26 **Abstract**

27 The Tibetan Plateau is generally considered to be a significantly clean area owing to its high altitude;
28 however, the transport of atmospheric pollutants from the Indian subcontinent to the Tibetan Plateau has
29 [influenced](#) the Tibetan environments. Nyingchi is located at the end of an important water vapor channel.
30 In this study, continuous monitoring of gaseous elemental mercury (GEM), gaseous oxidized mercury
31 (GOM), and particle-bound mercury (PBM) was conducted in Nyingchi from March 30 to September 3,
32 2019, to study the influence of the Indian summer monsoon (ISM) on the origin, transport and behavior
33 of Hg. [The GEM and PBM during the preceding Indian summer monsoon \(PISM\) period \(1.20±0.35 ng](#)
34 [m⁻³, and 11.4±4.8 pg m⁻³ for GEM and PBM, respectively\) were significantly higher than those during](#)
35 [the ISM period \(0.95±0.21 ng m⁻³, and 8.8±6.0 pg m⁻³\), the GOM during the PISM period \(13.5±7.3 pg](#)
36 [m⁻³\) was almost at the same level with that during the ISM period \(12.7±14.3 pg m⁻³\). The average GEM](#)
37 [concentration in the Nyingchi region was obtained using passive sampler as 1.12±0.28 ng m⁻³ \(from April](#)
38 [4, 2019 to March 31, 2020\). The GEM concentration showed that the sampling area was very clean](#)

39 compared to other high-altitude sites. The GEM has several patterns of diurnal variation during different
40 periods. Stable high GEM concentrations occur at night and low concentrations occur at afternoon during
41 PISM, which may be related to the nocturnal boundary layer structure. High values occurring in the late
42 afternoon during the ISM may be related to long-range transport. Low concentrations of GEM observed
43 during the morning in the ISM may originate from vegetation effects. The results of the trajectory model
44 demonstrate that the sources of pollutants at Nyingchi are different with different circulation patterns.
45 During westerly circulation in PISM period, pollutants mainly originate from central India, northeastern
46 India, and central Tibet. During the ISM period, the pollutants mainly originate from the southern part of
47 the SET site. The strong precipitation and vegetation effects on Hg species during the ISM resulted in
48 low Hg concentrations transmitted to Nyingchi during this period. Further, principal component analysis
49 showed that long-distance transport, local emissions, meteorological factors, and snowmelt factors are
50 the main factors affecting the local Hg concentration in Nyingchi. Long-distance transport factor
51 dominates during PISM and ISM3, while local emissions is the major contributor between PISM and
52 ISM3. Our results reveal the Hg species distribution and possible sources of the most important
53 water vapor channel in the Tibetan Plateau, and could serve a basis for further transboundary
54 transport flux calculations.

55

56 1. Introduction

57 Mercury (Hg) is classified as a hazardous pollutant because it is bio-accumulative and toxic (Mason
58 et al., 1994; Mason et al., 1995). Generally, atmospheric Hg can be categorized into three major types:
59 gaseous elemental mercury (GEM), gaseous oxidized mercury (GOM), and particle-bound mercury
60 (PBM) (Selin, 2009). The stable chemical properties of GEM coupled with its long atmospheric lifetime
61 (approximately 0.3 to 1 year) makes GEM an important global pollutant (Selin, 2009; Travnikov et al.,
62 2017). In contrast, GOM and PBM are easily removed from the atmosphere through chemical reaction
63 and deposition because of their chemical activity and water solubility, and could therefore bring
64 significant impacts to the local environment (Lindberg and Stratton, 1998; Seigneur et al., 2006). Both
65 GOM and PBM have complex fundamental physicochemical properties and may have complicated
66 relationships with other regional pollutants (Gustin et al., 2015). Understanding, identifying, and
67 characterizing Hg sources and their global and regional transport mechanisms is crucial for global
68 atmospheric Hg control and health effects research (UNEP, 2018). Since 2013, the Minamata Convention
69 was established to control the global mercury pollution (UNEP, 2013a). Monitoring atmospheric Hg is
70 an important prerequisite for implementing the convention. Currently, several Hg monitoring networks
71 and studies have been established to better understand atmospheric Hg cycling. The Atmospheric
72 Mercury Network (AMNet; Gay et al., 2013), the Global Mercury Observation System (GMOS;
73 Sprovieri et al., 2013; Sprovieri et al., 2016), the Canadian Atmospheric Mercury Network (CAMNet;
74 Kellerhals et al., 2003) and the Arctic Monitoring Assessment Programme (AMAP;
75 <https://mercury.amap.no/>) are the main monitoring networks operating in North America and Europe,
76 and the majority of them only monitor GEM concentrations (Gay et al., 2013; Sprovieri et al., 2013;
77 Sprovieri et al., 2016; Kellerhals et al., 2003). Researchers worldwide have also contributed to
78 monitoring the data from different regions (Gustin et al., 2015; Jiang and Wang, 2019; Stylo et al., 2016).

79 In China, which has received more attention, there are no reported atmospheric Hg observation networks,
80 but there has been considerable monitoring work by different organizations (Fu et al., 2012b; Fu et al.,
81 2008; Fu et al., 2016a; Fu et al., 2019; Fu et al., 2016b; Liu et al., 2011; Feng and Fu, 2016; Feng et al.,
82 2013; Wang et al., 2015b; Lin et al., 2019; Hu et al., 2014; Ci et al., 2011; Duan et al., 2017; Liu et al.,
83 2002; Yin et al., 2018; Yin et al., 2020). However, there exists some gaps in understanding the sources
84 and transport of atmospheric Hg in some remote areas, especially in harsh environmental areas where
85 performing monitoring is difficult.

86 Considering that GEM can be transported globally over long distances and that the transport
87 distances of GOM and PBM vary greatly in different environments, atmospheric Hg concentration
88 monitoring may not directly reflect the intensity of regional atmospheric Hg emissions. Our previous
89 study of the Qomolangma National Nature Preserve (QNNP) (Lin et al., 2019) demonstrated that the Hg
90 emitted from India can cross the Himalayas to reach the Tibetan Plateau. Further research on the
91 transboundary transport of Hg should be conducted to better understand the transport mechanisms. This
92 is particularly true in Asia, where the environmental pollution is generally severe. China and India are
93 reported to be the world's largest consumers of coal (BP Statistical Review of World Energy, 2018).
94 Considering that coal is the largest emission source of Hg in the atmosphere (approximately 86% of fuel-
95 related atmospheric Hg emissions come from fuel combustion (Chen et al., 2016)), both China and India
96 have great Hg emission potential. South Asia, and East and Southeast Asia accounted for 10.1% and 38.6%
97 of global emissions of mercury, respectively (UNEP, 2018; Zhang et al., 2015b). Further research on
98 pollutant transport in Asia should be conducted to support policy development and responsibility
99 allocation.

100 The Tibetan Plateau, with an average elevation of more than 4,000 m above sea level, is a natural
101 barrier between inland China and the Indian subcontinent (Qiu, 2008; Lin et al., 2019). In the southern
102 part of the Tibetan Plateau, the Himalayas, with an average altitude of 6,000 m, can serve as a solid
103 barrier to pollutant transport. However, this barrier cannot completely block the transboundary
104 transportation of pollutants according to previous studies. The transboundary and long-distance transport
105 of pollutants across the Himalayas has attracted considerable attention (Wang et al., 2018; Zhang et al.,
106 2015a; Yang et al., 2018; Li et al., 2016; Feng et al., 2019; Zhu et al., 2019). Several studies have shown
107 that the transboundary intrusion of atmospheric pollutants through the Himalayas on the Tibetan Plateau
108 is crucial for many pollutants (Yang et al., 2018; Li et al., 2016; Zhang et al., 2015c; Pokhrel et al., 2016;
109 Lin et al., 2019). Zhang et al. (2017) studied short-lived reactive aromatic hydrocarbons and indicated
110 that the cut-off low system that have lower altitude in the Himalayas is a major pathway for long-distance
111 transport of aromatic hydrocarbons in the Tibetan Plateau. Persistent organic pollutants have been
112 reported to be transported to the interior of the Tibetan Plateau by traveling along valleys or across ridges
113 (Gong et al., 2019a). The transport of aerosols and organic pollutants along the most important water
114 vapor channel, the Yarlung Zangbu/Brahmaputra Grand Canyon (hereafter referred to as the YZB Grand
115 Canyon), has been observed (Wang et al., 2015a; Sheng et al., 2013).

