**Abstract.** Efforts have been spent on investigating the isothermal evaporation of  $\alpha$ -pinene SOA particles at ranges of conditions  
10 and decoupling the impacts of viscosity and volatility on evaporation. However, little is known about the evaporation behavior of  
SOA particles from biogenic organic compounds other than  $\alpha$ -pinene. In this study, we investigated the isothermal evaporation  
behaviors of  $\alpha$ -pinene ( $\alpha$ pin) and sesquiterpene mixture (SQTmix) SOA particles under a series of relative humidity (RH)  
conditions. With a set of in-situ instruments, we monitored the evolution of particle size, volatility, and composition during  
15 evaporation. Our finding demonstrates that the SQTmix SOA particles evaporated slower than the  $\alpha$ pin ones at any set of RH  
(expressed with the volume fraction remaining (VFR)), which is primarily due to their lower volatility and possibly aided by higher  
viscosity under dry conditions. We further applied positive matrix factorization (PMF) to thermal desorption data containing  
volatility and composition information. Analyzing the net change ratios (NCRs) of each PMF-resolved factor, we can quantitatively  
20 compare how each sample factor evolves with increasing evaporation time/RH. When sufficient particulate water content was  
present in either SOA system, the most volatile sample factor was primarily lost via evaporation and changes in other sample  
factors were mainly governed by aqueous-phase processes. The evolution of each sample factor of SQTmix SOA particles was  
controlled by a single type of process, whereas for  $\alpha$ pin SOA particles it was regulated by multiple processes. As indicated by the  
coevolution of VFR and NCR, the effect of aqueous-phase processes could vary from one to another according to particle type,  
sample factors and evaporation timescale.

## 1 Introduction

25 Atmospheric oxidation of volatile organic compounds (VOCs) can lead to a complex mixture of condensable organic vapors  
spanning ranges of functionalities and structures, and hence volatilities (Hallquist et al., 2009). Parts of these organics contribute  
to the mass concentration of secondary organic aerosol (SOA) particles. Gas-particle partitioning is a dynamic process of  
importance, influencing the composition in the gas and particle phase as well as the atmospheric lifetime of SOA. For a long time,  
gas-particle partitioning has been considered as a near-instantaneous process (Odum et al., 1996; Donahue et al., 2006), under the  
30 assumptions that SOA particles consist mainly of intermediate/semi-volatile compounds and exists in a liquid state. Recent  
measurements suggest that SOA particles consist of large amounts of organic compounds with low or extremely low volatility  
(Cappa and Jimenez, 2010; Ehn et al., 2014; Mohr et al., 2019) and that particles can adopt viscous semisolid or amorphous solid  
states (Virtanen et al., 2010; Pajunoja et al., 2013; Zhang et al., 2015). All this emerging evidence challenges the abovementioned

assumptions, which underlie the treatment of SOA via the partitioning theory. When volatilities of organic compounds range from  
35 intermediate to extremely low volatile (Donahue et al., 2012), the equilibration timescales of phase partitioning span from seconds  
to hours in liquid particles (Shiraiwa and Seinfeld, 2012). In viscous particles, bulk diffusion limitations can increase equilibration  
timescales to the order of years (Li and Shiraiwa, 2019).

Monoterpenes ( $C_{10}H_{16}$ ) are the most abundant terpene emissions in boreal forests (Tarvainen et al., 2007; Bäck et al., 2012), driving  
SOA formation and growth in the atmosphere (O'Dowd et al., 2002; Jokinen et al., 2015). As the most representative monoterpene,  
40  $\alpha$ -pinene has been widely used to generate SOA as a proxy for boreal forest SOA. SOA yield studies using environmental chambers  
have suggested that  $\alpha$ -pinene SOA particles are dominated by semi-volatile organic compounds (Pathak et al., 2007; Shilling et al.,  
2008). But multiple studies which investigated the isothermal evaporation of  $\alpha$ -pinene SOA particles for a range of relative  
humidity (RH) consistently demonstrated that SOA particles do not evaporate as rapidly as expected for semi-volatile organic  
mixtures (Vaden et al., 2011; Wilson et al., 2014; Yli-Juuti et al., 2017; D'Ambro et al., 2018). These findings suggest the  
45 importance of unaccounted low-volatility organic compounds, particle phase reactions, and viscous phase states (Vaden et al.,  
2011; Wilson et al., 2014; Yli-Juuti et al., 2017; D'Ambro et al., 2018). While volatility distributions of organic compounds mainly  
determine the extent to which particles evaporate at high RH, diffusion limitations attributed to particle viscosity significantly  
hinder particle evaporation under dry conditions. Recent studies have also explored the oxidation and temperature dependence of  
the evaporation of  $\alpha$ -pinene derived SOA particles. For instance, increasing the oxygen to carbon ratio (O:C) of the initial particles  
50 reduces the particle evaporation rate and possibly induces aqueous phase processes which form low volatility compounds especially  
for highly oxidized SOA particles (Buchholz et al., 2019). Decreasing temperature can suppress particle evaporation by lowering  
the saturation concentrations of the SOA compounds and/or increasing particle bulk viscosity (Shiraiwa et al., 2017; Li et al., 2019).

Efforts have been spent on investigating the evaporation of  $\alpha$ -pinene SOA particles, but the diversity of VOC emissions from trees  
and the complexity of particulate constituents complicate the description of organic vapor partitioning in boreal forests. Branch  
55 enclosure measurements with boreal tree species have revealed that VOC emission profiles vary in terpene species and ratios,  
dependent on seasons (Hakola et al., 2017) or degrees of abiotic/biotic stress (Zhao et al., 2017a; Kari et al., 2019). Laboratory  
studies have shown that compared to  $\alpha$ -pinene derived SOA particles, those derived from oxidizing sesquiterpenes ( $C_{15}H_{24}$ ) or  
actual (stressed) Scots pine emissions feature distinct properties, in terms of mass yield, volatility, and molecular composition  
(Faiola et al., 2018; Ylisirnio et al., 2020). Given these observations, it is necessary to investigate the evaporation behavior of SOA  
60 particles derived from terpene precursors other than  $\alpha$ -pinene and even from real plant emissions. Current measurements have  
identified that large amounts of farnesenes and bisabolenes are emitted from boreal tree species (Hakola et al., 2017; Danielsson  
et al., 2019) and that their derived SOA are of potential climate significance by influencing cloud formation (Mentel et al., 2013;  
Zhao et al., 2017a).

To facilitate a better understanding of biogenic organic vapor partitioning in boreal forests,  $\alpha$ -pinene, and a sesquiterpene mixture  
65 were chosen as precursors to generate two different types of biogenic SOA particles for isothermal evaporation under a range of  
RH conditions at room temperature. The mixture consists of farnesenes and bisabolenes, which are acyclic and monocyclic  
sesquiterpenes, respectively. The aim of this study is to compare the evaporation behavior of sesquiterpene derived SOA to that of  
 $\alpha$ -pinene derived SOA. For this, both the particle size changes as well as particle composition evolution were measured, and their  
differences and similarities will be discussed.

## 70 2 Methods

### 2.1 Experimental setup

Two different types of biogenic SOA particles were generated in a 13 L oxidation flow reactor (OFR) (Kang et al., 2007; Lambe et al., 2011) for isothermal evaporation experiments taking place at a wide range of RH at 25 °C. The experimental setup and procedure were similar to our previous evaporation studies (Yli-Juuti et al., 2017; Buchholz et al., 2019; Li et al., 2019) and a detailed description of our experimental setup can be found in the Supplement. Briefly, the experimental sequence consisted of biogenic SOA production, followed by particle size selection with simultaneous dilution of the gas phase, and humidity-controlled isothermal particle evaporation.

