d~~) obtained from

290 the RHI scans of SLDR and the co-cross correlation coefficient of horizontal and vertically polarized channels in the slanted
291 basis ρ_{-} at 35 GHz (Fig. 4 b, c) ~~is obtained~~ allows to estimate a density-weighted hydrometeor shape. SLDR is more suited
292 for shape classification compared to LDR. By slanting the polarization basis by 45° ~~deg.~~, the returned LDR signatures are
293 much less sensitive to the canting angle distribution of the targets, especially at low elevation angles (Matrosov et al., 2001;
294 Myagkov et al., 2016). The polarimetric RHI scans and the Doppler spectra data enable the retrieval of the vertical profile of
295 the hydrometeors: Columnar-shaped bullet rosettes are formed between 2.5 km height and cloud top as indicated in the RHI
296 scans by an elevation-constant SLDR (Fig. 4b) and an increase of ρ_{-} with decreasing elevation (Fig. 4c). ξ_{-} values around 1.3
297 (Fig. 4d) ~~are~~ characteristic for slightly columnar crystals. The decreasing elevation-dependence of ρ_{-} already at around 3 km
298 height (-15 to -20°C) suggests more random particle orientations; here the W-band SLDR spectra (Fig. 4e) show reduced
299 values, likely due to the co-existence of dendritic ice crystals, which are formed preferably in this temperature range. The co-
300 location of dendrites and columnar crystals can be explained by either splintering of the arms of the dendritic crystals or a
301 mixing of locally produced dendrites with columnar crystals from higher up, or both. Below 2.5 km, ξ_{-} decreases toward unity,
302 indicating the growth of isometric particles. ~~Also~~ In addition, the vertical-pointing W-band SLDR slowly decreases toward
303 the cloud base, while fall velocities increase (Fig. 4e). Both features are characteristic for riming, which is corroborated by co-
304 located lidar observations that indicate liquid water in the cloud-base region (not shown). Doppler spectra profiles such as the
305 one presented in Fig. 4e are also used in a new neural-network-based riming detection algorithm recently tailored by Vogl. et
306 al. (2021) for vertical-pointing cloud radar observations. This new approach is insensitive to the mean Doppler velocity, which
307 is - especially at Punta Arenas - strongly influenced by orographic mountain waves, because the radar reflectivity factor,
308 skewness and the edge width of the Doppler spectrum is used instead.

309
310 The PROM-project *Investigating the impact of Land-use and land-cover change on Aerosol-Cloud-precipitation*
311 *interactions using Polarimetric Radar retrievals (ILACPR)* analyzes polarimetric radar observations and model simulations
312 simultaneously in order to improve our understanding of land-aerosol-cloud-precipitation interactions. The Terrestrial Systems
313 Modelling Platform (TSMP; Shrestha et al., 2014; Gasper et al., 2014) developed under the DFG-funded Transregional
314 Research Center TR32 (Simmer et al., 2015) is used ~~to~~ to simulate summertime convective storms passing the polarimetric X-
315 band radar (BoXPOL, e.g. Diederich et al., 2015a,b) located ~~in~~ never Bonn, Germany. TSMP generally underestimates the
316 convective area fraction, high reflectivities, and the width/magnitude of differential reflectivity (Z_{DR}) columns indicative of
317 updrafts, all leading to an underestimation of the frequency distribution for high precipitation values (Shrestha et al., 2021a).
318 A decadal scale simulation over the region using the hydrological component of TSMP also shows that much of the variability
319 in the simulated seasonal cycle of shallow groundwater could be linked to the distribution of clouds and vegetation (Shrestha,
320 2021), which further emphasizes the importance of ~~model-evaluating in the~~ representation of clouds and precipitation in
321 numerical models. The fusion of radar observations and models with the aid of observation operators, allows for an extended
322 interrogation of the effects of anthropogenic interventions on precipitation generating processes and the capabilities of
323 numerical models to reproduce them. Here, findings from one simulated hailstorm observed on 5 July 2015 passing the city of

Formatiert: Tiefgestellt

324 Bonn, Germany, are explained. Sensitivity simulations are conducted using large-scale aerosol perturbations and different
325 land-cover types reflecting actual, reduced and enhanced human disturbances. While the differences in modelled precipitation
326 in response to the prescribed forcing are below 5 %, the micro- and macrophysical pathways ~~are found to~~ differ, acting as a
327 buffered system to the prescribed forcings (Stevens and Feingold, 2009; Seifert and Beheng, 2012). Fig. 5 shows vertical cross-
328 sections reconstructed from volume scans measured with BoXPol together with simulated Z_H and Z_{DR} for the TSMP
329 simulations with actual land-cover but perturbed condensation nuclei (CN) and ice nucleating particle (INP) concentrations.
330 CN concentrations are 100 cm^{-3} for maritime and 1700 cm^{-3} for continental aerosol. Similarly, ~~default INP~~ concentrations for
331 dust, soot and organics are $162\text{E}3 \text{ m}^3$, $15\text{E}6 \text{ m}^3$ and $177\text{E}6 \text{ m}^3$, respectively, ~~for default INP~~. For low/high INP, the
332 concentration of soot and organics are decreased/increased by one order of magnitude. To generate the synthetic radar
333 observations the Bonn Polarimetric Radar observation Operator, B-PRO, (Xie et al., 2021; Xie et al., 2016; Heinze et al., 2017;
334 Shrestha et al., 2021b) is applied. B-PRO is based on the non-polarimetric version of EMVORADO (Zeng et al., 2016); its
335 code part for computing unattenuated radar reflectivity on the original model grid (Blahak, 2016) has been expanded to
336 unattenuated polarimetric variables based on spheroidal shape assumptions (T-matrix). Because the full polarimetric version
337 of EMVORADO (Pol-EMVORADO, see Section 4.1) was only released very recently, the model data in ILACPR has been
338 processed using B-PRO. Preliminary comparisons between B-PRO and Pol-EMVORADO (not shown here) exhibit negligible
339 differences in their results on the model grid, but Pol-EMVORADO is much more computationally efficient and takes effects
340 of beam broadening and attenuation along the actual radar ray paths into account. The vertical cross sections are compared at
341 different times marked by the vertical grey bars in the time series of Convective Area Fraction (CAF, Fig. 5 a), defined as the
342 ratio of area with $Z_H > 40 \text{ dBZ}$ (at 2 km a.g.l.) to total storm area. On average BoXPol observations show a bit higher CAF
343 compared to the simulations. The evolution is always similar in terms of an initial increase and intensification in the second
344 part of the observation period, where the experiment with maritime aerosols and low INP (Mar-lowIN) is closest to the
345 observations. All simulations show Z_H and Z_{DR} patterns comparable to BoXPol observations, however, the experiment with
346 continental aerosol and default INP (Con-defIN, Fig. 5c) shows weaker Z_H while Mar-lowIN (Fig. 5d) shows somewhat higher
347 Z_H values compared to BoXPol (see Fig 5a). The simulations with maritime CN produce low cloud droplet concentrations with
348 larger mean diameters compared to the simulations with continental CN. Accompanied by a very strong updraft, this also leads
349 to high concentrations of supercooled raindrops above the melting layer with broader spatial extent (due to a broader updraft
350 region) compared to the simulations with continental CN and contributes to an enhanced growth of hail resulting in higher Z_H .
351 Also, as shown in the ~~CAF time series of the CAF~~, simulations with continental aerosol and default/high IN tend to exhibit
352 similar behaviour in radar space, with the latter exhibiting higher CAF only at latter stages of the storm. The continental CN
353 simulations with default and high IN differ in terms of simulated updraft speed and total hydrometeor content, being higher
354 for the latter one. However, Cont-highIN produces smaller graupel and hail particles compared to Cont-defIN, resulting in
355 similar Z_H . The experiment with continental aerosol and high INP concentration (Con-highIN, not shown) generates similar
356 polarimetric moments to Con-lowIN. All experiments exhibit vertically extensive columns of (slightly) enhanced Z_{DR} ,
357 collocated with intense simulated updrafts reaching up to 13 to 14 km. Indeed, Z_{DR} columns emerged ~~recently~~ as proxies for