116 In the case of atmospheric Hg, monitoring in marginal areas depicted the basic spectrum of
117 atmospheric Hg in the Tibetan Plateau. Monitoring of atmospheric Hg at Shangri-La, Nam Co,
118 Qomolangma, Mt. Gongga, Mt. Waliguan and Mt. Yulong have illustrated atmospheric Hg concentrations

119 and transport patterns in the Tibetan Plateau from multiple perspectives, all of which also indicate the
120 effects of transboundary transport on the atmospheric Hg concentrations in the Tibetan Plateau (Zhang
121 et al., 2015a; Yin et al., 2018; Lin et al., 2019; Fu et al., 2008; Fu et al., 2012a; Wang et al., 2014). For
122 example, our previous study in the QNNP, on the southern border of the Tibetan Plateau, proved that
123 atmospheric Hg from the Indian subcontinent can be transported across high-altitude mountains, and
124 directly to the Tibetan Plateau under the action of the Indian monsoon and local glacier winds (Lin et al.,
125 2019). Studies of water vapor mercury and wet deposition of Hg in cities such as Lhasa have
126 demonstrated higher concentrations of Hg species (Huang et al., 2015; Huang et al., 2016b; Huang et al.,
127 2016a). But the monitoring of atmospheric Hg speciation is still rare. However, to the best of our
128 knowledge, the monitoring of the passage of atmospheric Hg in the main water vapor channel—the YZB
129 Grand Canyon, into the Tibetan Plateau has not been conducted. Through the water vapor and airflow
130 channel, air masses carrying large amounts of water vapor as well as pollutants may enter Tibet, resulting
131 in heavy precipitation during the monsoon season. Huang et al. (2015) reported that the total Hg wet
132 deposition in Nyingchi, located in the YZB Grand Canyon, was lower than that in other Tibetan Plateau
133 regions, and the concentration was lower in the monsoon season than in the non-monsoon season. As an
134 important transport channel for summer monsoon moisture into China (Xu et al., 2020; Feng and Zhou,
135 2012; Yang et al., 2013), the amount of water vapor transported into Tibet through this channel is
136 considerable, and the transport of pollutants needs further investigation.

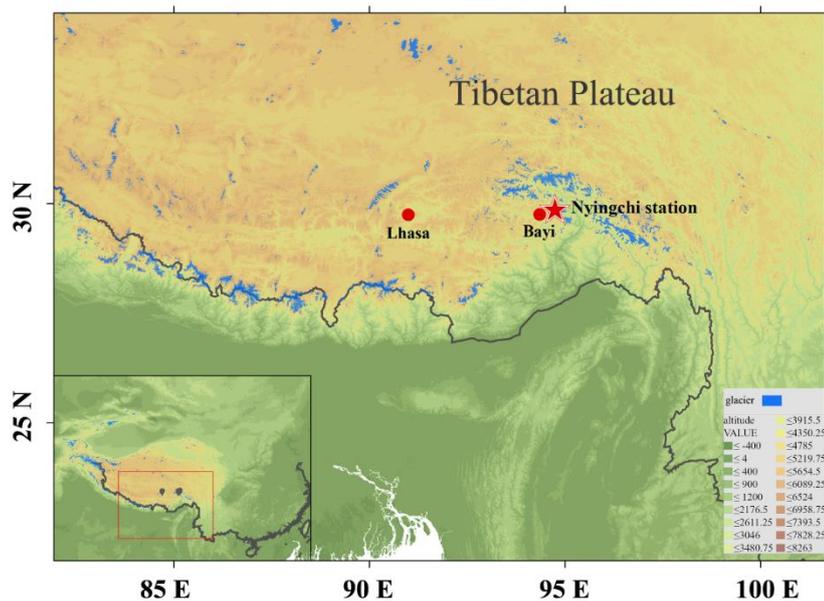

137 In this study, we set up high time resolution Hg species monitoring in Nyingchi, southeastern
138 Tibetan Plateau, covering both PISM and ISM periods. Hg passive sampling was also applied to cover
139 the monitoring of the entire year. To the best of our knowledge, this is the first monitoring study of
140 atmospheric Hg species in the most important water vapor channel of the Tibetan Plateau. To better
141 identify the sources of Hg pollution and potential pollution areas, we combined real-time GEM
142 monitoring data with backward trajectory analysis, and a follow-up cluster analysis of the trajectories.
143 We also collected other pollutant concentrations and rainfall data near the monitoring station during the
144 same period to better analyze the sources and transport characteristics of Hg. By combining the real-time
145 monitoring data and model simulations, we attempted to better characterize the process of Hg entering
146 Tibet through the water vapor channel, which could allow researchers to further analyze the transport of
147 Hg from the Indian subcontinent into Tibet and provide scientific support for managerial decision making.

148 **2. Materials and methods**

149 **2.1 Atmospheric Hg monitoring site**

150 Atmospheric Hg monitoring was performed at the South-East Tibetan Plateau Station for Integrated
151 Observation and Research of Alpine Environment (SET station, Figure 1) in Nyingchi, Tibet, China. The
152 SET station is located in the southeastern part of the Tibetan Plateau (29°45'59N, 94°44'16E, 3263 m
153 a.s.l.), in a water vapor transportation channel, from the Ganges River Plain to the Tibetan Plateau. The
154 meteorological factors at Nyingchi are mainly controlled by westerly winds (from September to April)
155 and ISM (from May to August), exhibiting sharp seasonal variations (controlling date was decided
156 according to Indian Monsoon Index, Figure S1). The average annual air temperature is 5.6 °C, the
157 average air temperature during PISM and ISM periods are 6.0 °C and 12.0 °C, respectively. The
158 Tibetan Plateau is generally a moisture sink in summer (Feng and Zhou, 2012; Xu et al., 2020), with

159 climatological moisture originating from the Indian Ocean and the Bay of Bengal intruding into the center
 160 of the Tibetan Plateau along the water vapor channels. The average annual precipitation is approximately
 161 700-1000 mm at the SET station, much higher than the annual precipitation in Tibet (596.3 mm in 2019).
 162 The precipitation at the SET station is 47.7 mm during the period of PISM, and is 528.5 mm during the
 163 period of ISM in 2019. During the westerly period, the air masses are mainly from mid-latitude inland
 164 areas with less water vapor, while during the ISM period, a large amount of water vapor from the Indian
 165 Ocean enters Tibet. The precipitation begins at the foot of the YZB Grand Canyon and is sustained along
 166 with the canyon into Tibet (Gong et al., 2019b), and the precipitation in the downstream Motuo County
 167 is more than twice that of the Nyingchi area (Ping and Bo, 2018). The unique geomorphological
 168 conditions and the effect of the strong monsoon have resulted in a unique high-altitude distribution
 169 pattern of various biomes and vegetation in the area. Interactions between terrestrial ecosystems and
 170 atmosphere have contributed to the development of diverse biomes and distinctive vegetation elevation
 171 distribution patterns from tropical rainforests to boreal forests and tundra. The SET station is 75 km from
 172 Bayi Town, where the capital of Nyingchi Prefecture is located, and 480 km from Lhasa, which is the
 173 capital city of the Tibet Autonomous Region. Owing to the high altitude and harsh living environment,
 174 the permanent population in Tibet is extremely small and only a few local pollutant emission sources
 175 have been observed (UNEP, 2013b; UNEP, 2018).
 176

177
 178 Figure 1. Location of the South-East Tibetan Plateau Station for Integrated Observation and
 179 Research of Alpine Environment (SET station or Nyingchi station, the red star). SET station is
 180 located in a water vapor channel from the Ganges River Plain to the Tibetan Plateau. The red dot is
 181 Lhasa, the capital city of the Tibet Autonomous Region, which is the most densely populated city in
 182 Tibet; the other red dot is the nearest town to the monitoring site, Bayi Town.