Either  $\alpha$ -pinene (Sigma-Aldrich, 98%) or a sesquiterpene mixture (Sigma-Aldrich, mixture of isomers) that contains farnesenes and bisabolenes was introduced into a heated N<sub>2</sub> flow with a syringe pump system (Kari et al., 2018). The VOC-containing flow was then mixed with a humidified flow of N<sub>2</sub> and O<sub>3</sub>. Overall, 5 L min<sup>-1</sup> of total flow containing VOCs (254 – 261 ppb) and O<sub>3</sub> (13.01 – 13.40 ppm) with RH of 41% – 44% was introduced into the OFR for photooxidation at controlled temperature (~25 °C). Under the illumination of 254-nm UV lamps, hydroxyl radicals (OH) were produced from the reaction of water vapor with O (<sup>1</sup>D) which was generated from photolysis of O<sub>3</sub>. We produced  $\alpha$ -pinene ( $\alpha$ pin) and sesquiterpene mixture (SQTmix) SOA with comparable oxidation conditions. The OH exposure ranges from 0.9 to 2.6×10<sup>11</sup> molec cm<sup>-3</sup> as calculated by the OFR model (Peng et al., 2015; Peng et al., 2016) which takes the external OH reactivity into account. The elemental composition of SOA particles was characterized by a high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS, Aerodyne Research Inc.). It should be noted that rather than by pure photooxidation, SOA was formed via both ozonolysis and photooxidation reactions, as O<sub>3</sub> levels of over 1 ppm were used. Experimental conditions and results for the SOA generation are summarized in Table S1.

The generated SOA was introduced into two parallel nanometer differential mobility analyzers (NanoDMA, model 3085, TSI) for particle size selection. The size selection process also diluted the organic vapors by 2 orders of magnitude with an open-loop sheath flow and thereby initiated particle evaporation. To vary the RH in samples, we humidified/dried the sheath flow of the NanoDMAs. The desired RH was set to one of three conditions: dry (< 7% RH), intermediate (40% RH) and high (80% RH). Eventually, a narrow distribution of SOA particles with 80 nm electrical mobility diameter was fed (i) to bypass lines with varying lengths for short evaporation measurements of up to 3 min, (ii) to a 25 L stainless-steel residence time chambers (RTC) for intermediate evaporation measurements of up to 40 min with 10 min intervals, and (iii) to a 100 L RTC for long evaporation measurements of up to 7.5 h with 1 h intervals. Prior to each particle evaporation experiment, the NanoDMAs, bypass tubing and RTCs were flushed for at least 12 h with purified air at the desired RH of the following experiment.

### 2.2 Characterization of particle evaporation

Size changes of SOA particles due to evaporation were periodically monitored using a scanning mobility particle sizer (SMPS, model 3080, TSI). The extent of particle evaporation was evaluated in the terms of volume fraction remaining (VFR). Assuming particles are spherical, VFR was calculated as follows:

$$VFR = \left(\frac{D_{p,t}}{D_{p,0}}\right)^3, \quad (1)$$

where  $D_{p,0}$  and  $D_{p,t}$  are the particle sizes measured at the start (i.e., as selected by the NanoDMAs) and after time  $t$  of evaporation, respectively. The time evolution of particle evaporation was illustrated by plotting VFR against residence time in the bypass tubing

105 or RTC ( $t_R$ ), defined as “evapogram”, as shown in Figure 1. The selected particle size was calibrated using dry ammonium sulfate particles.

The thermal desorption behavior and chemical composition of particle samples were characterized using a chemical ionization mass spectrometer (CIMS, Aerodyne Research Inc.) coupled with a custom-built Filter Inlet for Gases and AEROSols (FIGAERO) (Ylisirnio et al., 2021) using iodide-adduct ionization (Lopez-Hilfiker et al., 2014). The operation of FIGAERO-CIMS can be  
110 found in the Supplement. Particle samples were collected for analysis (i) right after size selection (fresh, avg.  $t_R = 0.25$  h, due to 0.5-h collection times), and (ii) after isothermal evaporation in the RTC (RTC, avg.  $t_R = 4.25$  h). After a 30 min sample collection, the collected particles were gradually desorbed with a heated  $N_2$  flow of which the temperature was firstly ramped from 25 °C to ~200 °C within 20 min (desorption period), and then maintained at above 190 °C for an additional 15 min (soak period) to evaporate any residual organics left on the filter. The relationship between the temperature of maximum desorption signal ( $T_{max}$ ) of a single  
115 compound and its saturation vapor pressure ( $C^*$ ) was calibrated against a set of polyethylene glycol (PEG, PEG 4 – 8) with known vapor pressures (Ylisirnio et al., 2021). The desorption temperature ( $T_{desorp}$ ) range is divided into three volatility ranges (i.e. semi-volatile organic compounds (SVOC), low-volatility organic compounds (LVOC) and extremely low volatility organic compounds (ELVOCs)) as defined by Donahue et al. (2012).

The desorption temperature-dependent change in the sum of the organic signals over the temperature range is referred to as sum  
120 thermogram, STG. The appearance of the STG depends on the number of molecules collected on the FIGAERO filter and the volatility distribution of the sample. We are interested in determining if some compounds in the particle phase are lost or produced during isothermal evaporation. To be able to investigate this, we need to account for changes in STG due to different collected sample mass and the isothermal evaporation. As it was not possible to determine the collected sample mass independently, we normalize the  $STG(T)$  with the total ion signal of each sample ( $N_{Tot}$ ):

$$125 \quad STG_N(T) = \frac{STG(T)}{N_{Tot}}. \quad (2)$$

In addition, we need to take into account how much material is expected to be removed from each individual particle due to the isothermal evaporation. We assume that this removal is proportional to the change in the average VFR ( $VFR_{avg}$ ) determined for the corresponding evaporation time and can be described with the removal factor ( $f_{removal}$ ):

$$f_{removal} = \frac{VFR_{avg,RTC}}{VFR_{avg,fresh}} \cdot \alpha_{MW_{avg}}^{-1} \cdot \beta_{\rho_{avg}}, \quad (3)$$

130 where  $VFR_{avg,fresh}$  and  $VFR_{avg,RTC}$  are the average VFR during the FIGAERO sampling time at fresh and RTC evaporation stages.  $\alpha_{MW_{avg}}$  is a parameter that describes the relative change in signal-weighted average molecular weight (MW) of the particle bulk,  $MW_{avg,RTC}/MW_{avg,fresh}$ , and  $\beta_{\rho_{avg}}$  is a parameter that captures the relative change in average particle density,  $\rho_{avg,RTC}/\rho_{avg,fresh}$ . These two parameters convert the isothermal evaporation effect from the volumetric base to the molecular base.

135 We scale the normalized STG for the RTC sample ( $STG_{N,RTC}(T)$ ) with  $f_{removal}$  expressed in Eq. (3) to obtain the scaled STG for the RTC sample ( $STG_{SC,RTC}(T)$ ):

$$STG_{SC,RTC}(T) = STG_{N,RTC}(T) \cdot \frac{VFR_{avg,RTC}}{VFR_{avg,fresh}} \cdot \alpha_{MW_{avg}}^{-1} \cdot \beta_{\rho_{avg}} \quad (4)$$

A more detailed justification for this approach can be found in Appendix A. The values of  $\alpha_{MW_{avg}}$  and  $\beta_{\rho_{avg}}$  which were used for the calculation of  $STG_{SC,RTC}(T)$  are given in Table C1. The ratio of  $VFR_{avg}$  is proportional to the material loss per particle, so is

140 the resulting  $STG_{SC,RTC}$ . Hence  $STG_{SC,RTC}(T)$  and  $STG_{N,fresh}(T)$  can be compared quantitatively (Figure 2a), and the differences between them directly indicate if compounds with certain desorption temperature are lost, produced or remained unchanged during the isothermal evaporation. The similar approach can be used to investigate the evolution of PMF factors as explained in section 3.3.

145 Previously,  $T_{max}$  of the  $STG(T)$  was used to compare the overall volatility between particle samples (Ylisirnio et al., 2021). Here, the median desorption temperature ( $T_{50}$ , at which half of the cumulative  $STG(T)$  is reached) was used instead because it is a more general measure of the overall desorption behavior. Typically, these  $T_{50}$  values were higher than the  $T_{max}$  values, as most signals were recorded at temperatures above  $T_{max}$ .