Formatiert: Nicht Hochgestellt/ Tiefgestellt

358 updraft strength and ensuing precipitation enhancement (Weissmann et al., 2014; Simmer et al., 2014; Kumjian et al., 2014;
359 Kuster et al., 2020), and research on their exploitation for nowcasting and data assimilation is ongoing. In Fig. 5c/d synthetic
360 Z_{DR} columns are vertically extensive, while Z_{DR} values within the column stay below 0.3 dB. BoXPol observations show Z_{DR}
361 columns reaching up to 6 km height only but with Z_{DR} values exceeding 1dB. While Z_{DR} values in the lower part of the columns
362 are mostly generated by large raindrops, freezing drops and wet hail determine Z_{DR} in the upper parts of the column (Kumjian
363 et al., 2014; Snyder et al., 2015). The diverging appearance of observed and synthetic Z_{DR} columns may point to deficiencies
364 in the treatment of raindrops undergoing freezing and motivates further research. Too rapid freezing of drops combined with
365 graupel generated from the frozen drops may generate enhanced but still low Z_{DR} up to high altitudes. Following Ilotoviz et
366 al. (2018) such attributes of Z_{DR} columns are highly determined by the vertical velocity, hail size, and aerosol concentration,
367 e.g. higher CN concentrations lead to higher columns with higher Z_{DR} values inside and also higher Z_H . In this case study and
368 the specific time step shown, Mar-lowIN (i.e. with lower CN concentration) shows a wider and somewhat taller Z_{DR} column
369 together with a more intense Z_H core (compare Fig. 5c/d). Further explanations require an improved representation of the Z_{DR}
370 columns in the model.

371 4 Fusion of radar polarimetry and atmospheric models

372 Probably the most important and central tool for connecting polarimetric observations with numerical atmospheric models are
373 observation operators, which generate virtual observations from the model state. These virtual observations can be directly
374 compared with the real observations and signatures of microphysical processes including their temporal evolution. Thus, the
375 accuracy of precipitation and cloud parameterizations can be indirectly evaluated and a database established for model
376 optimization. Missing polarimetric process fingerprints (e.g. Kumjian, 2012) in the virtual observations may hint at model
377 deficiencies, and model parameterizations can be adapted in order to increase the coherence between real and virtual
378 observations. Moreover, sufficiently accurate and fast observation operators are mandatory for the direct assimilation of
379 observations using ensemble methods.

380 However, bulk cloud microphysical parameterizations required for NWP models include assumptions on several critical
381 parameters and processes which are not explicitly prognosed ~~respectively or~~ resolved by the governing numerical model. An
382 example are the inherently assumed particle size distributions and their relations to the prognostic moments (hydrometeor mass
383 and number densities). Another challenge is the handling of hydrometeor parameters that ~~are not or only insufficiently~~
384 ~~constrained are insufficiently or not at all constrained~~ by the model's microphysics but are highly relevant for the calculation
385 of virtual observations in the (radar) observation operator. For example, the melting state as well as shape, microstructure, and
386 spatial orientation of the different hydrometeors are not prognostic (or not even implicitly assumed) in most operational bulk
387 schemes. Therefore, suitable assumptions ~~need to be made are required~~ in observation operators in order to compute meaningful
388 virtual observations. Moreover, bulk cloud microphysical schemes may only insufficiently approximate the natural variability,
389 and the interactions between the few assumed hydrometeor classes and the size distribution moments are mainly tuned to get,

390 e.g., the surface precipitation right. The current approximations in both numerical models and observation operators may hence
391 translate into different sources of errors and biases of the simulated radar variables (e.g. Schinagl et al., 2019; Shrestha et al.,
392 2021b). As an example, Fig. 7 shows too low polarimetric signals above the melting layer, which are partly caused by
393 assumptions inherent in the observation operator (see Sect. 4.2.1). Such problems challenge both model evaluation and data
394 assimilation. ~~The Accordingly,~~ central science questions ~~are therefore concern~~ the realism of the sensitivities of simulated radar
395 variables to parameters in the observation operators and the models as well as effective approaches ~~to-for~~ the evaluation and
396 improvement of moist processes parameterizations.

397 Another challenge for large-scale applications such as long-term model evaluations or operational real-time data assimilation
398 based on large radar networks is the high computational demand and low speed of- current polarimetric radar observation
399 operators. Often, the operators apply some kind of pre-calculated lookup tables (LUT) of scattering properties and
400 parallelization techniques for speed optimizations (e.g. Wolfensberger and Berne, 2018; Matsui et al., 2019; Oue et al., 2020).
401 Despite that, radar simulations for a single ~~time step~~ time step take - depending on the computer - on the order of minutes for
402 one single plan position indicator (PPI) scan (Wolfensberger and Berne, 2018) or for a single model scene (CR-SIM; Oue et
403 al., 2020). Matsui et al. (2019) state the LUT generation process of their POLARRIS-~~f~~ operator to only take a few minutes
404 when distributed to few thousands of processors, but do not elaborate on the required times for the actual simulation of the
405 radar measurement. The operator B-PRO (Xie et al., 2016), which uses neither of these techniques, is much slower, as
406 applications within SPP-PROM have demonstrated (Shrestha et al., 2021b). While acceptable for research, real-time operational
407 applications may pose much stricter time constraints. Therefore, an important technical goal is to provide an efficient, yet
408 physically accurate and “state-of-the-art”, polarimetric radar operator to the community, which reduces the simulation time
409 for multi-elevation PPI scans of many stations to a few seconds.