183
 184 **2.2 GEM, GOM and PBM active monitoring**

185 Real-time continuous measurements of GEM, GOM, and PBM concentrations were carried out
186 using Tekran Model 2537B, 1130, and 1135 instruments (Tekran Inc., Toronto, Canada) at the SET station
187 from March 30 to September 3, 2019, which could show the diurnal and daily changes in atmospheric
188 Hg concentration in detail. During the operation of the Tekran instruments, the sampling inlet was set at
189 ~1.5 m above the instrument platform (shown in Figure S2). Considering the high altitude at which the
190 instrument was installed, as well as to mitigate the impacts of low atmospheric pressures on the pump's
191 operation, a low air sampling rate of 7 L min⁻¹ for the pump model and 0.75 L min⁻¹ (at standard pressure
192 and temperature) for model 2537B were applied, based on the previous studies (Swartzendruber et al.,
193 2009; Zhang et al., 2015a; Zhang et al., 2016; Lin et al., 2019). Air was drawn in from the atmosphere
194 into the Tekran instrument, and the Hg was divided into GOM, PBM, and GEM inside the instrument for
195 analysis. A complete measurement cycle takes two hours. During the first hour, GOM was enriched on a
196 KCL-coated annular denuder, PBM was enriched on a quartz fiber filter (QFF), and GEM was directly
197 enriched on the gold tube of the Tekran 2537B and measured directly by cold vapor atomic fluorescence
198 spectroscopy (CVAFS). The collected PBM and GOM were desorbed in succession to Hg(0) at
199 temperatures of 800 °C and 500 °C in the following hour, respectively. Then the Hg(0) was measured by
200 Tekran 2537B. To ensure high data quality, the Tekran 2537B analyzer was set to use the internal Hg
201 source for automatic calibration every 23 h. The instrument was calibrated using an external Hg source
202 at the beginning and end of the monitoring period. The Tekran ambient Hg analyzer has been described
203 in detail in previous studies (Landis et al., 2002; Rutter et al., 2008; de Foy et al., 2016; Lin et al., 2019).
204 The monitoring data were also modified using the method from Slemr et al. (2016) as previous studies
205 suggested that there may be a low bias for low sampling loads (Slemr et al., 2016; Ambrose, 2017).

206 **2.3 Passive sampling of GEM concentration**

207 Passive samplers were set up at the same station during and after the active monitoring period to
208 better reflect the long-term pattern of local GEM concentration changes from April 4, 2019 to March 31,
209 2020. Sulfur-impregnated carbon (Calgon Carbon Corporation) was used as the sorbent for GEM (Guo
210 et al., 2014; Zhang et al., 2012; Tong et al., 2016; Lin et al., 2017). Passive samplers were deployed in
211 triplicate near the Tekran instrument at a height of ~2 m above the ground, and generally the passive
212 samplers were replaced three times per month (Table S1). After sampling, all samplers were sealed in a
213 three-layer zip-lock bag and transported to the laboratory, where they were then measured with the DMA-
214 80 (Milestone Inc., Itália). DMA-80 is an instrument that was used in accordance with US EPA Method
215 7473, using a combined sequence of thermal decomposition, mercury amalgamation and atomic
216 absorption spectrophotometry (Zhang et al., 2012). Hg concentrations in the atmosphere are then
217 calculated from the mass of sorbed Hg according to the equation obtained from our previous work (Guo
218 et al., 2014). The passive sampling method has been successfully applied to the Tibetan Plateau (Guo et
219 al., 2014; Tong et al., 2016) and North China (Zhang et al., 2012) in past studies. The use and quality
220 control of the Hg passive sampler have been described in detail in our previous studies (Zhang et al.,
221 2012; Guo et al., 2014; Lin et al., 2017). Similar passive sampling methods for Hg have been widely
222 used worldwide (McLagan et al., 2018).

223 **2.4 Meteorological data and other pollutants data**

224 During the monitoring period, the local temperature (with a precision of 0.1 °C), relative humidity

225 (with a precision of 1%), wind speed (with a precision of 0.1 m s^{-1}), wind direction (with a precision of
226 1°), air pressure (with a precision of 0.1 hPa), solar radiation (with a precision of 1 W m^{-2}), and UV index
227 (with a precision of 0.1 MEDs) were recorded at a 5-minute resolution by the Vantage Pro2 weather
228 station (Davis Instruments, USA).

229 Hourly measurement data of $\text{PM}_{2.5}$, PM_{10} , SO_2 , NO_2 , O_3 , and CO concentrations and AQI index
230 were obtained from a nearby monitoring station in Nyingchi, which was hosted by the China Ministry of
231 Ecology and Environment and published by the China National Environmental Monitoring Center. The
232 measurements were conducted following the technical regulations for the selection of ambient air quality
233 monitoring stations (National Environmental Protection Standards HJ 664-2013) (Yin et al., 2019).

234 **2.5 Backward trajectory simulation**

235 To better understand the source of atmospheric GEM, the Hybrid Single-Particle Lagrangian
236 Integrated Trajectory (HYSPLIT) model was applied to calculate the backward trajectory many
237 atmospheric particles (Stein et al., 2015; Chai et al., 2017; Chai et al., 2016; Hurst and Davis, 2017; Lin
238 et al., 2019). HYSPLIT was developed by the US National Oceanic and Atmospheric Administration
239 (NOAA) and is a known tool for explaining atmospherically transported, dispersed, and deposited of
240 particles. The HYSPLIT model (<https://www.arl.noaa.gov/hysplit/hysplit/>) is a hybrid method that
241 combines the Lagrangian and Euler approaches. The Lagrangian method calculates the movement of air
242 parcels under the action of advection and diffusion, and the Euler method uses a fixed three-dimensional
243 grid to calculate the pollutant concentration. The backward trajectory simulation used Global Data
244 Assimilation System (GDAS) data with $1^\circ \times 1^\circ$ latitude and longitude horizontal spatial resolution and 23
245 vertical levels at 6 h intervals. The trajectory arrival height was set to 200 m a.g.l., which is about half
246 of the boundary layer height. We examined the effects of arrival height on the trajectories using
247 different arrival heights (20m, 50m, 200m and 500m respectively) in June 2019. The results show
248 that the calculated trajectories of the air masses are almost the same when the arrival height is below
249 500m (Figure S3). Each backward trajectory was simulated for 120 hours at 3 hours intervals for GEM,
250 which can cover China, Nepal, India, Pakistan, and the majority of western Asia. Cluster analysis was
251 performed after the trajectory calculation. Cluster analysis can help identify the average air masses
252 transport path by averaging similar or identical paths in the existing air masses paths, and provide
253 major directions of GEM transported to the measurement site.

254 **2.6 Principal components analyses**

255 Principal component analysis (PCA) is a data reduction method that can group some measured
256 variables into a few factors that can represent the behavior of the whole dataset (Jackson, 2005). PCA
257 has been employed in many previous Hg studies to analyze the relationships between Hg and multiple
258 pollutants and meteorological variables (Brooks et al., 2010; Cheng et al., 2012; Liu et al., 2007; Zhou
259 et al., 2019). All variables were normalized by standard deviation prior to running the PCA. To ensure
260 that the PCA is a suitable method for the data set in this study, the Kaiser-Meyer-Olkin measure of
261 sampling adequacy (> 0.5) and Bartlett's test of sphericity ($p < 0.05$) tests were performed in the initial
262 PCA run. Total variance and scree plots after rotation were used in the PCA analysis to determine the
263 factor numbers. Components with variance ≥ 1.0 were retained. Variables with high factor loadings

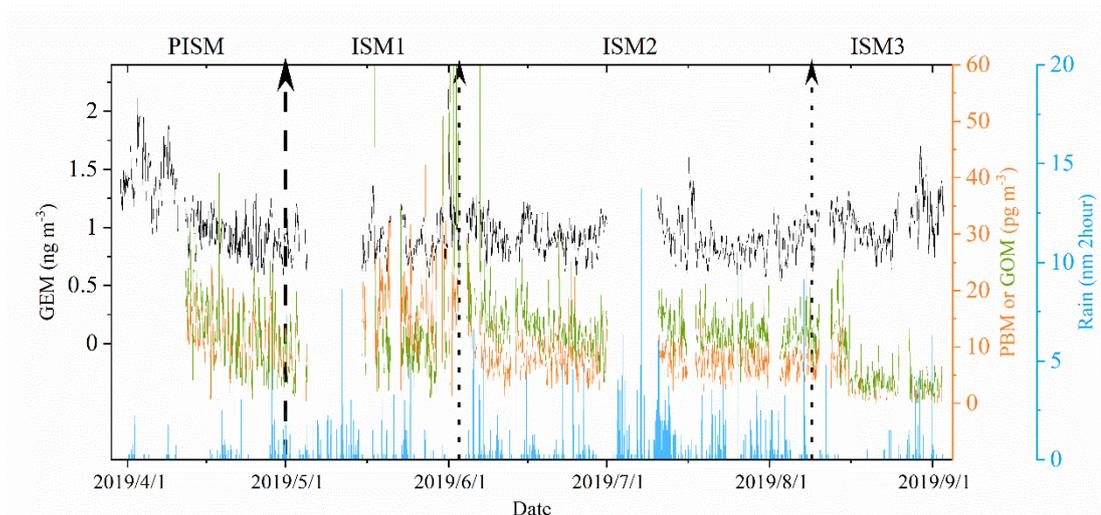

264 (generally > 0.5) were used to interpret the potential Hg source.