### 2.3 Deconvolution of FIGAERO-CIMS data set with Positive Matrix Factorization (PMF)

150 Since it was introduced by Paatero and Tapper (1994), PMF has been widely used to identify the contribution of different sources of trace compounds in ambient measurements (Ulbrich et al., 2009; Zhang et al., 2011; Yan et al., 2016). More recently, PMF has been adapted to analyze laboratory experiments for understanding chemical or physical aspects of systems of interest (Craven et al., 2012; Zhao et al., 2017b; Buchholz et al., 2020). Regarding a FIGAERO-CIMS data set, PMF can separate sample signals from filter background and contamination. But more than that, this method can also identify multiple factors which represent not only isomeric compounds with different volatilities but also thermally decomposed products for each ion. Following the procedure  
155 outlined in Buchholz et al. (2020), constant error values (CNerror) which are derived from the noise at the end of thermogram scans were applied to all ions without further down-weighting. The PMF results were calculated using the PMF Evaluation Tool (PET 3.05) with one to ten factors and five fpeak rotations from -1 to +1. Additional information about the PMF analysis is described in the Supplement including justification for the selected solution. The PMF analysis was applied independently for each precursor to sets of FIGAERO-CIMS samples. Each set represents particles from one SOA precursor ( $\alpha$ pin or SQTmix), which  
160 were collected at both evaporation stages (fresh and RTC) under dry and high RH conditions. Two types of blank measurements were added to the data set: (i) Measurements of the clean FIGAERO filter without sampling from the setup. These blanks characterize the overall instrument background. (ii) Measurements of filters sampled directly after size selection for 30 min but with the DMA voltage set to 0 V. These blanks represent the background due to, e.g., adsorption of remaining gas-phase compounds onto the filter during the normal sample collection procedure.

## 165 3 Results and Discussion

### 3.1 Bulk volatility of SOA particles

#### 3.1.1 Isothermal evaporation behaviour of SOA particles

170 The isothermal evaporation behavior of SOA particles is illustrated by VFR as a function of  $t_R$  in Figure 1. The evaporation rate of dry SOA particles is the slowest, due to the considerable kinetic limitations arising from high particle viscosity. As RH increases, the evaporation rate becomes faster for both SOA systems, highlighting decreasing particle viscosity due to the water plasticization effect. Comparable evaporation rates under intermediate and high RH conditions suggest that particle evaporation can be approximated as a liquid-like process for both conditions (i.e., at  $RH \geq 40\%$ ), in agreement with previous observations of  $\alpha$ -pinene SOA particle evaporation (Yli-Juuti et al., 2017; Buchholz et al., 2019; Li et al., 2019). Additionally, particulate water content may also induce aqueous-phase processes during isothermal evaporation (Buchholz et al., 2019; Petters et al., 2020). For the investigated

175 SOA particles, we observed strong evidence of such processes under high RH conditions (RH = 80%), which indicates the presence of aerosol-water-induced chemistry (see section 3.3.3).

At any set RH, the evaporation rate of SQTmix SOA particles was slower than that of  $\alpha$ pin ones, although both SOA were produced under comparable oxidation conditions. Such distinguishable evaporation patterns are most likely driven by (i) the distinct particulate volatility distributions jointly controlled by molecular weight and functionality, expressed by elemental composition as a proxy (Li et al., 2016), and/or (ii) the possible differences in particle bulk viscosities especially under dry conditions.

### 3.1.2 Thermal desorption behaviour of SOA particles

In Figure 2, the thermal desorption behavior of particle samples which were collected at fresh (avg.  $t_r = 0.25$  h) and RTC (avg.  $t_r = 4.25$  h) evaporation stages under dry (RH < 7%) and high RH (RH 80%) conditions are displayed as normalized  $STG(T)$  ( $STG_{N,fresh}(T)$ , solid line) and scaled ones ( $STG_{SC,RTC}(T)$ , dashed line), respectively (Figure 2a, b). These two types of  $STG(T)$  together are hereinafter referred as STGs for simplicity unless otherwise specified. The corresponding  $T_{50}$  and  $VFR_{avg}$  are shown in Figure 2c and the sampling periods for FIGAERO-CIMS thermograms are highlighted in colored areas in Figure 1.

Compared to the STGs of fresh samples, the STGs of the RTC samples shifted to higher  $T_{desorp}$  values with increases in  $T_{50}$ , regardless of the RH conditions. When examining the particle desorption profiles (i.e., STGs), we note that the removal of compounds which were thermally desorbed below 120 °C, and the corresponding changes in  $T_{50}$ , is more pronounced between fresh and RTC samples at high RH as compared to that under the dry condition. Such difference in the changes of STGs between two RH conditions agrees with our observation of faster particle evaporation rates in the presence of water (see Figure 1).

Under dry conditions, a larger fraction of (E)LVOC contributed to the STGs of SQTmix SOA particles, with higher values of  $T_{50}$  when compared to  $\alpha$ pin particles (Figure 2a, c). Consistent with the changes in  $VFR_{avg}$  under dry conditions, relatively less increase in  $T_{50}$  and decrease in the STGs were observed in SQTmix SOA particles as well. On the other hand, similar STGs were observed for fresh samples at high RH, regardless of SOA particle type. According to the evaporation model simulations described in a previous study using a similar measurement setup (Li et al., 2019), a majority of I/SVOC is expected to evaporate rapidly from fresh particles during the first 8 – 30 min at high RH. It should be noted that during the same evaporation timescale ( $\leq 0.5$ h), the evaporation of (E)LVOC is expected to be negligible. Therefore, the  $VFR_{avg}$  ( $t_r = 0.25$  h) is approximately determined by the ratio of (IVOC + SVOC)/(LVOC + ELVOC) in the initial particles. As the FIGAERO sampling periods last for 30 min, it follows that under high RH conditions, the fresh particles lost a significant fraction of the initially present I/SVOC during sample collection. Thus, the similarity in STGs between  $\alpha$ pin and SQTmix SOA particles suggests that the (E)LVOC fraction in both SOA types has a similar volatility distribution and/or thermal desorption behavior. Note that this does not mean that the same type of compounds is present in the two different SOA types. For the same reason, the difference in  $T_{50}$  between two different types of fresh particles is less noticeable than the difference in  $VFR_{avg}$  at high RH (Figure 2c, solid circles).

### 205 3.2 PMF factors of SOA particles

Depending on the RH conditions or SOA precursors, the particle size and volatility appear to evolve differently during isothermal evaporation (Figure 1 and Figure 2). To better assess the compositional and volatility changes of the investigated SOA particles, we performed PMF analyses to deconvolute the thermal desorption profiles. Each derived factor constitutes a group of organic compounds with the same thermal desorption behavior. Details about sample and background factor interpretation are described in Buchholz et al. (2020). In brief, factors with unimodal desorption behavior are defined as type V (“volatility”) factors. Factors

with mass spectra dominated by small MW compounds in combination with very broad peaks with no clear maximum before the soak period is reached are classified as type D (“decomposition”) factors. Moreover, factors occurring in particle samples but predominantly in filter blank measurements are defined as type B (“background”) factors.

PMF solutions with eight and ten factors were chosen for  $\alpha$ pin and SQTmix SOA particles, respectively. In both PMF results, five factors are assigned as sample factors (i.e., type V and type D factors) and the rest are considered background factors (i.e., type B factors). In the following discussion (Figure 3 and Figure 4), the B factors and the blank measurements are omitted. All mass spectral profiles and all factor thermograms of all samples of each data set can be found in Figure S2 and S3. Furthermore, chemical properties of sample factors are visualized in the form of Kroll diagrams (Kroll et al., 2011) in Figure S6 by plotting the average carbon oxidation state (OSc) versus the carbon number (Cnum). The OSc values were grouped into a grid with an interval of 0.2 to enhance readability.