410 **4.1 Polarimetric radar observation operator development**

411 Within the PROM-project *Operation Hydrometeors*, the up-to-now non-polarimetric radar observation operator
412 EMVORADO (Zeng et al., 2016; Blahak and de Lozar, 2020; Blahak, 2016) has been extended to polarimetry (Mendrok et
413 al., 2021). (Non-polarimetric) EMVORADO has been designed to efficiently simulate PPI volume scan measurements of entire
414 radar networks from the prognostic model state of an NWP model for direct comparisons with the radar observations.
415 EMVORADO is part of the executable of both the COSMO and ICON NWP models, which allows to run the operator within
416 a NWP model run and to access the model state and radar variables in memory. The code is MPI- and OpenMP-parallelized
417 and thus fully exploits the computational power of modern HPCs and avoids storing and re-reading extensive model state data
418 to/from hard drives. This enables large-scale real-time applications such as operational data assimilation and extensive NWP
419 model verifications using whole radar networks at high temporal resolution. Its modular nature allows for relatively easy
420 interface development to other NWP models. An offline framework is also available, which accesses model states of one model
421 time step from hard disk. EMVORADO includes detailed modular schemes to simulate beam bending, beam broadening and
422 melting effects, and allows users to choose for each process between computationally cheap and physically accurate options.

423 The operator has been used for the assimilation of radar reflectivity with positive impact on precipitation forecasts (Bick et al.,
424 2016; Zeng et al., 2018, 2019, 2020). Currently, DWD uses EMVORADO to operationally assimilate 3D volumetric
425 reflectivity and radial wind observations of its C-band radar network. Key for this application is also the extensive use of
426 precomputed lookup tables that relate (Mie-theory based) bulk reflectivity directly to hydrometeor densities and temperature.
427 The effects of neglecting radar beam pattern and broadening and of hydrometeor fall speeds on data assimilation have been
428 investigated in a joint effort together with the PROM-project *Representing model error and observation Error uncertainty*
429 *for Data assimilation of POLarimetric radar measurements (REDPOL)* (Zeng et al., 2021a).

430 The polarimetry-extended EMVORADO, in the following referred to as Pol-EMVORADO, has inherited all features of
431 EMVORADO, which in turn have been expanded where necessary to calculate and handle polarimetric variables. This
432 includes, e.g., beam bending, beam broadening, and beam smoothing schemes, effective medium approximations allowing 1-
433 and 2-layered hydrometeors with different water-ice-air mixing schemes and melting topologies, and a lookup table approach
434 for an efficient access to polarimetric observables such as Z_{DR} , LDR, ρ_{HV} , and K_{DP} . Optionally, attenuation effects can be
435 considered, specific and differential attenuation (A_H and A_{DP} , respectively) provided, and further output quantities derivable
436 from the complex scattering amplitudes easily added. Pol-EMVORADO applies state-of-the-art scattering properties of
437 spheroidal particles derived by one-layered (Mishchenko, 2000) and two-layered T-Matrix approaches (Ryzhkov et al., 2011).
438 Assumptions on spheroid shape and orientation follow parameterizations introduced in Ryzhkov et al. (2011). The lookup
439 table approach has been revised to accommodate additional parameters necessary to derive the full set of polarimetric radar
440 output. For a given set of parameters affecting the hydrometeor scattering properties, the lookup tables are created only once,
441 stored in files, and re-used for subsequent runs.

442 Using pre-existing lookup tables, the computations for virtual polarimetric volume scans of radar networks are very fast. For
443 example, simulating the volume scan observations of all polarimetric parameters for all 17 German radars takes a few
444 seconds only on a Linux workstation (8 cores) and adds only about 1 s per radar output time_step to the model runtime when
445 performed online during a run of ICON-D2 (DWD's operational convection-allowing ICON version with 2 km grid spacing)
446 on DWD's NEC Aurora supercomputer. That is, simulating polarimetric radar data in intervals of 5 min as observed by DWD's
447 weather radar network adds up to only a few percent of the total model runtime (Mendrok et al., 2021) making it possible to
448 re-enabling the exploitation of Pol-EMVORADO for the assimilation of high temporal resolution polarimetric radar data in
449 an operational framework. Pol-EMVORADO has been incorporated into the official version of EMVORADO and can be run
450 online (i.e. within a COSMO or ICON run) as well as offline (i.e. stand-alone with model fields from data files). Although
451 designed as a PPI volume scan observation operator for a radar network, its output can also be provided on NWP model grids.
452 An example of a Z_{DR} volume scan simulated by Pol-EMVORADO for the REDPOL project is shown in Fig. 6 (see also Sect.
453 4.2.3).

454 In summary, (Pol-)EMVORADO comprises a wide set of state-of-the-art features. While each of these features is provided
455 also by other observation operators, (Pol-)EMVORADO is, to our knowledge, unique in combining them into an one operator
456 that allows to simulate virtual observations, including instrumental effects and in formats directly comparable to real

457 observational scans, from ~~within~~-NWP model runs in a comparably accurate and very fast manner targeted at operational
458 applications. Mendrok et al. (2021) give a comprehensive description of the features developed or updated for Pol-
459 EMVORADO including details on their implementation and performance.

460 ~~However, From from~~ the application of Pol-EMVORADO (or- B-PRO, see Sect. 3.2) within PROM, a number of problems
461 became evident. Modeling hydrometeors as homogeneous effective-medium particles (e.g. oblate spheroids) does not
462 reproduce well the polarimetric signatures of low density hydrometeors like dendrites or aggregates typical for snow while
463 keeping their microphysical properties (e.g. aspect ratio, degree of orientation) within realistic - observed or model-predicted
464 - ranges and consistent between different radar frequencies. This deficiency has been demonstrated and explained from
465 electromagnetic theory by Schrom et al. (2018).- It is obvious in one case study (Shrestha et al., 2021b) and in Fig. 7, where
466 Z_{DR} and K_{DP} in the snow-dominated layer between 2.5 and 5 km height almost entirely lack the typical observed features, i.e.
467 bands of enhanced Z_{DR} and K_{DP} in the dendritic growth layer that then smoothly decrease to mostly positive, non-zero values
468 towards the melting layer. This deficiency can also be observed with other polarimetric observation operators applying a T-
469 matrix approach (see simulation-to-observation comparisons in Wolfensberger and Berne (2018), Matsui et al. (2019), Oue et
470 al. (2020), where the lack of Z_{DR} and K_{DP} - signatures is not discussed at all or exclusively explained by a lack of secondary
471 ice, though), which nevertheless currently constitutes the state-of-the-art in radar polarimetry. Orientation and shape of frozen
472 and melting hydrometeors are very variable, both in nature and in the assumptions used in observation operators, which
473 translates into large uncertainties in polarimetric radar signatures (e.g., Matsui et al., 2019; Shrestha et al., 2021b).