265 **3. Results and discussion**

266 **3.1 Hg species concentrations in Nyingchi**

267 During the whole monitoring period, the GEM, GOM and PBM concentrations at SET station were
268 $1.01 \pm 0.27 \text{ ng m}^{-3}$, $12.8 \pm 13.3 \text{ pg m}^{-3}$, and $9.3 \pm 5.9 \text{ pg m}^{-3}$ (mean \pm SD), respectively. Figure 2 shows the
269 GEM, GOM, and PBM concentrations and rainfall over the sampling period. Table S2 summarizes the
270 statistical metrics of Hg species, meteorological factors, and other pollutants in every monitoring period.
271 To further discuss the patterns of Hg concentrations, the entire monitoring period was divided into the
272 PISM period (before May 1) and the ISM period. The ISM period was further subdivided into three
273 periods (ISM1 – ISM3) according to changes in precipitation. The atmospheric Hg concentrations during
274 the PISM period ($1.20 \pm 0.35 \text{ ng m}^{-3}$, $13.5 \pm 7.3 \text{ pg m}^{-3}$, and $11.4 \pm 4.8 \text{ pg m}^{-3}$, for GEM, GOM and PBM
275 respectively) were higher than those during the ISM period ($0.95 \pm 0.21 \text{ ng m}^{-3}$, $12.7 \pm 14.3 \text{ pg m}^{-3}$, and
276 $8.8 \pm 6.0 \text{ pg m}^{-3}$, for GEM, GOM and PBM respectively). From ISM1 to ISM3, the average GEM
277 concentrations increased from $0.92 \pm 0.23 \text{ ng m}^{-3}$, $0.92 \pm 0.18 \text{ ng m}^{-3}$ to $1.04 \pm 0.21 \text{ ng m}^{-3}$, while GOM
278 concentrations decreased sharply from $18.2 \pm 29.2 \text{ pg m}^{-3}$, $13.5 \pm 5.5 \text{ pg m}^{-3}$ to $6.0 \pm 5.0 \text{ pg m}^{-3}$, PBM
279 concentrations decreased sharply from $15.4 \pm 7.9 \text{ pg m}^{-3}$, $7.9 \pm 3.4 \text{ pg m}^{-3}$ to $3.9 \pm 3.6 \text{ pg m}^{-3}$. During the
280 PISM period, the GEM concentrations decreased continuously as the Indian monsoon developed and
281 intensified (Figure 2), which may indicate a change in the local GEM source as the wind field changes
282 from westerly to Indian monsoon. GEM concentrations remained relatively stable during ISM1 and ISM2
283 (0.92 ± 0.23 to $0.92 \pm 0.18 \text{ ng m}^{-3}$), which may indicate that the source of GEM was relatively stable during
284 this period. However, at the end of the monsoon (ISM3), the GEM concentration started to increase
285 gradually to $1.04 \pm 0.21 \text{ ng m}^{-3}$. There was no significant correlation between GEM concentration and
286 precipitation during the ISM period, which may be due to the stable chemical properties of GEM because
287 the air mass sources are relatively stable during the ISM period (Selin, 2009), while GOM and PBM
288 concentrations are strongly influenced by precipitation (Figure 2). With the increase in rainfall from
289 113.75 mm during ISM1 period to 373.28 mm during ISM2 period (total precipitation), the
290 concentrations of GOM and PBM decreased sharply from $18.2 \pm 29.2 \text{ pg m}^{-3}$ and $15.4 \pm 7.9 \text{ pg m}^{-3}$ to
291 $13.5 \pm 5.5 \text{ pg m}^{-3}$ and $7.9 \pm 3.4 \text{ pg m}^{-3}$, respectively. The considerable precipitation increase may be
292 responsible for the rapidly reduced GOM and PBM concentrations, as they are easily deposited in the
293 atmosphere with precipitation (Lindberg and Stratton, 1998; Seigneur et al., 2006). GOM and PBM
294 concentrations continued to decline from ISM2 to ISM3, however, the trend in precipitation was reversed.
295 This may indicate that less GOM and PBM were transported to the SET station or with fewer local
296 sources during ISM3. In a previous study, Huang et al. (2015) found that even with heavy rain during the
297 monsoon period, the total Hg concentration in precipitation in the SET region was small but still
298 considerable, suggesting that there may be a stable source of Hg in the SET region during the ISM period.
299 The high total Hg concentration in precipitation during ISM may indicate that local emissions could be
300 important sources during ISM period.

Figure 2. Time series of GEM, GOM, and PBM concentrations and the rainfall over the sampling period. The GEM concentration resolution is 5 min, and the GOM, PBM, and rain resolutions are 2 hours. According to the characters of monsoon development and precipitation, the monitoring periods are divided into four segments, namely PISM (before May), ISM1 (1 May- 2 June), ISM2 (3 June – 8 August), and ISM3 (after 9 August).

Figure 3 shows the results of the GEM concentrations obtained through passive samplers throughout the year. The average GEM concentration is $1.12 \pm 0.28 \text{ ng m}^{-3}$, which is slightly higher than the average GEM concentration during the Tekran monitoring period ($1.01 \pm 0.27 \text{ ng m}^{-3}$). **In terms of seasonal variation, average GEM concentrations were the lowest in summer ($1.03 \pm 0.09 \text{ ng m}^{-3}$), with almost identical average concentrations in spring, autumn and winter ($1.14 \pm 0.28 \text{ ng m}^{-3}$, $1.16 \pm 0.35 \text{ ng m}^{-3}$ and $1.14 \pm 0.28 \text{ ng m}^{-3}$, respectively). This is different from the trends of GEM concentrations in the surrounding areas, where the highest GEM concentrations in Nam co, Mt. Ailao, Mt. Waliguan and Mt. Gongga (Yin et al., 2018; Zhang et al., 2016; Fu et al., 2012; Fu et al., 2008) were all seen in summer, which may indicate that the Indian summer winds that bring high GEM concentrations to these areas do not present similar effect on the SET region.** For the variation throughout the year, the GEM concentration in May and June is the lowest with an average concentration of only $0.97 \pm 0.18 \text{ ng m}^{-3}$, while November and December have the highest GEM concentrations ($1.24 \pm 0.37 \text{ ng m}^{-3}$). The average GEM concentration is lower ($1.02 \pm 0.09 \text{ ng m}^{-3}$) during the ISM period (from May to August) and higher during the westerly circulation period ($1.16 \pm 0.32 \text{ ng m}^{-3}$); however, the GEM concentration during westerly circulation period has large fluctuations. Since there are almost no local industries and less human activity in Nyingchi, this difference may indicate a higher input of pollutants introduced by westerly circulation.

328

329 Figure 3. GEM concentrations obtained through passive samplers throughout the year. The black
 330 squares represent the atmospheric Hg concentrations obtained by passive sampling, and the upper
 331 and lower error lines are the standard errors of the passive samples monitored during the same time
 332 period. The red dots represent the GEM concentrations obtained through the Tekran instrument. The
 333 green horizontal line indicates the average of the atmospheric mercury concentrations during this
 334 period.