### 3.2.1 $\alpha$ pin SOA particles

In total, four type V factors (i.e., AV1, AV2, AV3 and AV4; colored) and one type D factor (i.e., AD5; black) were identified for  $\alpha$ pin SOA particles as shown in Figure 3. Five main sample factors from an eight-factor PMF solution for  $\alpha$ pin SOA particles. On the panel (a), factor thermograms are shown with color bands on the abscissa indicating volatility classes. On the panel (b), normalized factor mass spectrums are presented with average molecular composition, molecular weight, and oxidation state. For the type V factors, average MW increased with higher  $T_{50}$  (i.e., lower volatility). While factor mass spectra of all type V factors were dominated by compounds with  $C \leq 10$ , as expected for a precursor composition of  $C_{10}H_{16}$ , additional amounts of compounds with  $C > 10$  (i.e., dimers/oligomers) contributed to the total signal of AV3 and especially to that of AV4 (see also Figure S6a). With increasing  $T_{50}$  values, factors had longer carbon chain lengths and higher oxygen contents, as indicated by their average molecular composition. There was no clear association between OSc and  $T_{max}$  for type V factors, since the increase in carbon chain lengths is counterbalanced by the simultaneous addition of oxygen and hydrogen numbers. Therefore, the decrease in volatility of type V factors was mainly driven by the increase in average MW.

For the type D factor (i.e., AD5), its bulk properties and composition distribution (Figure 3 and Figure 5a) were closest to those of AV2 and AV3 with compounds with MW < 200 Da dominating their factor mass spectra. However, the thermal desorption behavior of AD5 was completely different with almost all of its signal occurring at  $T_{desorp} > 100$  °C and a continuous increase with  $T_{desorp}$  until the soak period starts. Many of the compounds assigned to AD5 also showed contributions to other factors at lower  $T_{desorp}$  values. It is very unlikely that all these were isomeric compounds spanning 5 or more orders of magnitude in  $C^*$  between the isomeric forms. It is much more probable that those compounds with small MW in AD5 were decomposition products of thermally unstable compounds with larger MW and lower volatility; and hence the type-D designation was chosen for this factor.

### 3.2.2 SQTmix SOA particles

In a similar way as for  $\alpha$ pin SOA particles, four type V factors (i.e., SV1, SV2, SV3 and SV4) and one type D factor (i.e., SD5) were identified for SQTmix SOA particles, as shown in Figure 4. For those type V factors, lower volatilities characterized by higher  $T_{50}$  values again correlated with increasing average MW but not with average OSc. Furthermore, the type V factors mostly comprise compounds with  $C \leq 15$  (Figure S6b), as expected for a precursor composition of  $C_{15}H_{24}$ . Due to the prevalence of acyclic structures in the  $C_{15}$  carbon skeletons of both farnesene and bisabolene (in particular exocyclic double bonds), the investigated SQTmix is more prone to undergo fragmentation, compared with those sesquiterpenes dominated by cyclic structures (e.g.  $\beta$ -caryophyllene) (Faiola et al., 2019). As these smaller fragments can undergo oligomerization reaction, compounds with  $C < 15$

can also be oligomers (e.g. a  $C_{14}$  compound as combination of two  $C_7$  fragments). However, elucidating the detailed formation mechanisms of the observed compounds in SQTmix SOA particles goes beyond the scope of this study.

250 Like the AD5 factor in  $\alpha$ pin SOA particles, the SD5 factor in SQTmix SOA particles contains mainly small compounds with MW < 200 Da despite displaying a continuous increase in signals at temperature above 100 °C (Figure 4). This, again, suggests that thermal decomposition is the main source process when compounds of SD5 were being desorbed from the FIGAERO filter. Consistently, the compositional profile of SD5 was also dominated by compounds with small carbon numbers (Figure 5b).

### 3.3 Evolution of PMF factors

255 As shown in the evapogram and STGs above, increasing RH enhanced evaporation rates of SOA particles and shifted particle volatility towards lower  $C^*$ . These observed changes were caused not only by decreasing particle viscosities (Yli-Juuti et al., 2017; Buchholz et al., 2019; Li et al., 2019) but also possibly by aqueous-phase reactions, especially for highly oxidized particle samples (Buchholz et al., 2019). To further investigate how particulate water impacts particle evaporation processes here, we need to analyze how the factor volatility and the relative contribution of each factor to the signal of each sample change with isothermal  
260 evaporation and humidification. The volatility of each factor can be characterized by its characteristic  $T_{desorp}$  values (the 25<sup>th</sup>, 50<sup>th</sup> and 75<sup>th</sup> percentile desorption temperature ) of factor thermogram. The 50<sup>th</sup> percentile is equivalent to  $T_{50}$  as used before, while the 25<sup>th</sup> and 75<sup>th</sup> ones indicate the width of a factor thermogram.

Due to different and uncertain amounts of sample mass, it is challenging to investigate changes in the contribution of factors between two evaporation stages by comparing their absolute signals. By normalizing the sum signal of a sample factor  $k$  to the  
265 total signal (excl. background factors) at the condition  $j$  ( $F_{k,j}$ ), we can account for the difference in sample mass. Note that  $F_{k,j}$  is not independent of the change in other factors. For instance, if the contribution of the most volatile factor decreases as it is removed by isothermal evaporation faster than other factors, the  $F_{k,j}$  values of all other factors will increase. It would not be possible to separate such behavior from an absolute increase/decrease in the contribution of a factor (e.g. due to a formation/evaporation/  
270 decomposition process in the particles) based on the values of  $F_{k,j}$  directly. To avoid this issue, we introduce the net change ratio (NCR) using the same rationale as for the scaled STG (see section 2.2). We define the NCR as the ratio between the relative contribution of factor  $k$  at a given condition  $j$  ( $F_{k,j}$ ) and that at the reference condition ( $F_{k,ref}$ ) scaled by the changes caused by the overall evaporation of the particles:

$$NCR_{k,j} = \frac{F_{k,j}}{F_{k,ref}} \cdot \frac{VFR_{avg,j}}{VFR_{avg,ref}} \cdot \alpha_{MW_{avg,j}}^{-1} \cdot \beta_{\rho_{avg,j}} \quad (5)$$

where  $F_{k,j}$  and  $F_{k,ref}$  are contribution of a sample factor  $k$  to the total signal (excl. background factors) measured by FIGAERO-  
275 CIMS at the condition  $j$  and reference condition, respectively.  $VFR_{avg,j}$  and  $VFR_{avg,ref}$  are the mean value of VFR retrieved from SMPS measurement at the condition  $j$  and reference condition.  $\alpha_{MW_{avg,j}}$  and  $\beta_{\rho_{avg,j}}$  are similar to the  $\alpha_{MW_{avg}}$  and  $\beta_{\rho_{avg}}$  parameters used in Eq. (4). It is not possible to capture the true initial state of particles, as particles start to evaporate directly after size selection. The dry and fresh condition exhibited the least amount of isothermal evaporation and thus was chosen as the reference case. More details about the derivation of Eq. (5) and the estimation of the parameters can be found in the Appendices B and C, respectively.

280 NCR represents the net effect of change in a factor, which is a combination of material loss (i.e., evaporation, chemical reactions) and production (i.e., chemical reactions), at a given condition as compared to the reference condition. If NCR is 1, the loss pathway counterbalances the production one, or no change occurs. NCR values significantly smaller than 1 (taking into account the possible uncertainties and limitations of the methodology, we consider  $NCR_{k,j} < \frac{1}{2} NCR_{k,ref}$  being significantly smaller) suggests that the

loss pathway outweighs the production one, and vice versa. There are two possible loss pathways: evaporation of compounds or transformation of compounds through chemical reactions. If the NCR is smaller than 1 and simultaneously decreases with evolving isothermal evaporation (i.e., decreasing VFR), it implies that the dominant loss mechanism may be evaporation. On the other hand, if NCR doesn't decrease with decreasing VFR but the behavior is more complex, this indicates that the main loss mechanism of the compounds is likely chemical transformation. When NCR is clearly larger than 1 (taking into account the possible uncertainties and limitations of the methodology, we consider  $NCR_{k,j} > 2 NCR_{k,ref}$  being significant larger), it implies that the compounds are produced in the particle phase. In addition to the trends in NCR values, the shape of the factor thermograms and their inferred  $C^*$  values also give further insights into the possible production and loss mechanisms as discussed below.