474 To tackle these challenges, it is planned to interface- Pol-EMVORADO to scattering databases or other scattering models in
475 order to enable more realistic cloud ice and aggregate snowflake scattering properties and allow for improvements or
476 extensions of the polarimetry-related microphysical assumptions (shape/habit/microstructure, orientation and their
477 distribution, e.g., Wolfensberger et al., 2018), particularly for (partly-)frozen hydrometeors. For PROM's 2nd phase, we have
478 proposed to take this up guided with Lagrangian particle model information as well as to test the application of Pol-
479 EMVORADO in an operational data assimilation environment.

480 4.2 Model evaluation and improvements using forward simulations and microphysical retrievals

481 4.2.1 Convection-resolving simulations with COSMO

482 In a joint effort, the PROM-projects *Operation Hydrometeors* and *ILACPR* evaluate simulated stratiform precipitation events
483 in radar observation space and develop a sophisticated polarimetry-based hydrometeor classification and quantification for the
484 evaluation of the representation of hydrometeors in numerical models.- Based on a stratiform event monitored on 7 October
485 2014 with the Bonn polarimetric X-~~bB~~ and radar BoXPol, Fig. 7 illustrates the potential of using polarimetric observations for
486 the evaluation and improvement of microphysical parameterizations. Fig. 7 a-f compare QVPs of measured and virtual Z_H ,
487 Z_{DR} , and K_{DP} with the Bonn Polarimetric Radar observation Operator B-PRO (Xie et al., 2021) to forecasts simulated with
488 COSMO version 5.1 using its 2-moment cloud microphysics scheme (itype_gscp=2683; Seifert and Beheng, 2016). Due to a
489 small spatial shift of the precipitation event in the simulations, the observations at 50.7305 N, 7.0717 E are compared with

Formatiert: Tiefgestellt

Formatiert: Tiefgestellt

490 simulations at a close-by grid point at 51.1 N, 7.0717 E. As demonstrated in Shrestha et al. (2021b) using a similar stratiform
491 precipitation event, COSMO tends to simulate considerable amounts of melting graupel partly reaching the surface, which
492 results in higher synthetic Z_{DR} than observed (compare Fig. 7c/d) within and below the melting layer (ML). Above the ML,
493 however, synthetic Z_{DR} already approaches 0 dB at around 6 km height, which indicates deficiencies in the ice-snow
494 partitioning in COSMO as well as in the assumed snow morphology (soft spheroids) in the observation operator, both resulting
495 in too low polarimetric signals. While the observed and simulated Z_H is comparable in terms of structure and magnitude -
496 except a more pronounced observed ML - larger differences exist with respect to K_{DP} above the ML (Fig. 7e/f). While
497 observations show bands of enhanced K_{DP} within the dendritic growth layer (DGL) centred around -15°C , the simulated K_{DP}
498 is very weak indicating a lower ~~crystal~~ concentration of crystals and early aggregates compared to observations (e.g. Moisseev
499 et al., 2015). Ice water content (IWC) above the ML retrieved from measured K_{DP} and differential reflectivity in linear scale
500 Z_{dr} , i.e. $IWC(K_{DP}, Z_{dr})$ following Ryzhkov et al. (2018), agrees well with IWC modelled by COSMO in terms of structure, but
501 has lower magnitudes (compare Fig. 7 g/h) in line with the lower simulated K_{DP} . Overall, Fig. 7 supports the hypothesis of a
502 too strong graupel production in the simulations. **Operation Hydrometeors** also developed a robust radar-based hydrometeor
503 classification (HMC) and mixing ratio quantification algorithm following Grazioli et al. (2015) and Besic et al. (2016, 2018)
504 for the evaluation of the representation of hydrometeors in NWP models (standard output is the dominant hydrometeor type
505 only). This HMC is based on clustering and has the advantage that the radar data are separated into clusters based on their
506 polarimetric similarity (no theoretical preliminary calculation is needed), which are then identified as hydrometeor classes.
507 Various clustering methods can be used here (e.g. Lukach et al. (2021)). The new method is relatively insensitive to
508 uncertainties in the scattering properties of ice particles. Its application to the BoXPOL observations ~~above~~ does not indicate
509 graupel below the ML (Fig. 8a), while COSMO simulates a pronounced, thick graupel layer (Fig. 8b) including some melting
510 graupel particles reaching the ground around at 1:45 UTC. Applying the HMC to the virtual observations, however, does not
511 reproduce a graupel layer of similar intensity (Fig. 8c), probably caused by a too strong Z_H and temperature influence (compare
512 with Fig. 7) relative to the polarimetric variables in the classification scheme which needs further investigation. A persistent
513 challenge in according routines is that clusters are always separated by the 0°C -level (e.g. Ribaud et al., 2019), i.e. hail or
514 graupel are identified as clusters only below or above the melting layer. For the case study in Shrestha et al. (2021b) the
515 simulated graupel ~~layer~~ was even more pronounced and sensitivity experiments were performed to guide model improvement:
516 increasing the minimum critical particle diameter D_{crit} , which is required for self-collection of ice particles (aggregation)
517 increased/improved the ice-snow partitioning, and a lower temperature threshold for snow and ice riming, T_{rime} , considerably
518 reduced the graupel production.

519 Comparing state-of-the-art polarimetric retrievals of liquid water content (LWC), ice water content (IWC), particle number
520 concentration N_t and mean particle diameter D_m (e.g. Ryzhkov et al., 2018; Ryzhkov and Zrnicek, 2019; Bukovčić et al., 2020;
521 Reimann et al., 2021; Trömel et al., 2019) with their simulated counterparts can also be used for evaluating NWP models and
522 for data assimilation (Carlin et al., 2016). Fig. 7g/h, e.g., shows higher $IWC(K_{DP}, Z_{dr})$ than simulated by COSMO for the case
523 study discussed earlier. ~~However, For~~ more solid conclusions about possible model errors, as well as for the use of retrieved

524 quantities for data assimilation, the retrieval uncertainties must be estimated. The analysis of data collected in the ice regions
525 of tropical convective clouds indicates e.g., that $IWC(K_{DP}, Z_{dr})$ yields a root-mean-square error of 0.49 gm^{-3} with the bias
526 within 6% (Nguyen et al., 2017; 2019). Murphy et al. (2020) introduced the columnar vertical profile (CVP) methodology to
527 follow the track of research aircrafts and better co-locate in-situ data to radar microphysical retrievals. Applying the
528 methodology to two mesoscale convective systems, they found the best performance of polarimetric microphysical retrievals
529 in regions of high Z_{DR} and high K_{DP} but recommend a much larger dataset to fully finally conclude on the accuracy of these
530 retrievals.