335

336 Table 1 summarizes the GEM, GOM, and PBM concentrations from research papers of high-altitude
 337 regions around the world. Compared to other high-altitude sites, the GEM concentrations in the SET
 338 region were relatively low and did not reach the average GEM concentration level in the Northern
 339 Hemisphere ($\sim 1.5\text{-}1.7 \text{ ng m}^{-3}$). Compared to previous studies of high elevation ($> 2000 \text{ m a.s.l}$) regions,
 340 only Concordia Station in Antarctica had lower GEM concentrations than those observed at the SET
 341 station. Ev-K2, Nam Co, Qomolangma, and Shangri-La, the nearest monitoring stations to the SET
 342 station and at higher altitudes, had higher GEM concentrations than those at the SET station. In particular,
 343 the GEM concentration at Shangri-La was more than two-fold of that at the SET station. The differences
 344 in the GEM concentrations among them may be mainly due to their different climatic conditions and
 345 different monsoon control zones, which result in different pollutant source regions and air mass transport
 346 trajectories. The Shangri-La station may be influenced by anthropogenic emissions within and outside
 347 China, and therefore, has higher GEM concentrations. For Ev-K2 and Qomolangma stations, which are
 348 under the influence of the ISM, they may be directly exposed to air masses with high concentrations of
 349 pollutants transported from India and Nepal. [Although there are extreme deposition processes during the](#)
 350 [climbing process to both Ev-K2 and Qomolangma stations, some Hg may survive reach the stations \(Lin](#)
 351 [et al., 2019\)](#). The GOM concentrations at the SET station were approximately at the average level among
 352 the monitored sites. PBM concentrations were relatively low at the SET station, which may be due to the
 353 high rainfall in the YZB Grand Canyon, easily washing away particulate Hg by rainwater.

354

355

The lower GEM concentrations during the ISM period may indicate that the pollutant sources of the

356 SET region changed with the weakening of the westerly circulation and the strengthening of the Indian
357 monsoon. Previous studies (Lin et al., 2019; Gong et al., 2019a; Wang et al., 2015a) indicated that
358 pollutants from the heavily polluted Indian subcontinent may be transported to the Tibetan Plateau under
359 the action of ISM, resulting in increased local pollutant concentrations on the plateau. This was verified
360 at the Qomolangma, Nam Co, and Mt. Ailao stations, where GEM concentrations were higher during the
361 ISM period than the PISM period (Lin et al., 2019; Yin et al., 2018; Zhang et al., 2016). However, in our
362 study, the SET station observed lower Hg species concentrations during the ISM than the PISM period.
363 For GEM, the decrease in concentration may be due to the absorption effect from the dense vegetation
364 during the monsoon period (Fu et al., 2016b), while air masses from the Indian Ocean bring large amounts
365 of halogens (Fiehn et al., 2017), which may react with and deplete GEM. For GOM and PBM, increased
366 concentrations were observed during the ISM1 period, whereas their concentrations decreased sharply
367 during the ISM2 and ISM3 periods. The decreases in GOM and PBM concentrations may be mainly due
368 to the rapid increase in local precipitation during the Indian monsoon period, which starts after the
369 monsoon enters China from northwestern India. A large amount of water vapor from the Indian monsoon
370 climbs more than 3,000 m within ~100 km in the YZB Grand Canyon, producing considerable
371 precipitation. Therefore, GOM and PBM may deposit during transportation and are unable to reach the
372 Nyingchi area.

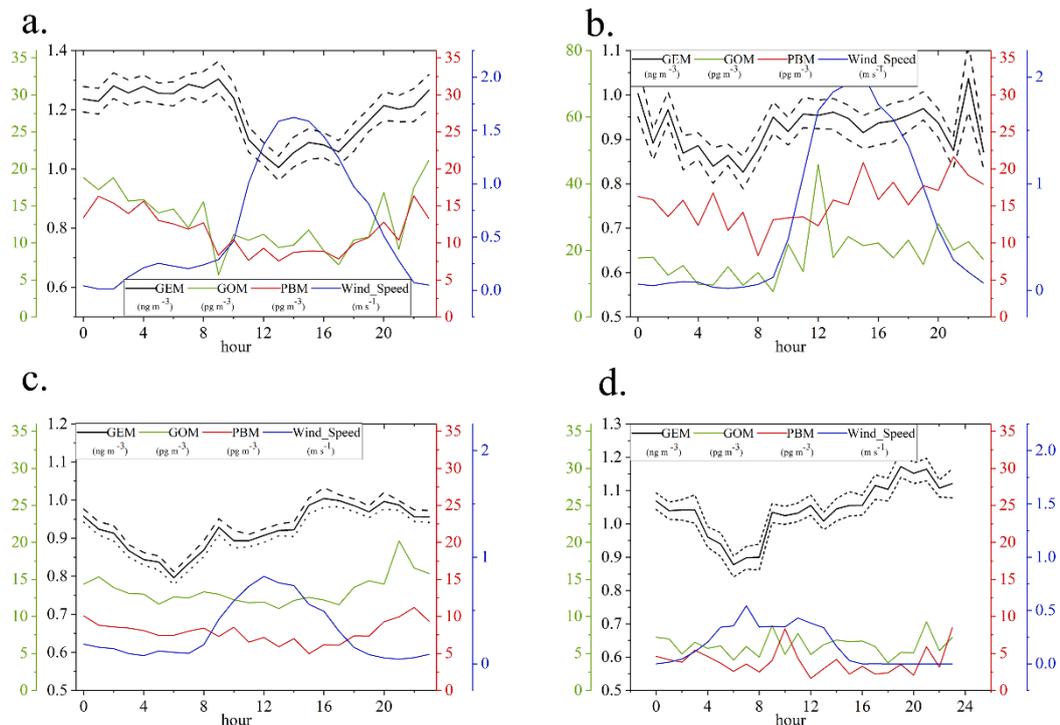

373 Table S3 shows the variations of Hg species, meteorological factors and other pollutants from
374 June 1 to 4, 2019. High GOM concentrations were observed on June 2 and 3, and very high solar
375 radiation and UV Index were also observed in these days. PBM concentrations, relative humidity
376 and O₃ were low during this period. The solar radiation was nearly twice the mean value of the ISM1
377 phase (162.79 W m⁻², Table S2), and thus higher solar radiation might contribute to the higher GOM
378 concentrations. PBM might be partly converted to GOM, but the decrease in PBM concentration
379 was less than the increase in GOM concentration. Generally, high O₃ concentrations should be
380 observed at higher solar radiation (Kondratyev et al., 1996), but low O₃ concentrations were found
381 at Nyingchi, suggesting that O₃ may contribute to the formation of GOM. The oxidation of GEM
382 by OH and O₃ to generate GOM has been discussed in previous studies with model simulation
383 (Sillman et al., 2007), which may explain the reduced concentration of O₃, while OH radicals may
384 be associated with high solar radiation. The mechanism of GOM formation should be further
385 explored in future studies.

386 **3.2 Diurnal Variation**

387 Figure 4 shows the diurnal variation of Hg species and the concentrations of other pollutants during
388 the entire monitoring period. In general, the Hg species concentrations varied significantly during the
389 PISM period, and the diurnal variation was relatively small after entering the ISM period. During the
390 PISM period, the GEM concentrations were relatively low during the daytime (average 1.07 ng m⁻³ from
391 11:00 to 18:00), gradually accumulated after sunset, and finally reached a relatively stable high value
392 (average 1.26 ng m⁻³) at night. During the ISM period, the GEM concentration variation pattern was not
393 as pronounced as during the PISM period, with the lowest GEM concentration of the day usually
394 occurring around sunrise (0.83, 0.80, 0.88 ng m⁻³ for ISM1-3, respectively). During ISM1, the GEM