### 3.3.1 SQTmix SOA particles

Consistent with the small change in VFR (< 12% in volume), the particle composition in dry SQTmix SOA particles barely changed (Figure 5, red colors), with negligible shifts only in the NCR of SV1. As seen in Figure 5, for the factors SV1, SV2 and SV4, the NCR decreased with decreasing VFR, implying the contribution of evaporation to the material loss. At high RH, SV1 and SV4 were no longer present after isothermal evaporation in the RTC.

As the range of  $C^*$  assigned to the characteristic  $T_{desorp}$  of SV1 is high enough to enable significant evaporation during the experimental timescale of up to 4.25 h and its NCR exhibits a decreasing trend with evolving evaporation, we can conclude that the decrease in NCR of SV1 is primarily driven by evaporation. In this case, the particulate water mainly accelerated the evaporation as an effective plasticizer. The decrease of NCR for SV2 and SV4, which have volatilities in the (E)LVOC range, was even stronger than that of SV1 at high RH. This was surprising as compounds in that volatility range are not expected to evaporate significantly from particles within 4.5 h at room temperature (Li et al., 2019). Hence this observation indicates that in addition to evaporation, there was another loss mechanism driving the evolution of SV2 and SV4 under high RH conditions.

When investigating the factors SV3 and SD5, changes in their NCR were negligible under dry conditions, but significant increases in their NCR were seen at high RH (Figure 5). At the same time, we can see that both of these factors accounted for substantial amounts of the total particle composition at high RH (Figure 4). This clearly indicates that compounds in SV3 or SD5 were not only retained in particle phase due to their low  $C^*$  values in the range of (E)LVOC, but also formed in particle phase at high RH. These processes must be relatively fast as the changes in abundance and NCR were already clear at the fresh stage (i.e., within 0.25 h).

Except for SV1, all factors showed a distinct shift to higher values of characteristic  $T_{desorp}$  under high RH conditions as compared to dry conditions. This also indicates that the presence of water content has a more complex impact on the particle composition than simply enhancing the isothermal evaporation of volatile compounds. The correlations induced by the aqueous phase processes are more important than the grouping solely by volatility class. I.e., compounds with a wider range of volatilities may be grouped into a factor if they are produced by the same chemical process.

We will further elaborate on the possible reasons for these observed changes in NCR together with those described in the next section for  $\alpha$ pin SOA particles in section 3.3.3.

### 3.3.2 $\alpha$ pin SOA particles

The response of STG to isothermal evaporation and humidification appeared very similar for  $\alpha$ pin and SQTmix SOA particles (Figure 2). The investigation of the NCR values of PMF factors revealed that, while the overall behavior is indeed similar, there were also some distinct differences in chemical composition between these two types of SOA particles.

As expected from the isothermal evaporation measurements and the comparison of the STGs before and after isothermal evaporation in the RTC,  $\alpha$ pin SOA particles showed very little change for the NCR under dry conditions (Figure 6, red colors). Under high RH conditions, AV1, AV2, and AV4 exhibited lower NCR values ( $\text{NCR} < 1$ ) compared to the dry conditions (Figure 6). However, a continuous reduction in NCR with decreasing VFR (to the point that no contribution of the factor is detectable) was only observed for AV1. Similar to the case of SV1, we concluded that the evolution of AV1 was primarily driven by the evaporation process controlled by its average  $C^*$  which lies in the volatility range between SVOC and LVOC.

The evolution of NCR with decreasing VFR was more complex for AV2 and AV4 as compared with that for AV1: their NCR values did not decrease with decreasing VFR but instead showed an increase with decreasing VFR at high RH. These observations imply that the aqueous-phase chemical transformation were the dominant processes affecting the evolution of AV2 and AV4 at high RH instead of simple evaporation. Such chemical transformations could also cause the increases in the characteristic  $T_{\text{desorp}}$  and the factor thermogram width observed at high RH (Figure 3 and Figure 6), in particular for AV2 with  $T_{50}$  increasing from 105 °C to 135 °C.

AV3 exhibited an  $\text{NCR} > 1$  in the fresh case under high RH conditions, which means an additional amount of compounds grouped into that factor were formed in the presence of an aqueous phase in the particles. Note that many of the ions grouped into AV3 also showed an increase in the absolute measured signal under high RH conditions after accounting for the different amount of collected sample mass on the filter. With longer isothermal evaporation time, NCR decreased for AV3, which means that some of the compounds grouped into AV3 must have evaporated from the particles or continued to react to form different products grouped into other factors. The change of the factor thermogram shape (i.e. loss of compounds with higher  $C^*$  and lower  $T_{\text{desorp}}$ ) in Figure 3 together with a minor shift in the characteristic  $T_{\text{desorp}}$  in Figure 6 suggest that the removal due to evaporation is the more likely explanation. Hence, the evolution of NCR of AV3 at high RH suggests complex behavior including the formation of compounds at the particle phase but also the loss of some compounds mainly by evaporation.

Negligible changes in NCR of AD5 alone indicates minor changes in composition during evaporation under dry or high RH conditions. In addition, when considering that AD5 is (mainly) in the ELVOC range (see Figure 3), the isothermal evaporation of compounds should not be significant in the experimental timescale of up to 4.5h (Li et al., 2019). But when investigating the factor thermograms (Figure 3) in detail, the changes in the shape of the factor thermogram and  $T_{\text{desorp}}$  (Figure 3) together implied that apart from evaporation, water driven aqueous-phase processes also affected at least some of the compounds with extremely low  $C^*$  which are grouped into AD5.

### 3.3.3 Interpretation of the evolution of NCRs

Overall, particulate water not only accelerates the evaporation of sample factors by reducing bulk diffusion limitations, but also alters the chemical composition of particles by inducing chemical aqueous-phase processes (e.g., hydrolysis or oligomerization). Accelerated evaporation primarily driven by the water plasticizing effect was observed for those sample factors with smallest average MW and highest volatility in both SOA systems (i.e.,  $\alpha$ pin: AV1 and SQTmix: SV1). On the other hand, changes in NCR

together with changes in the absolute abundance and/or the characteristic  $T_{\text{desorp}}$  for other sample factors very likely suggest the presence of aqueous-phase processes that generally modify the composition and volatility of the (remaining) SOA particles.

355 The factors affected by chemical aqueous-phase processes can be classified as (i) “educt” factors with  $\text{NCR} < 1$  and (ii) “product” factors with  $\text{NCR} > 1$  under the same conditions. “Educt” factors contain water-labile compounds which are stable under dry conditions but undergo chemical reactions in the presence of water. Likely aqueous-phase reactions are the fragmentation (hydrolysis) of organic (hydro)peroxides (Krapf et al., 2016; Zhao et al., 2018; Qiu et al., 2019) or accretion reactions. Examples for these “educt” factors were SV2, SV4, AV2, and AV4. All these factors exhibited NCR values clearly  $< 1$ , while their volatilities  
360 were in the (E)LVOC range which makes a substantial isothermal evaporation within 0.25 h very unlikely.

The products of these aqueous-phase reactions will evaporate from the particle phase if their volatility is high enough (e.g. small fragments from fragmentation reactions). Products with sufficiently low volatility will remain in the particle phase and contribute to the “product” factors. Such compounds with sufficiently low volatility may be the larger fragments of fragmentation reactions, but the majority is likely formed from accretion reactions such as (i) non-oxidate reactions involving two or more carbonyls (i.e.,  
365 (hemi)acetal formation, aldol condensation, and esterification), or (ii) reactions incorporating carbonyls and organic hydroperoxides (i.e., peroxy(hemi)acetal formation) (Kroll and Seinfeld, 2008; Herrmann et al., 2015). The predominant non-oxidative nature of these reactions is dictated by the fact that the average OSc of the particles does not increase under high RH conditions.