531

532 The PROM-project *POLarimetric signatures of ICE microphysical processes and their interpretation using in-situ*
533 *observations and cloud modelling (POLICE)* evaluates radar retrievals and models using in particular in-situ observations of
534 microphysical cloud parameters from the research aircrafts HALO (e.g. Wendisch et al., 2016; Voigt et al., 2017) and Falcon
535 (e.g. Voigt et al., 2010; Voigt et al., 2014; Flamant et al., 2017). Currently, ground-based polarimetric radar measurements and
536 aircraft in-situ data from the Olympic Mountain Experiment OLYMPEX (Houze et al., 2017; Heymsfield et al., 2018) are
537 exploited to investigate riming processes and to evaluate retrievals of ice water content (IWC), particle number concentration
538 N_t , and mean particle diameter D_m (e.g. Ryzhkov et al., 2018; Ryzhkov and Zrnic, 2019; Bukovčić et al., 2020; Carlin et al.
539 2021). The OLYMPEX mission took place on the Olympic Peninsula of Washington State (USA) from November 2015
540 through February 2016. University of North Dakota's (UND) Cessna Citation II equipped with an in-situ cloud payload
541 overpassed the National Science Foundation (NSF) Doppler On Wheels (DOW, - mobile polarimetric X-band radar with about
542 60 km range and 74 m radial resolution), placed in the Chehalis Valley at Lake Quinault (47.48° N , 123.86° W , 64 m altitude)
543 performing RHI scans within an azimuthal sector of 22° -deg. Measurements and microphysical retrievals of the DOW and
544 the Citation, respectively, are currently evaluated and will then be compared at matched space-time coordinates for several
545 flight transects.

546

547 4.2.2 Climate simulations with ICON-GCM

548 A major part of the uncertainties in representing clouds and precipitation in atmospheric models can be attributed to unresolved
549 variability that affects resolved variables via non-linear processes. Current climate model horizontal resolutions are on the
550 order of 100 km. But even for NWP models, which have resolutions between 10 km for global and 1 km for regional
551 simulations, most cloud processes remain unresolved. The project *Climate model PArameterizations informed by RAdar*
552 (*PARA*) evaluates and improves the representation of cloud and precipitation processes in particular for climate models and
553 focuses on precipitation formation in ice clouds. Since most surface precipitation over continents and extra-tropical oceans
554 involve the ice phase (Mülmenstädt et al., 2015; Field and Heymsfield, 2015) its reliable representation is paramount and thus
555 the focus of *PARA*. Microphysical parameterizations typically consider only the mean cloud liquid or ice water content to
556 compute process rates, which causes biases in all nonlinear processes including radiation (e.g., Cahalan, 1994; Carlin et al.,

Formatiert: Tiefgestellt

Formatiert: Tiefgestellt

557 2002) and precipitation formation (e.g., Pincus and Klein, 2000). Realistic results thus require the tuning of process rates (e.g.,
558 Rotstayn, 2000) or realistic estimates of subgrid-scale cloud variability and its inclusion in the process parameterizations. To
559 tackle this issue, *PARA* exploits inherent model assumptions for treating fractional cloudiness. Since the early works of
560 Sommeria and Deardorff (1977), atmospheric models assume or predict some notion of subgrid-scale variability of relative
561 humidity.- Some models do so by predicting cloud fraction (e.g., Tiedtke, 1993), others use a diagnostic representation of the
562 subgrid-scale probability density function (PDF) of total water specific humidity, q_t (e.g., Sundqvist et al., 1989; Smith, 1990;
563 Le Treut and Li, 1991; Rosch et al., 2015). Another option is to utilize a prognostic **probability density function (PDF)** of q_t
564 by assuming a functional form and predicting the shape parameters of the PDF (e.g., Tompkins, 2002; Neggers, 2009). The
565 German climate and weather prediction model ICON in its version dedicated to climate simulations (general circulation model
566 version; ICON-GCM) inherits the representation of physical processes from its predecessor ECHAM6 (Stevens et al., 2013)
567 and uses the Sundqvist et al. (1989) parameterization for a diagnostic PDF of the total-water specific humidity, q_t .

568 As a first step, *PARA* analyses the implied PDF of cloud ice using satellite observations from combined CloudSat-CALIPSO
569 radar-lidar satellite observations (DARDAR, Delanoë et al., 2014). Interestingly, a first direct comparison of IWC profiles
570 obtained from DARDAR with polarimetric retrievals based on the ground-based BoXPOL radar shows an overall good
571 agreement, except for columns with an integrated ice water path IWP $> 1 \text{ kg m}^{-2}$.- In these regions pronounced polarimetric
572 signatures result in high IWC at higher altitudes, which are neither reproduced by reflectivity-only retrievals nor by the
573 DARDAR retrievals. The statistics are currently evaluated on a larger database, which is also used to investigate the impact
574 on the parameterizations in ICON-GCM. In the second step, a stochastic parameterization approach is taken to allow for an
575 unbiased computation of cloud microphysical process rates on average. Based on the cumulative distribution function (CDF),
576 a random number generator draws from the CDF according to the simulated likelihood a plausible value of the specific ice
577 mass based on which the microphysical process is computed. This specifically considers the formation of solid precipitation
578 (snow) from ice clouds via aggregation and accretion processes (Lohmann and Roeckner, 1996; Stevens et al., 2013), and
579 subsequently the evaporation of precipitation below the clouds. The result of the revised aggregation parameterizations is
580 shown in Fig. 9. The increased aggregation rate, which is a linear function of the specific cloud ice, q_i , leads to an average
581 decrease in q_i . The aggregation rate is directly linked to the accretion rate, which lowers the effect of q_i decrease. An
582 investigation of the influence of the revised aggregation parameterizations on the different microphysical process rates - which
583 are related to the ice phase - is currently performed.- A detailed evaluation of the new versus old parameterizations with the
584 ground-based polarimetric radar is on its way, and will in particular focus on the time scales of evaporation of precipitation
585 below the cloud.