395 concentration reached a high value around 9:00 a.m., fluctuated less during the daytime, reached a
 396 maximum value in the evening, and gradually dissipated in the early morning. During ISM2, the
 397 maximum value was reached at approximately 16:00, was more stable in the evening, and gradually
 398 dissipated in the early morning. During ISM3, the maximum value was reached at approximately 20:00
 399 and dissipated in the early morning. The average of the daily maximum values were 1.04, 1.00, 1.16
 400 m^{-3} for ISM1-3 periods, respectively. After midnight, GEM concentrations gradually decreased. In
 401 general, the daily variation of GEM in previous research were about 0.2-0.9 ng m^{-3} globally (Fu et al.,
 402 2012a; Fu et al., 2008; Fu et al., 2010; Lin et al., 2019; Zhang et al., 2015a), and were lower at the SET
 403 site (0.21, 0.20, 0.28 for ISM1-3 periods, respectively). For GOM and PBM, the diurnal variations
 404 showed U-shaped variation patterns during the PISM period. During this period, the concentrations of
 405 GOM and PBM reached low values between 10:00 and 14:00, then gradually accumulated and peaked
 406 around midnight. After midnight, the concentration gradually decreased to its lowest point. During the
 407 ISM1 period, GOM and PBM concentrations were higher in the afternoon and evening, and showed a
 408 decreasing trend after midnight. During ISM2-3, GOM and PBM did not show clear daily variation
 409 patterns. Except for the ISM2 period, there was little difference between GOM and PBM concentrations
 410 during the other periods, which may be due to similar sources and behavioral patterns in the environment.
 411 In contrast, during the ISM2 period, more precipitation (Figure 2) led to a sharp decrease in PBM
 412 concentrations, and it is speculated that GOM may have additional sources during this period. The
 413 oxidation of GEM by OH and O_3 to generate GOM may be a possible reason for the high GOM
 414 concentration (Sillman et al., 2007). However, the mechanism of GOM formation should be further
 415 explored.

416

417

418 Figure 4. Diurnal variation of Hg species, concentrations of some other pollutants and
419 meteorological information from PISM to ISM1-3 periods. The short horizontal line represents the
420 concentration error range for each time period.

421

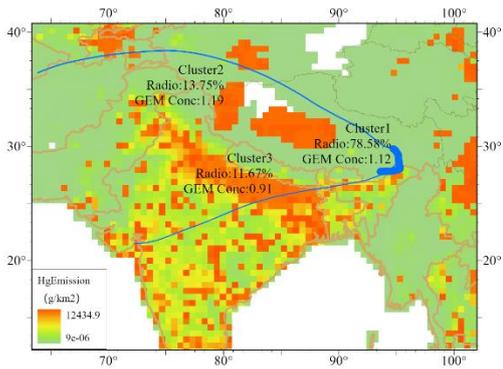

422 Compared with other Hg monitoring in previous studies, some diurnal variation trends of Hg at the
423 SET site were unique. In previous studies (Sprovieri et al., 2016; Yin et al., 2018; Zhang et al., 2015a;
424 Zhang et al., 2016; Fu et al., 2012a; Fu et al., 2010; Lan et al., 2012), a common pattern of highest
425 concentration around noon and lowest concentration before sunrise was mostly observed. [The decrease
426 in GEM concentration at night may be due to the interaction of pollutants from regional emissions and
427 long-range transport\(Fu et al., 2008; Fu et al., 2010\)](#). After sunrise, partial GEM re-emission occurs in
428 the sunlight, along with the mixing effect of the residual boundary layer downward, which may lead to
429 an increase in GEM concentration (Mao and Talbot, 2012; Selin et al., 2007; Weiss-Penzias et al., 2009;
430 Talbot et al., 2005). The height of the boundary layer increases after noon during the daytime, which
431 produces dilution of GEM at the surface and may be the reason for the decrease in GEM concentration
432 in the afternoon. The GEM diurnal variation pattern at the SET is particularly special during the PISM
433 period, while a similar variation pattern was also observed at the Qomolangma site in our previous
434 research (Lin et al., 2019), which is another high-altitude site with a sparse population and rare industry.
435 This similar pattern suggests that they have a similar mechanism of GEM diurnal variation. Considering
436 that neither site has an obvious local source of GEM, the variation in GEM concentrations may only be
437 subject to these mechanisms. Similar to the study of Qomolangma, the variation in the boundary layer
438 height may be one of the reasons for the diurnal variation of GEM concentration in the SET region. The
439 stable and low height nocturnal boundary layer at night causes the GEM concentration to gradually
440 concentrate, and the boundary layer gradually increases to a higher altitude after sunrise. [The gradual
441 increase in GEM concentration during the daytime may be due to the reduction of GOM from nearby
442 local snowy mountains \(Lalonde et al., 2003; Lalonde et al., 2002\) or long-range transported GEM
443 brought in by airflow \(Lin et al., 2019\)](#). During the ISM period, the nighttime GEM dissipation may be
444 due to the fact that this area enters a rapid leaf-growing season (Fu et al., 2016b) after entering the ISM
445 period, that the air masses from the Indian Ocean bring a large amount of halogens ([Fiehn et al., 2017](#)),
446 and that depletion of GEM occurs under the boundary layer at night.

447 **3.3 Source identification for atmospheric Hg in Nyingchi**

448 To further investigate the contributions of different sources to the SET site, air mass back trajectory
449 simulation and trajectory cluster analyses were performed for GEM. Figure 5 shows the cluster analysis
450 results for the PISM and ISM1-3 periods. Based on the results of the total spatial variation index, 3-5
451 clusters were grouped for each period. Each clustered trajectory contained detailed information about the
452 trajectory from the source region to the SET site, the trajectory frequency during the period, and the
453 concentrations of the pollutants carried by the air mass when the trajectory arrives.

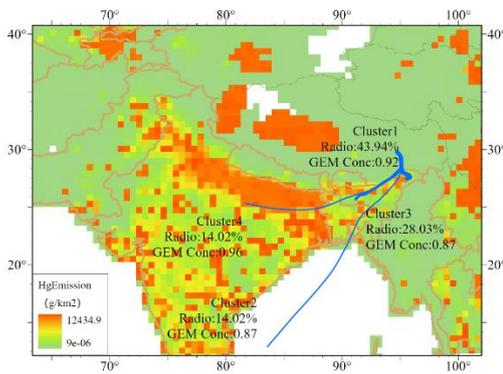

454

455 a.

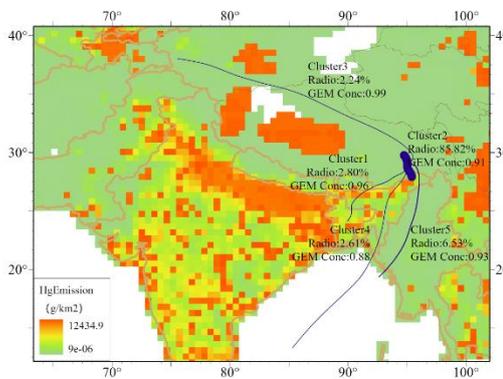

456

457 b.

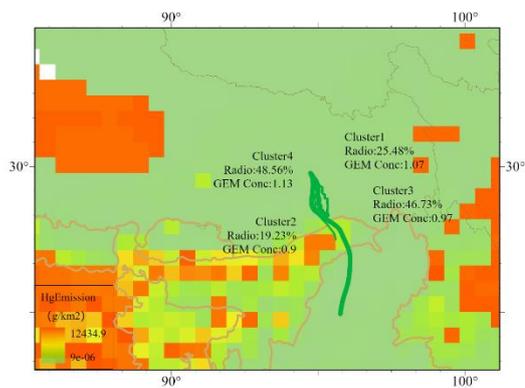

458

459 c.

460

461 d.

462

463 Figure 5. Clusters of the back trajectory analysis from SET site during PISM to ISM3 periods. The
464 thickness of the line represents the ratio of the cluster in the time period, the background is the
465 globally Hg emission inventory developed by UNEP(UNEP, 2013a).

466

467 During the PISM period (Figure 5a), the trajectories mainly originated from or passed through
468 central India, northeastern India, and central Tibet, and moved along the southern border of the Himalayas
469 Mountains. During this period, the meteorological factors at Nyingchi were mainly controlled by
470 westerly circulation. The cluster with the highest concentration (cluster2, with GEM concentration of
471 1.19 ng m^{-3}) originated from or passed through central Tibet, accounting for 13.75% of all trajectories in
472 this period. Although the GEM concentrations of the cluster were relatively high during this period, they
473 were still lower than the background GEM concentration in the Northern Hemisphere ($\sim 1.5\text{-}1.7 \text{ ng m}^{-3}$),
474 indicating that the air mass transported to the SET station is relatively clean. Cluster1, from the southern
475 border of the Himalayas, was relatively high in proportion (with a frequency of 78.58%), mainly
476 controlled by the southern branch of the westerly circulation, and has a relatively low concentration (1.12
477 m^{-3}). This cluster made a turn in the south of SET station and began to ascend toward the Tibetan Plateau.
478 According to the UNEP reports, Hg emission intensities along the trajectory paths were weak (UNEP,
479 2018; UNEP, 2013b).