The “product” factors for SQTmix SOA particles (SV3 and SD5) were also identifiable by the fact that they almost have no  
370 contribution to the total signal under dry conditions. The comparable “product” factor for  $\alpha$ pin SOA (AV3) already contributed to the particles under dry conditions and then showed an increase in contribution under high RH conditions. This behavior is probably linked to the SOA production inside the OFR which was at  $\sim 40\%$  RH. For  $\alpha$ pin SOA, compounds grouped into AV3 could be already produced inside the OFR either in the gas phase or by particle-phase processes. The absence/very small contribution of SV3 or SD5 under dry conditions indicates that the processes leading to their formation were too slow to produce significant  
375 amounts during the short residence time prior to the particle size selection.

Another difference between the two SOA types lies with the evolution of the “educt” and “product” factors in the RTC under high RH conditions. For SQTmix SOA particles, the evolution of the NCR values of all factors was monotonic (i.e., either increasing or decreasing with decreasing VFR). This may indicate that the underlying dominant process is either a removal or a production process for each factor. It should be noted that multiple loss and production processes may coexist for a factor, especially at high  
380 RH where aqueous-phase processes may play a role. For instance, the removal of compounds grouped into the “educt” factor AV2 or AV4 via chemical reaction was dominant over any production process. But with increasing isothermal evaporation time at high RH, the balance between these processes shifted slightly, leading to a small increase in NCR. The balance between the removal and production of compounds may vary over time. This is probably the cause of the complex behavior of NCR values for AV2, AV4 and AV3.

#### 385 4. Atmospheric implications and conclusions

This isothermal evaporation study demonstrates that the SQTmix SOA particles evaporate slower than  $\alpha$ pin ones. Additional compositional measurements with FIGAERO-CIMS enabled the separation of particulate constituents by their volatilities. By examining particle samples at two different evaporation stages (fresh vs. RTC), we observed relatively less changes in  $T_{50}$  and smaller decreases in the STGs of SQTmix SOA particles, in comparison with  $\alpha$ pin SOA particles. This is in line with the

390 observation of slower evaporation rate of SQTmix SOA particles during the isothermal evaporation. Compared to  $\alpha$ pin SOA particles generated under comparable oxidation conditions, the overall less evaporation of SQT mix SOA can be attributed to its higher value of OSc which is consistent with its lower volatility and possibly higher viscosity.

As the monoterpene with the largest emissions globally,  $\alpha$ -pinene has commonly served as a model precursor to generate biogenic SOA particles for laboratory studies. Results from these studies have been used to represent properties of many other terpene-derived SOA particles (excl. isoprene-derived SOA) in aerosol-climate models (O'Donnell et al., 2011; Gordon et al., 2016). Or  
395 study corroborates previous findings that sesquiterpene-derived particles are more viscous (Saukko et al., 2012), less hygroscopic (Pajunoja et al., 2015) and less volatile (Ylisirnio et al., 2020), compared to  $\alpha$ pin SOA particles. These findings are generally corroborated by our study. Since the interplay of particle viscosity and volatility does impact the evaporation dynamics of particles, future studies should focus on particles derived from terpene precursors other than  $\alpha$ -pinene to provide better parameterization to  
400 comprehensively constrain gas-to-particle partitioning behavior of different biogenic SOA particles.

We applied PMF to deconvolute the FIGAERO-CIMS data by grouping desorbed organic compounds into several sample factors. Such statistical analysis provides a useful simplification, compared to the full mass spectra, for describing how particle composition evolves during isothermal evaporation. In line with the minor change in the VFR under dry conditions, there was little difference in the particulate composition between fresh and RTC samples. On the other hand, the presence of particulate water dramatically  
405 altered the dry particle composition at high RH, likely by acting both as a plasticizer for bulk-surface diffusion and a catalyzer for aqueous-phase processes. In each SOA system, the most volatile factor was primarily lost via evaporation when high content of particulate water was present. As suggested by the change in NCR, the water-driven aqueous processes mainly governed the production and/or removal of other sample factors at high RH. Depending on the particle type, sample factors, and evaporation timescale, the effect of aqueous processes could be net production or net loss, which is indicated by the coevolution of particle  
410 VFR and factor NCR. While each sample factor of SQTmix SOA particles is largely controlled by a single type of process, the factors of  $\alpha$ pin ones evolve according to the complex and time-dependent interplay of production and removal processes.

The observed aqueous-phase processes are not unique to SOA particles formed in the OFR. Prevalence of ether groups has been observed in ambient particles with high aerosol liquid water content, suggesting abundant formation of (hemi)acetals from carbonyls (Gilardoni et al., 2016; Ditto et al., 2020). Additionally, the prevalence of terpene-derived oligomers as well as carbon  
415 chain lengths have been found to decrease in cloud-water samples as compared to particle samples collected below cloud, indicating the possible presence of hydrolysis in cloud water (Boone et al., 2015). Although increasing evidence from laboratory and field observations have suggested the importance of aqueous-phase processes, such reactions are still underrepresented in the existing models because of a lack of fundamental knowledge (McNeill, 2015). While the aqueous-phase processes of simple, typically small carbonyl compounds have been well studied so far (De Haan et al., 2009; Schwier et al., 2010; Yasmeen et al., 2010; Li et al., 2011; Zhao et al., 2012; Zhao et al., 2013; Petters et al., 2020), more studies should investigate the processes involving complex  
420 and large molecules with multiple functional groups.

## Appendix A. Scaled sum thermograms of RTC samples

To investigate the changes in volatility of SOA particles, we need to compare the number of ions at each desorption temperature between fresh (0.25 h,  $N_{fresh}(T)$ ) and RTC (4.25 h,  $N_{RTC}(T)$ ) samples collected by on the FIGAERO filter. The remaining fraction of all ions (RF) observed at a given temperature in each sample can be described as:

$$RF_{fresh}(T) = \frac{N_{fresh}(T)}{N_{0,fresh}(T)} \quad (A1)$$

$$RF_{RTC}(T) = \frac{N_{RTC}(T)}{N_{0,RTC}(T)} \quad (A2)$$

where  $N_{0,fresh}(T)$  and  $N_{0,RTC}(T)$  are the number of ions at each desorption temperature at the each initial stage, i.e., before any isothermal evaporation occurred for the fresh and RTC samples, respectively. Note that  $N_{0,fresh}(T)$  and  $N_{0,RTC}(T)$  depend on the collected sample amount in each case.

The total remaining fraction of ions across the whole range of desorption temperatures ( $RF_{Tot}$ ) is equal to:

$$RF_{Tot,fresh} = \frac{\sum_0^T N_{fresh}(T)}{\sum_0^T N_{0,fresh}(T)} = \frac{N_{Tot,fresh}}{N_{Tot,0,fresh}} \quad (A3)$$

$$RF_{Tot,RTC} = \frac{\sum_0^T N_{RTC}(T)}{\sum_0^T N_{0,RTC}(T)} = \frac{N_{Tot,RTC}}{N_{Tot,0,RTC}} \quad (A4)$$

where  $N_{Tot,fresh}$  and  $N_{Tot,RTC}$  are the sum of all ions over all desorption temperatures at the fresh and RTC stages.  $N_{Tot,0,fresh}$  and  $N_{Tot,0,RTC}$  are the same sums at the initial stage before any isothermal evaporation occurred for each sample.