586 4.2.3 Data assimilation

587 Within an idealized framework, Jung et al. (2008-; 2010) and Zhu et al. (2020) demonstrated benefits of assimilating simulated
588 polarimetric data for the estimation of microphysical state variables. Up to now, however, direct assimilation of real

Formatiert: Schriftart: Fett, Kursiv

589 polarimetric data poses great challenges due to the deficiencies of cloud and precipitation schemes in NWP models in
590 realistically representing and providing the necessary information (optimally the distribution of particle size, shape and
591 orientations in all model grid boxes) required by a polarimetric radar observation operator and therefore causing large
592 representation error (Janjic et al., 2018). Both the specification of model error to examine uncertainty in microphysics (Feng
593 et al., 2021) and the specification of the observation error for polarimetric radar observations that include estimates of the
594 representation error (Zeng et al., 2021b), are investigated in the PROM-project *REDPOL*. For the assimilation of radar
595 reflectivity with an ensemble Kalman filter, several approaches for including model errors during data assimilation are
596 explored, including 1) additive noise with samples representing large-scale uncertainty (see Zeng et al., 2018), 2) combination
597 of large scale and unresolved scale uncertainty (Zeng et al., 2019), and finally 3) adding to these warm bubble triggering of
598 convective storms in case they are missing in the one hour forecast but present in corresponding observations (Zeng et al.,
599 2020). Applying Pol-EMVORADO to the analysis obtained by assimilating radar reflectivity from the German C-bB and
600 network), Fig. 6 illustrates the resulting differences of these three techniques in Z_{DR} -space. Obviously, synthetic Z_{DR} values
601 depend on the strategy used to specify the model error, putting another weight to the argument that assimilation of radar
602 reflectivity alone is not sufficient to constrain the estimation of microphysical state variables, and that polarimetric information
603 is required in addition. First results in this direction were reported by Putnam et al. (2019), who assimilated Z_{DR} below the
604 melting layer but reported problems ~~in~~ with the assimilation of K_{DP} data for a supercell case due to high observation errors as
605 a result of contamination from wet hail, dust and debris and nonuniform beam filling.
606 .

607 5 Summary and Perspectives

608 The Priority Programme *Polarimetric Radar Observations meet Atmospheric Modelling (PROM)* (SPP 2115,
609 <https://www2.meteo.uni-bonn.de/spp2115/>) was established in April 2017 by the Senate of the Deutsche
610 Forschungsgemeinschaft (DFG, German Research Foundation) and is designed to run for six years. PROM is a coordinated
611 effort to foster partnerships between cloud modelers and radar meteorologists and thus to accelerate the exploitation of
612 polarimetric weather radars to improve the representation of cloud and precipitation processes in numerical models. The first
613 funding phase engaged in an as-complete-as-possible exploitation and understanding of nation-wide polarimetric
614 measurements complemented by state-of-the-art measurement devices and techniques available at supersites. Bulk
615 polarimetric measurements available over Germany are complemented with multi-frequency observations and spectral
616 polarimetry for detailed studies of ice and cloud microphysics. Thus, modellers now hold an unprecedented amount of three-
617 dimensional microphysics-related observational data in their hands to improve parameterizations. Key tools for the fusion of
618 radar polarimetry and atmospheric modelling, e.g. the Monte-Carlo Lagrangian particle model McSnow and the polarimetric
619 observation operator Pol-EMVORADO, have been developed. PROM started with detailed investigations of the representation
620 of cloud and precipitation processes in the COSMO and ICON atmospheric models exploiting polarimetric observation

621 operators. First improvements of the 2-moment cloud- and precipitation microphysics scheme are made and more are expected
622 in phase 2. ~~Also~~In addition, intercomparisons of microphysics schemes in radar space have been performed. Phase 1 further
623 developed microphysical retrievals, determined their uncertainties and started their exploitation for model evaluation and
624 radar-informed parameterizations. The developed prerequisites pave the way to finally exploit polarimetry for indirect and
625 direct data assimilation in the upcoming second funding phase.

626 Some tools developed in pPhase 1, however, still require refinement in pPhase 2. The T-matrix calculations for
627 electromagnetic scattering by spheroidal particles represent only a crude approximation to frozen and mixed-phase
628 hydrometeors, especially for pristine ice particles and aggregate snowflakes at cloud radar wavelengths. It is not possible to
629 reproduce observed polarimetric signatures of snow with the T-Matrix approach (i.e. homogeneous ice-air spheroids) and
630 realistic microphysics (shape, orientation). Refinements include interfacing to a new discrete dipole approximation (DDA)-
631 based scattering data base for realistic ice and snow particles for all relevant weather radar wavelengths and improvements of
632 the melting scheme of graupel and hail.

633 Based on the progress made, the fusion of radar polarimetry and atmospheric modelling can be approached even more
634 aggressively in pPhase 2. While objective 1 received most attention in pPhase 1, more projects will exploit the observational
635 insights and tools developed to finally improve parameterizations and assimilate polarimetric information, i.e. more emphasis
636 will be put on ~~Objectives-objectives~~ 2 and 4 in pPhase 2. Direct assimilation of polarimetric variables remains challenging,
637 because NWP models need to realistically represent and provide the necessary information required by a polarimetric radar
638 observation operator; ideally the distribution of particle size, shape and orientation would be required in all model grid boxes.
639 Indirect assimilation of polarimetric information (e.g. microphysical retrievals, and process signatures), however, is less
640 demanding to the model and should be pursued in parallel. Modern Bayesian data assimilation techniques are sensitive to both
641 model- and observation operator biases, so that further work on these issues is of great importance for a successful data
642 assimilation.

644 **Data availability**

645 The data presented in this paper are available through the authors upon request. Polarimetric radar data from the operational
646 C-band radar network is also available from the German Weather Service (DWD). Specific campaign data will be published
647 in addition.

649 **Author contributions**

650 Silke Trömel had the initial idea and mainly organized and structured the joint publication. Silke Trömel, Johannes Quaas, and
651 Clemens Simmer formed the editorial team consolidating the text. All authors contributed to specific sections of the paper and
652 commented on the paper.

653

654 **Competing interests**

655 Johannes Quaas is editor of ACP. The authors declare to have no additional conflict of interest.

656

657 **Special issue statement**

658 This article is the overview article of the ACP/AMT/GMD inter-journal special issue “Fusion of radar polarimetry and
659 numerical atmospheric modelling towards an improved understanding of cloud and precipitation processes”. It is not associated
660 with a conference.

661

662 **Acknowledgments**

663 We gratefully acknowledge the funding of the German Research Foundation (DFG) to initialize the special priority program
664 on the Fusion of Radar Polarimetry and Atmospheric Modelling (SPP-2115, PROM). The work of contributing authors was
665 carried out in the framework of the projects Operation Hydrometeors (Grants TR 1023/16-1 and BL 945/2-1), IcePolCKa (HA
666 3314/9-1 and ZI 1132/5-1), ILACPR (Grant SH 1326/1-1), IMPRINT (Grant KN 1112/3-1), POLICE (Grants TR 1023/13-1
667 and VO 1504/5-1), PARA (Grants QU 311/21-1 and TR 1023/15-1), HydroColumn (Grant FR 4119/1-1), REDPOL (Grant JA
668 1077/5-1), and PICNICC (Grants KA 4162/2-1 and SE 2464/1-1). ILACPR gratefully acknowledges the computing time
669 (project HBN33) granted by the John von Neumann Institute for Computing (NIC)
670 and provided on the supercomputer JUWELS at Jülich Supercomputing Centre (JSC).