480 During the ISM period (Figure 5b-d), the trajectories of arrivals at the SET site changed significantly
481 with the onset and rise of the Indian monsoon. The clusters undergo a slight counter-clockwise rotation.
482 As the source of the air mass changes and the monsoon enters the plateau, it is possible that the
483 concentrations of pollutants decrease because of the change in the source region. With the development
484 of the Indian monsoon, it brings an abundance of water vapor (Ping and Bo, 2018), which may cause
485 strong deposition during transportation. During the ISM1 period (Figure 5b), both the rising monsoon
486 and the tail of the westerly circulation control the meteorological factor at the region, causing the
487 transported air masses to exhibit complex trajectories and combined effects. The cluster with the highest
488 concentration (cluster4, 0.96 ng m^{-3} , and 14.02%) mainly came from or passed through central India.
489 Cluster3 share almost the same transport path with cluster4 while having shorter length and lower GEM
490 concentration, which may indicate that cluster4 was affected by GEM emission in central India. The
491 trajectory with the largest proportion (cluster1, 43.94%) had a relatively short path, mainly from northeast
492 India, and showed very low GEM concentration (0.92 ng m^{-3}). Based on the existing atmospheric Hg
493 emission inventories (Simone et al., 2016; UNEP, 2018; UNEP, 2013b), the Hg emission intensities in
494 cluster1 transport path are very low, which may be the reason for the low GEM concentration in this
495 cluster.

496 During the ISM2 period (Figure 5c), a typical period of Indian monsoon, almost all trajectories came
497 from or passed through the southern part of the SET site and were influenced by the monsoon. The GEM
498 concentration of cluster trajectories at this stage was below 1.00 ng m^{-3} . The majority of trajectories
499 (cluster2, 85.82%) through the YZB Grand Canyon to the SET station and have a short transport path,
500 which may be related to the high resistance of the dense vegetation in summer. Only about 2.24% of the
501 trajectories originated from central Tibet with very low GEM concentration (cluster3 with 0.99 ng m^{-3}).
502 During this period, the ISM originated from the Indian Ocean brought a large amount of water vapor and

503 caused considerable precipitation during the transportation. At the same time, the areas through which
504 the trajectory passed were sparsely populated and underdeveloped and were unable replenish Hg species
505 to the air masses. The range of GEM concentrations during the ISM2 phase was extremely small (Figure
506 2), which may indicate that under the strongly Indian monsoon, the main source region, transport path,
507 and mechanism of transportation during this period remain stable.

508 During the ISM3 period (Figure 5d), the Indian monsoon remained controlling the meteorological
509 factors at the SET station, but its intensity was weakened, and the precipitation in the Nyingchi area was
510 greatly reduced. The trajectories transmission distances are all short. All of the trajectories still came
511 from south of SET station and transported through the YZB Grand Canyon. It is difficult to distinguish
512 these clusters, but according to the UNEP (2018) Report, it is clear that the areas for which the clusters
513 passed through have very little emission. The GEM concentration at SET increased compared with the
514 ISM1-2 periods (average at 0.92 ng m^{-3} in ISM1 and ISM2, and 1.04 ng m^{-3} in ISM3 period, respectively).
515 This may indicate that the GEM source is farther away. At the end of the ISM3 period, the GEM
516 concentration showed an upward trend (Figure 2), which may be due to the weakening of the influence
517 of the monsoon. A shortened trajectory at the end of the monsoon period was also observed in another
518 study at a nearby site (QNNP) (Lin et al., 2019), which may indicate the withdrawal of the monsoon.

519 We also calculated backward trajectories for the passive sampler monitoring period. Figure S4
520 shows the trajectories of air masses arriving at the SET station in different seasons. Due to the low
521 accuracy of the data obtained from passive sampling, we didn't combine the GEM concentrations from
522 the passive sampler monitoring with the trajectories here. Except for winter, the vast majority of
523 trajectories originated from the south of the SET station, and most of the trajectories are short in distance.
524 This may be related to the complex local topography, which may also suggest that long-distance transport
525 has limited effect on SET station. There is a partial shift of the backward trajectory from the southwest
526 to the south in spring, compared to summer, which may originate mainly from the influence of the Indian
527 monsoon. The abundance of precipitation, halogens from the Indian monsoon, and rapid growth of
528 vegetation during the monsoon period may have depleted Hg species, and resulted in the lower GEM
529 concentrations in summer. Trajectories from the northern branch of the westerly circulation were more
530 abundant in autumn compared to winter, but did not appear to have an impact on local mean GEM
531 concentrations. Because of the large concentration variations in the passive sampling monitoring, we
532 aggregated the trajectories for the periods of high concentrations (GEM concentrations above 1.5 ng m^{-3}
533 ³) and low concentrations (GEM concentrations below 1.0 ng m^{-3}), and performed a cluster analysis. The
534 majority of trajectories in both categories were from the southern part of the SET station and were of
535 similar length (Figure S5), which indicates that the differences in concentrations monitored by passive
536 sampling may not be related to external transport.

537 **3.4 Hg concentration controlling factor indicated by PCA results in Nyingchi**

538 Overall, 4-5 factors were resolved for each period from the PISM to ISM3 periods. Some factors
539 are unique to each period, and certain factors are found throughout the monitoring period. Only Hg-
540 related components were reserved here and four underlying PCA factors are summarized (Table 2). They
541 were assigned as long-distance transport, local emissions, meteorological factor, and snow melt factor.

Table 2. PCA Factor Loadings (Varimax Rotated Factor Matrix) for Hg in Nyingchi, Tibet, China

542

543

544

545

The long-distance transmission factor (F1) found in the PISM and ISM3 periods mainly contain GEM, wind speed, CO (positive loading), temperature, and SO₂ (negative). GEM could be considered an indicator of long-distance transportation due to its long lifetime in the atmosphere, especially when

546 GOM and PBM are not significant in this factor. This factor indicates that the long-distance transportation
547 of GEM may mainly occurs in the pre-monsoon and the end of the monsoon period, which is similar to
548 the trajectory analysis in Section 3.3. The negative correlation between GEM and temperature may
549 indicate that the long-distance transport of GEM during the PISM period occurs mainly during periods
550 of lower temperatures. Compared with the diurnal variation of GEM during the ISM period (Figure 4),
551 it is possible that the increasing GEM concentration in the evening in the PISM period is mainly due to
552 the long-distance transportation of GEM.

553 Factor 2 involved GOM and PBM (high positive loading) in each period, mainly with positive O₃,
554 PM₁₀, PM_{2.5}, and negative temperature. GOM concentrations were positively correlated with PBM
555 concentrations, which implies that these two species probably originated from the same sources. The
556 high positive loadings of PBM, GOM, and some particle pollutants may indicate that the main source of
557 PBM and GOM is local emissions. The long-distance transport of particle pollutants from the Indian
558 subcontinent may have heavy wet deposition when the air mass climbs into the Tibetan Plateau and
559 cannot reach Nyingchi successfully. Thus, the local monitored particle pollutants, as well as easy-
560 deposition pollutants, may mainly originate from regional emissions. One possible source is from yak
561 dung; in the Tibetan Plateau, yak dung is a widely used household biofuel (Xiao et al., 2015) and the
562 burning of yak dung may release Hg and other particulate matter (Rhode et al., 2007; Xiao et al., 2015;
563 Chen et al., 2015).

564 Meteorology factor (F3) was found during the ISM period with positive temperature, wind speed,
565 solar radiation, and negative humidity and rain, which are likely associated with meteorological
566 conditions. This factor shows that meteorological conditions may profoundly affect the overall local
567 pollutant distributions during the ISM period, which suggests that the air mass carried by the ISM not
568 only cannot increase the long-distance transportation of pollutants to the Nyingchi area, but may also
569 reduce the local contribution of pollution. For existing pollutants, the strong positive loading of solar
570 radiation may indicate that pollutant reactions under strong radiation are relatively active in this high-
571 altitude region. The strong negative humidity and rain may indicate that rain has played a strong role in
572 the cleaning process, especially during the ISM1 and ISM2 periods, when precipitation is relatively
573 strong.