In the absence of a reliable sensitivity calibration of the CIMS, the measured STG at a given desorption temperature ( $STG_{fresh}(T)$  and  $STG_{RTC}(T)$ ) is equivalent to the number of ions detected at this desorption temperature ( $N_{fresh}(T)$  and  $N_{RTC}(T)$ ). To account for different amounts of mass loadings on the FIGAERO filter, we normalize the measured STG with the total ion signal of each sample ( $N_{Tot}$ ):

$$STG_{N,fresh}(T) = \frac{N_{fresh}(T)}{N_{Tot,fresh}} \quad (A5)$$

$$STG_{N,RTC}(T) = \frac{N_{RTC}(T)}{N_{Tot,RTC}} \quad (A6)$$

With Eq. (A2) – (A5), the expressions for the normalized STGs can be converted to:

$$STG_{N,fresh}(T) = \frac{N_{0,fresh}(T) \cdot RF_{fresh}(T)}{N_{Tot,0,fresh} \cdot RF_{Tot,fresh}} \quad (A7)$$

$$STG_{N,RTC}(T) = \frac{N_{0,RTC}(T) \cdot RF_{RTC}(T)}{N_{Tot,0,RTC} \cdot RF_{Tot,RTC}} \quad (A8)$$

Due to experimental limitations, different amounts of sample were collected in the fresh and RTC cases. Thus, the total signal at the corresponding initial stage is not equal either. However, the ratio between  $N_0(T)$  and  $N_{Tot,0}$  is independent of the amount of sample and can be expressed as:

$$k(T) = \frac{N_{0,fresh}(T)}{N_{Tot,0,fresh}} = \frac{N_{0,RTC}(T)}{N_{Tot,0,RTC}} \quad (A9)$$

450 Comparing the normalized STG is not equivalent to the direct comparison between  $RF_{fresh}(T)$  and  $RF_{RTC}(T)$ , since  $RF_{Tot,fresh}$  and  $RF_{Tot,RTC}$  are not equal. We assume that the change in  $RF_{Tot}$  is determined by the isothermal evaporation, which is proportional to the change in the mean value of volume fraction remaining ( $VFR_{avg}$ ). The  $VFR_{avg}$  from the isothermal evaporation experiment must be converted to the molar scale first:

$$VFR_{avg,fresh} = \frac{N_{Tot,0,fresh} \cdot RF_{Tot,fresh}}{N_{Tot,0,fresh}} \cdot \frac{MW_{avg,fresh}}{MW_{avg,0}} \cdot \frac{\rho_{avg,0}}{\rho_{avg,fresh}}$$

$$= RF_{Tot,0,fresh} \cdot \frac{MW_{avg,fresh}}{MW_{avg,0}} \cdot \frac{\rho_{avg,0}}{\rho_{avg,fresh}} \quad (\text{A10})$$

455

$$VFR_{avg,RTC} = \frac{N_{Tot,0,RTC} \cdot RF_{T,RTC}}{N_{Tot,0,RTC}} \cdot \frac{MW_{avg,RTC}}{MW_{avg,0}} \cdot \frac{\rho_{avg,0}}{\rho_{avg,RTC}}$$

$$= RF_{Tot,0,RTC} \cdot \frac{MW_{avg,RTC}}{MW_{avg,0}} \cdot \frac{\rho_{avg,0}}{\rho_{avg,RTC}} \quad (\text{A11})$$

where  $MW_{avg,fresh}$ ,  $MW_{avg,RTC}$  and  $MW_{avg,0}$  are the average molecular weight of the organic compounds and  $\rho_{avg,fresh}$ ,  $\rho_{avg,RTC}$  and  $\rho_{avg,0}$  are the average particle density for the fresh, RTC, and initial stage, respectively.

Using Eq. (A10) and Eq. (A11), we can express the change in  $VFR_{avg}$  between fresh and RTC samples as:

460

$$\frac{VFR_{avg,RTC}}{VFR_{avg,fresh}} = \frac{RF_{Tot,RTC}}{RF_{Tot,fresh}} \cdot \frac{MW_{avg,RTC}}{MW_{avg,fresh}} \cdot \frac{\rho_{avg,fresh}}{\rho_{avg,RTC}} \quad (\text{A12})$$

Changes in the average molecular weight ( $MW_{avg}$ ) of organic compounds and the average particle density ( $\rho_{avg}$ ) during the isothermal evaporation can be expressed using  $\alpha_{MW_{avg}}$  and  $\beta_{\rho_{avg}}$ :

$$\alpha_{MW_{avg}} = \frac{MW_{avg,RTC}}{MW_{avg,fresh}} \quad (\text{A13})$$

$$\beta_{\rho_{avg}} = \frac{\rho_{avg,RTC}}{\rho_{avg,fresh}} \quad (\text{A14})$$

465 Rearranging Eq. (A12) and using the definitions in Eq. (A13) and Eq. (A14), we can express the change in  $RF_{Tot}$  with the removal factor,  $f_{removal}$ :

$$f_{removal} = \frac{RF_{Tot,RTC}}{RF_{Tot,fresh}} = \frac{VFR_{avg,RTC}}{VFR_{avg,fresh}} \cdot \alpha_{MW_{avg}}^{-1} \cdot \beta_{\rho_{avg}} \quad (\text{A15, Eq. (3) in main text})$$

To remove the term  $RF_{Tot,RTC}$  in Eq. (A8), we multiple Eq. (A8) with Eq. (A15) to calculate the scaled STG ( $STG_{SC,RTC}(T)$ ).

$$STG_{SC,RTC}(T) = STG_{N,RTC}(T) \cdot f_{removal} = \frac{N_{0,RTC}(T) \cdot RF_{RTC}(T)}{N_{Tot,0,RTC} \cdot RF_{Tot,fresh}} \quad (\text{A16})$$

470 Eq. (A16) can be also expressed in the form in Eq. (A17) which is equivalent to Eq. (4) in the main text.

$$STG_{SC,RTC}(T) = STG_{N,RTC}(T) \cdot \frac{VFR_{avg,RTC}}{VFR_{avg,fresh}} \cdot \alpha_{MW_{avg}}^{-1} \cdot \beta_{\rho_{avg}} \quad (\text{A17, Eq. (4) in main text})$$

Now we can rearrange Eq. (A7) and Eq. (A16) as follows:

$$RF_{fresh}(T) = \frac{N_{Tot,0,fresh} \cdot RF_{Tot,fresh}}{N_{0,fresh}(T)} \cdot STG_{N,fresh}(T) \quad (\text{A18})$$

$$RF_{RTC}(T) = \frac{N_{Tot,0,RTC} \cdot RF_{Tot,fresh}}{N_{0,RTC}(T)} \cdot STG_{SC,RTC}(T) \quad (\text{A19})$$

475 Using Eq. (A9), these can be simplified as:

$$RF_{fresh}(T) = \frac{RF_{Tot,fresh}}{k(T)} \cdot STG_{N,fresh}(T) \quad (A20)$$

$$RF_{RTC}(T) = \frac{RF_{Tot,fresh}}{k(T)} \cdot STG_{SC,RTC}(T) \quad (A21)$$

These two equations show that comparing  $STG_{N,fresh}(T)$  with  $STG_{SC,RTC}(T)$  is equivalent to the direct comparison between  $RF_{fresh}(T)$  and  $RF_{RTC}(T)$ .

#### 480 Appendix B. Calculation of net change ratio (NCR) for each PMF sample factor

We want to investigate the evolution of each sample factor  $k$  during isothermal evaporation by comparing its contribution to the total particle composition at different conditions  $j$  (fresh vs RTC; dry vs. high RH). To account for different amounts of collective sample material on the FIGAERO filter, we normalize the measured sum of ions from a factor  $k$  ( $N_{k,j}$ ) to the total ion signal of each sample ( $N_{Tot,j} = \sum_{k=1}^5 N_{k,j}$ ) excluding the contribution of background factors. The contribution of a factor  $k$  ( $F_{k,j}$ ) to each sample can be calculated as:

$$F_{k,j} = \frac{N_{k,j}}{\sum_{k=1}^5 N_{k,j}} = \frac{N_{k,j}}{N_{Tot,j}} \quad (B1)$$

The remaining fraction of a sample ( $RF_{Tot,j}$ ) can be calculated as follows:

$$RF_{Tot,j} = \frac{N_{Tot,j}}{N_{Tot,0,j}} \quad (B2)$$

490 where  $N_{Tot,j}$  is the total ion signal of each sample and  $N_{Tot,0,j}$  is the total ion signal at the initial state, i.e., before any isothermal evaporation occurred for the collected sample. It should be noted that the value of  $N_{Tot,0,j}$  depends on the collected mass at each condition  $j$ .