1178

1179

1180 Figure 1: Observations at JOYCE-CF shows a) DWR_{KaW}, b) Z_{DR} (measured at a 30° elevation angle), c) K_{DP} (also measured at 30°

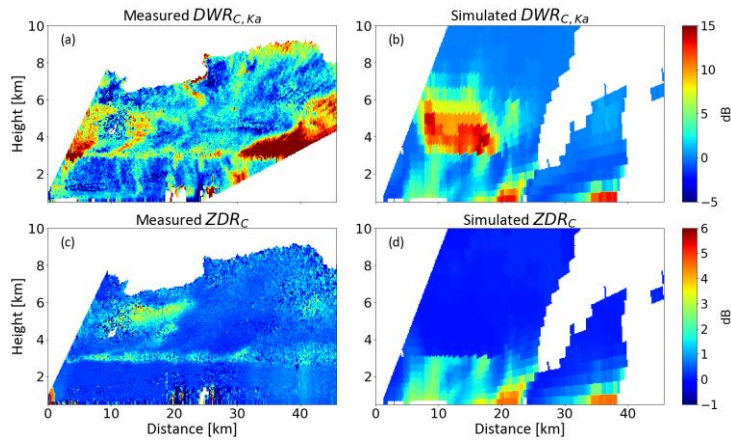

1181 elevation angle) on 22 January 2019. Panels d)-f) show the observed DWR-spectrum, Z_{DR}-spectrum and K_{DP}-profile at 15:00 UTC

1182 (indicated by the red line in panels a)-c))

1183

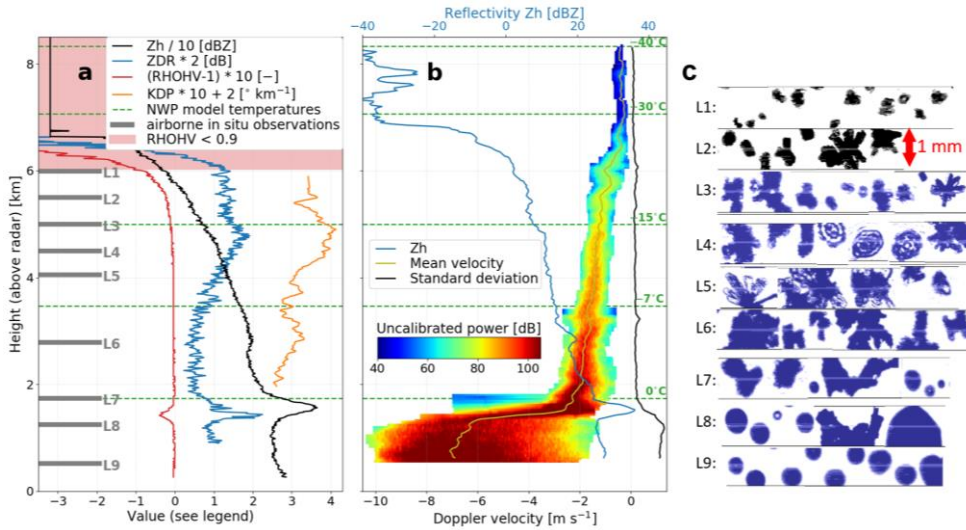

1184

1185

1186

1187 Figure 2 (a) Dual-wavelength ratio between the C-band POLDIRAD and Ka-band miraMACS measurements on the 7th July 2019,
 1188 (b) simulated dual-wavelength ratio, (c) differential radar reflectivity Z_{DR} measured by the C-band radar POLDIRAD, and (d)
 1189 simulated Z_{DR} of a comparable, but not identical, precipitation event using the P3 scheme (Morrison and Milbrandt, 2015).

1190

1191 **Figure 3:** Measurements of slant-viewing and zenith-pointing polarimetric C-band weather radar scans with NWP model based
 1192 temperature levels and airborne in-situ observations: (a) quasi-vertical profiles (QVPs) of radar reflectivity Z_H , differential
 1193 reflectivity Z_{DR} , copolar cross-channel correlation coefficient ρ_{HV} , and the specific differential phase K_{DP} estimated from (noisy)
 1194 measurements of the differential phase by aggressive filtering above the melting layer; (b) average Doppler spectra from a 15 s
 1195 birdbath scan and corresponding first 3 moments at each radar bin height: reflectivity, power-weighted mean velocity and standard
 1196 deviation; (c) in situ particle images (downward-looking projection images) collected at altitudes L1 to L9.

1201 **Figure 4:** Case study of a deep mixed-phase cloud event observed with multiwavelength polarimetric cloud radars at Punta Arenas,
 1202 Chile, on 30 August 2019. (a) vertical-pointing W-Band (94-GHz) radar reflectivity factor Z_e and isolines of modeled air
 1203 temperature, (b) and (c) Ka-Band (35-GHz) RHI scans (90°-30° elevation) of slanted linear depolarization ratio SLDR and co-cross
 1204 correlation coefficient in the slanted basis ρ_s , respectively, from 08:30-08:31 UTC, (d) profile of the shape index polarizability ratio
 1205 (ξ_e) obtained from the RHI scans shown in (b) and (c), and (e) height spectrogram (at 90° elevation) of W-Band SLDR from 08:30:00
 1206 UTC. The time and height frame of panels (b-e) is indicated by the black rectangle in (a).
 1207