574 Factor 4 had a strong positive correlation with GEM, ROM, and solar radiation, and negative loading
575 with humidity during the ISM1 period. This suggests that as solar radiation increases in the afternoon,
576 more GEM and GOM are emitted to the air. [The influence of increasing solar radiation may reflect the
577 snow/ice melt process. which have been proved to be able to increase atmospheric GEM concentration
578 \(Huang et al., 2010; Dommergue et al., 2003\). GEM may originate from the evaporation of snow melting
579 and/or be driven by the photoreduction of snow Hg^{II} \(Song et al., 2018\). The simulation indicated that
580 the oxidation of GEM may occur at the snow/ice interface in the action of solar radiation, and may lead
581 to extra GOM release.](#) The peak concentrations of GEM and GOM both appeared in the afternoon during
582 the ISM1 period, when the solar radiation was the highest and humidity was the lowest. The increase in
583 GEM and GOM concentrations may be related to solar radiation, according to the PCA results.

584 [The PCA results provide some new insights into the sources of Hg species. During active monitoring
585 period, long-distance transport of GEM was the main source of SET station and only occurred at PISM](#)

586 and ISM3. Given the low GEM concentrations in ISM1 and ISM2, it is reasonable that PISM and ISM3
587 are the main long-distance transport periods for GEM. For GOM and PBM, on the other hand, local
588 sources appear to be more important during active monitoring period. This may be related to the fact that
589 GOM and PBM deposit more easily and have complex transport paths to the SET station. The local
590 sources of GOM and PBM are inconclusive. The concentrations of GOM and PBM monitored at the SET
591 station are not high and the local emissions can be assumed to be small. They might come from yak dung
592 burning or other local sources by the local residents (Rhode et al., 2007; Xiao et al., 2015; Chen et al.,
593 2015), and/or the strong solar radiation and snow surface reaction, which needs to be confirmed by further
594 field experimental studies.

595 **3.5 Implications**

596 The Tibetan Plateau is a direct invasion target of the ISM. Blocked by the high altitude of the
597 Himalayas, the Indian monsoon could bypass the high mountains and enter Tibet via the YZB Grand
598 Canyon. When the summer monsoon enters Tibet, pollutants from India and the Indian Ocean, as well as
599 large amounts of water vapor, may be carried along with the air masses (Lin et al., 2019; Yang et al.,
600 2013; Wang et al., 2018). Located in the water vapor channel where the Indian monsoon enters, Nyingchi
601 is believed to receive a large amount of foreign air masses (Yang et al., 2013). Considering that Nyingchi
602 has little local emission because of the sparse population and lack of industry, the pollutants present in
603 the area should mostly have been transported by monsoons over long distances. However, our monitoring
604 results show that during the ISM period, the GEM concentrations in the Nyingchi are extremely low
605 (0.95 ± 0.21 ng m⁻³); lower than the background GEM concentration in the Northern Hemisphere and the
606 GEM concentrations observed at surrounding monitoring sites in the literature (Table 1).

607 The low concentration during the ISM period may be related to the regional deposition process and
608 complex regional terrain. When monsoon winds carry large amounts of Indian Ocean moisture and enter
609 the YZB Grand Canyon, strong wet deposition occurs during transport due to an increase in elevation
610 and a decrease in temperature. The process of rainwater scouring from wet deposition may result in
611 significant deposition of pollutants from carried air masses (Lindberg and Stratton, 1998; Seigneur et al.,
612 2006). Meanwhile, the air flow in the canyon is slow owing to the complex terrain. The slow migration
613 of the air mass further strengthens the deposition process. In addition, during the ISM period, the dense
614 forest in the canyon may deplete some of the Hg during transport (Fu et al., 2016b). Therefore, pollutants
615 from the Indian subcontinent struggle to go deep into the Tibetan Plateau during the ISM period. The
616 deposited pollutants may flow into the downstream area via rivers to Southeast Asia and South Asia.
617 Additional wet deposition monitoring along the YZB Grand Canyon in the future may provide more
618 evidences on transportation mechanisms. However, long-distance transboundary transport remains an
619 important mechanism of GEM distribution in this area during the period of westerly circulation. As
620 discussed in Section 3.1, the GEM concentration in Nyingchi during PISM period (1.20 ± 0.35 ng m⁻³)
621 was much higher than that during the ISM period (0.95 ± 0.27 ng m⁻³). The high GEM concentration
622 during the PISM period may indicate that a large amount of external Hg entered the Nyingchi area during
623 the non-ISM period, and thus monitoring of isotopic atmospheric Hg in future studies or accurate model
624 simulations are needed to provide better evidences.

625 The results of our previous study on Qomolangma were different from those in Nyingchi.

626 Qomolangma site locates on the northern side of the Himalayas, a typical terrain on the southern edge of
627 the Tibetan Plateau. The Nyingchi site locates in a typical pathway for air masses to enter the Tibetan
628 Plateau. Both sites locate in sparsely populated areas, far from human activity, making them ideal clean
629 locations to study the behavior of Hg species. Hg species monitoring in both sides could help explain the
630 possible transboundary transport patterns. In terms of the concentration distributions of Hg species, both
631 sites showed low concentrations, with slightly higher GEM concentrations identified at Qomolangma
632 site. The diurnal variations in the concentrations of Hg species are unique in both areas, as there are
633 relatively little anthropogenic disturbances, but Nyingchi is surrounded by greater elevation variation
634 and more complex terrain, and thus the diurnal variation is subject to more natural disturbance factors.
635 In terms of Hg species from long-range transport, Qomolangma was mainly affected by monsoonal
636 transport from India during the ISM period, showing the increases in the concentrations of GEM.
637 Nyingchi, on the contrary, has low GEM concentrations during the ISM. Although receiving almost the
638 same monsoonal influences from India, the intensity of the transport and the subsidence on the transport
639 path may be responsible for the large differences in the concentrations of Hg species and their
640 environmental behavior between the two sites. Together, they represent two typical transboundary
641 transport patterns of Hg in the Tibetan Plateau.

642 **4. Conclusions**

643 Comprehensive Hg species monitoring was carried out in Nyingchi, a high-altitude site in the
644 southeast of the Tibetan Plateau. Nyingchi is located on the main pathway for water vapor carried by the
645 monsoon to enter the Tibet Plateau during the ISM period, which could characterize the spread of
646 pollutants from the Indian subcontinent. The concentrations of GEM and PBM during the PISM period
647 were significantly higher than those during the ISM period, and the concentration of GOM during the
648 PISM period was relatively higher than that during the ISM period. Data from passive sampler
649 monitoring showed that, average GEM concentrations were the lowest in summer, with almost identical
650 average concentrations in spring, autumn and winter. The concentrations of Hg species in Nyingchi is
651 particularly low, compared with other high-altitude stations around the world. GEM concentration shows
652 a distinct and unique diurnal variation, with a gradual increase in GEM concentration during the day and
653 a maximum concentration at night. This diurnal variation may be due to the re-emission of GEM by
654 snowmelt and the trapping effects of pollutants by the very low planetary boundary layer at night.

655 According to the trajectory model, the trajectories of arrivals changed significantly with the onset
656 and rise of ISM. Except for winter, the vast majority of trajectories originated from the south of the SET
657 station, and most of the trajectories are short in distance. Through comprehensive PCA analysis using
658 local meteorological conditions and multiple pollutants, long-distance transport, local emissions,
659 meteorological factor, and snowmelt factor have been identified to affect local Hg species concentrations.
660 PCA analysis results also indicate that local emission contributes between PISM and ISM3, while the
661 long-distance transportation plays a role during PISM and ISM3. The deposition condition and vegetation
662 distribution in the YZB Grand Canyon have significant influences on the transport of Hg species. The
663 Grand Canyon on the one hand reduces atmospheric Hg species concentrations in Nyingchi, but at the
664 same time poses some risks of high Hg species concentrations downstream. Our work reveals the effect
665 of the YZB Grand Canyon on atmospheric Hg transport, while the pathways associated with the

666 deposition of GOM and PBM, and the destinations of GEM should be studies in more detail in the future.