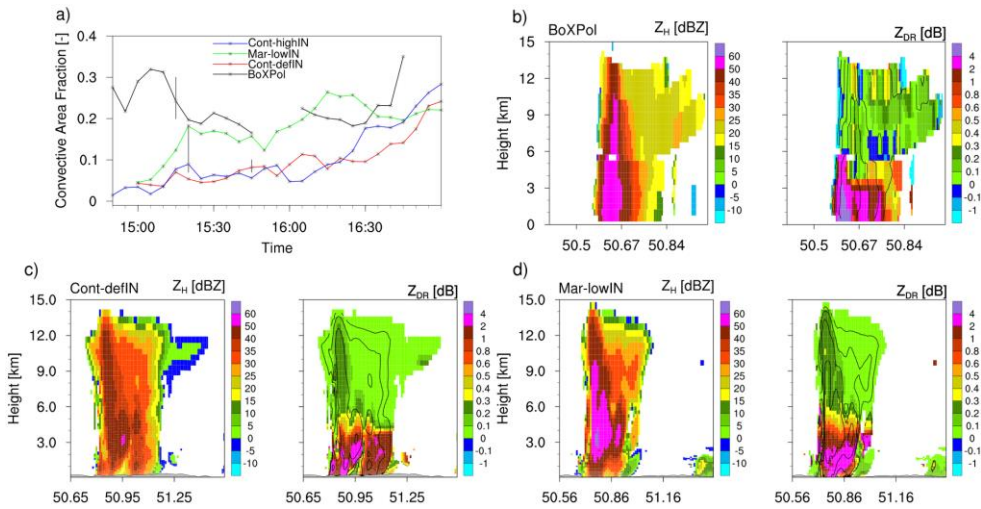

Figure 5: Time-series of Convective Area Fraction (CAF) evolution (panel a) and reconstructed observed (panel b) and simulated/synthetic range-height-indicators (RHI) of horizontal reflectivity Z_H and differential reflectivity Z_{DR} (panels c and d). Synthetic RHIs are based on simulations for actual land-cover with different perturbations of CN and IN concentrations, where Cont-defIN indicates continental aerosol with default IN concentration and Mar-lowIN indicates maritime aerosol with low IN concentration. The gaps in the BoXPol-observed CAF time series are due to strong attenuation. The vertical grey bars (panel a) indicate the times at which the RHIs are compared.

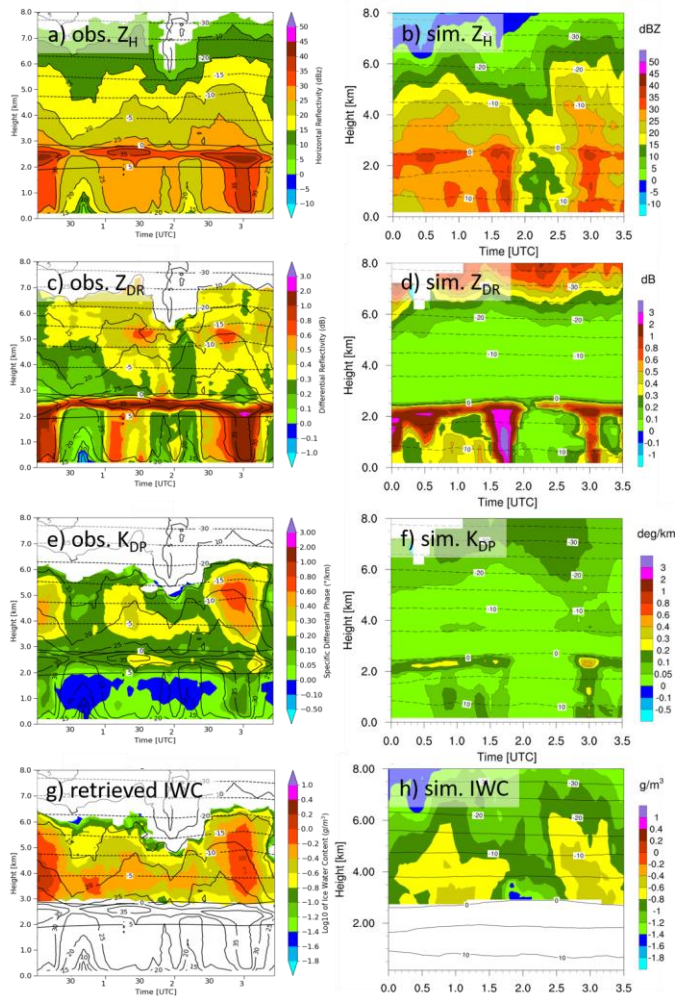

Figure 6: Synthetic PPI of Z_{DR} at 0.5 deg elevation for the DWD radar site Neuheilenbach based on the analysis obtained for June 4 at 16:00 UTC by assimilation of radar reflectivity and using three different ways to specify the model error: large scale uncertainty (left), large plus unresolved scales uncertainty (middle) and in addition the use of the warm bubble approach (right).

1221

1222 **Figure 7: Quasi-vertical profiles (QVPs) of observed (left column) and simulated (right column) polarimetric radar variables**
 1223 **horizontal reflectivity Z_H (panels a and b), differential reflectivity Z_{DR} (panels c and d), specific differential phase K_{DP} (panels e and**
 1224 **f), together with radar-retrieved (panel g) and simulated ice water content (IWC, panel h). The QVPs show a stratiform rain event**

1225 observed on 7 October 2014 between 0:00 and 3:30 UTC with the polarimetric X-band radar in Bonn, BoXPoL, and simulated with
1226 COSMO version 5.1 and the 2-moment cloud microphysics scheme.

1227

1228

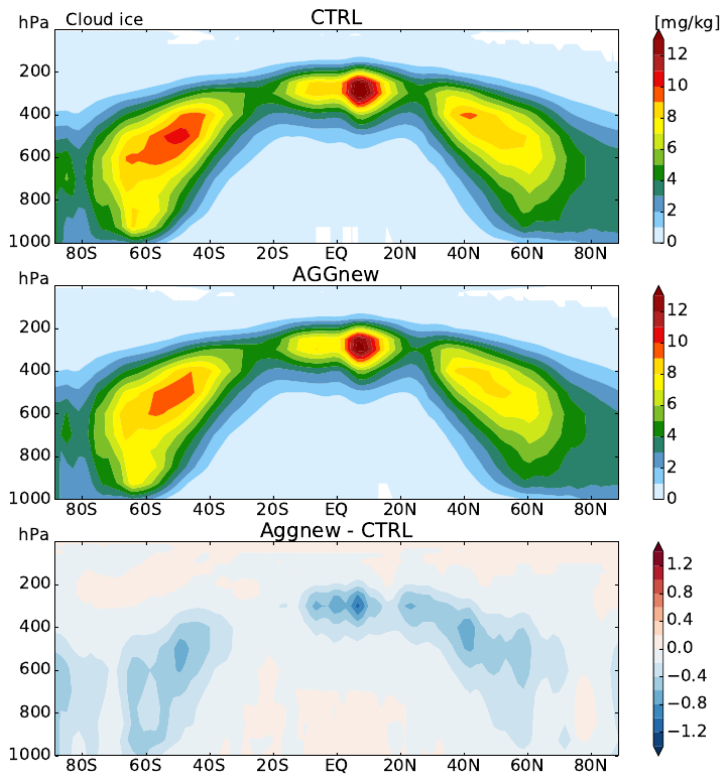

1229 **Figure 8: Retrieved and simulated graupel mixing ratios, defined as the percentage of graupel in the total hydrometeor mass, for**
1230 **the stratiform rain event shown in Fig. 7 (7 October 2014, 0:00-3:30 UTC). An advanced hydrometeor classification and**
1231 **quantification algorithm has been applied to polarimetric BoXPoL measurement (panel a) and to simulated radar variables based**
1232 **on COSMO simulations (panel c) and compared to the COSMO-simulated graupel mixing (panel b).**