In the same manner, the remaining fraction of a sample factor  $k$  at a condition  $j$  ( $RF_{k,j}$ ) can be defined as:

$$RF_{k,j} = \frac{N_{k,j}}{N_{k,0,j}} \quad (B3)$$

495 where  $N_{k,0,j}$  is the total ion signal of a factor  $k$  at the initial state. Similar to  $N_{Tot,0,j}$ , the value of  $N_{k,0,j}$  also depends on the total sum signal of a sample  $k$  at a condition  $j$ .

Expressing  $N_{Tot,j}$  and  $N_{k,j}$  in Eq. (B1) with Eq. (B2) and Eq. (B3) yields:

$$F_{k,j} = \frac{N_{k,j}}{N_{Tot,0,j} RF_{T,j}} = \frac{N_{k,0,j} RF_{k,j}}{N_{Tot,0,j} RF_{Tot,j}} \quad (B4)$$

In the same manner as  $\frac{N_0(T)}{N_{Tot,0}}$  expressed in Eq. (A9), the ratio between  $N_{k,0}$  and  $N_{Tot}$  is also independent of the amount of sample

$$\frac{N_{k,0,j}}{N_{Tot,0,j}} = \frac{N_{k,0,ref}}{N_{Tot,0,ref}} \quad (B5)$$

500 It is not possible to capture the true initial state of particles, as particles start to evaporate directly after size selection. The dry and fresh condition exhibited the least amount of isothermal evaporation and thus was chosen as the reference case. By comparing  $RF_{k,j}$  of the other sample with  $RF_{k,ref}$ , we could gain insights into the effect of increasing evaporation time and/or RH on each

sample factor  $k$ . Here, we introduce the net change ratio (NCR) which is defined as the ratio between the remaining fraction of a sample factor  $k$  at a condition  $j$  ( $RF_{k,j}$ ) and that at the reference condition ( $RF_{k,ref}$ ). The principle of NCR is comparable to the scaling treatment applied to STG(T) of RTC samples (Appendix B). The NCR for a sample factor  $k$  at a condition  $j$  ( $NCR_{k,j}$ ) can be expressed as follows:

$$NCR_{k,j} = \frac{RF_{k,j}}{RF_{k,ref}} \quad (\text{B6})$$

Using Eq. (B4) and Eq. (B5), we rearrange Eq. (B6) and present  $NCR_{k,j}$  as follows:

$$NCR_{k,j} = \frac{F_{k,j}}{F_{k,ref}} \cdot \frac{RF_{Tot,j}}{RF_{Tot,ref}} \quad (\text{B7})$$

Note that the value of  $NCR_{k,j}$  is not equivalent to the ratio of contribution of a factor  $k$  between the condition  $j$  and reference condition, since  $RF_{Tot,j}$  is not equal to  $RF_{Tot,ref}$ . Similar to the scaled STG approach, the change in  $RF_{Tot}$  is assumed to be proportional to that in the VFR between two conditions (the condition  $j$  vs the reference condition). Similar to Eq. (A12), the ratio of  $RF_{Tot}$  between a condition  $j$  and reference condition can be solved as

$$\frac{RF_{Tot,j}}{RF_{Tot,ref}} = \frac{VFR_{avg,j}}{VFR_{avg,ref}} \cdot \frac{MW_{avg,ref}}{MW_{avg,j}} \cdot \frac{\rho_{avg,j}}{\rho_{avg,ref}} = \frac{VFR_{avg,j}}{VFR_{avg,ref}} \cdot \alpha_{MW_{avg,j}}^{-1} \cdot \beta_{\rho_{avg,j}} \quad (\text{B8})$$

where  $\alpha_{MW_{avg,j}}$  and  $\beta_{\rho_{avg,j}}$  capture changes in signal-weighted molecular weight ( $\frac{MW_{avg,j}}{MW_{avg,ref}}$ ) and particle density ( $\frac{\rho_{avg,j}}{\rho_{avg,ref}}$ ) between a condition  $j$  and reference condition, respectively.

We replace  $\frac{RF_{Tot,j}}{RF_{Tot,ref}}$  in Eq. (B7) with Eq. (B8) and then the  $NCR_{k,j}$  of a factor  $k$  at a condition  $j$  can be expressed with the following equation:

$$NCR_{k,j} = \frac{F_{k,j}}{F_{k,ref}} \cdot \frac{VFR_{avg,j}}{VFR_{avg,ref}} \cdot \alpha_{MW_{avg,j}}^{-1} \cdot \beta_{\rho_{avg,j}} \quad (\text{B9, Eq. (5) in main text})$$

## 520 Appendix C. Estimation of average molecular weight ( $MW_{avg,j}$ ) and average particle density ( $\rho_{avg,j}$ ) using PMF sample factors

For converting the VFR from the volumetric scale to the molar one, values of  $MW_{avg,j}$  and  $\rho_{avg,j}$  are needed at the condition  $j$ . For each sample factor  $k$  at a condition  $j$ , we calculate its signal-weighted average molar mass ( $MW_{k,j}$ ) and then estimate its density ( $\rho_{k,j}$ ) using its average O:C and H:C values (Kuwata et al., 2012). For those compounds grouped into factors classified as type D, we are uncertain about the degree of thermal decomposition and that if the decomposition products can be detected by the instrument. In such case, we consider that either none or all of compounds grouped into type D factors can undergo thermal decomposition at the FIGAERO inlet and we also assume that at least 50% of these thermally liable compounds can be detected by the CIMS. Eventually, we calculate the  $MW_{avg,j}$  and  $\rho_{avg,j}$  as follows:

$$MW_{avg,j} = \sum_{k=1}^5 MW_{k,j} \cdot F_{k,j} \quad (\text{C1})$$

$$525 \quad \rho_{avg,j} = \sum_{k=1}^5 \rho_{k,j} \cdot F_{k,j} \quad (\text{C2})$$

Using the  $MW_{avg,j}$  and  $\rho_{avg,j}$  at each condition  $j$ , we calculate the values of  $\alpha_{MW_{avg}}$  and  $\beta_{\rho_{avg}}$  used for Eq. (A17) or those of  $\alpha_{MW_{avg,j}}$  and  $\beta_{\rho_{avg,j}}$  used for Eq. (B9), as summarized in Table C1 and Table C2, respectively. Error bars of these parameters account for the uncertainty arising from the calculation of  $MW_{k,j}$  and  $\rho_{k,j}$  for type D factors.

**Table C1.** Ranges of parameters for scaling the normalized sum thermograms of RTC stages

SOA System	Fresh Condition	RTC Condition	$\frac{VFR_{avg,RTC}}{VFR_{avg,fresh}}$	$\alpha_{Mw}$	$\beta_{\rho_{org}}$
$\alpha_{pin}$	Dry, Fresh	Dry, RTC	[0.85, 0.91]	[0.99, 1.01]	[1, 1]
	High RH, Fresh	High RH, RTC	[0.57, 0.73]	[1.02, 1.07]	[1.01, 1.01]
SQTmix	Dry, Fresh	Dry, RTC	[0.92, 0.95]	[1.01, 1.03]	[1, 1]
	High RH, Fresh	High RH, RTC	[0.73, 0.82]	[0.98, 1.03]	[1, 1.01]

535 **Table C2.** Ranges of parameters for calculating the net change ratio (NCR) for each PMF sample factor

SOA System	Ref. Condition	Condition j	$\frac{VFR_{avg,j}}{VFR_{avg,ref}}$	$\alpha_{Mw}$	$\beta_{\rho_{org}}$
$\alpha_{pin}$	Dry, Fresh	Dry, RTC	[0.85, 0.91]	[0.99, 1.01]	[1, 1]
		High RH, Fresh	[0.77, 1.05]	[1.01, 1.07]	[0.99, 0.99]
		High RH, RTC	[0.56, 0.60]	[1.03, 1.14]	[1, 1]
SQTmix	Dry, Fresh	Dry, RTC	[0.92, 0.95]	[1.01, 1.03]	[1, 1]
		High RH, Fresh	[0.94, 1.07]	[0.98, 1.33]	[1.01, 1.01]
		High RH, RTC	[0.76, 0.80]	[1.00, 1.31]	[1.01, 1.01]

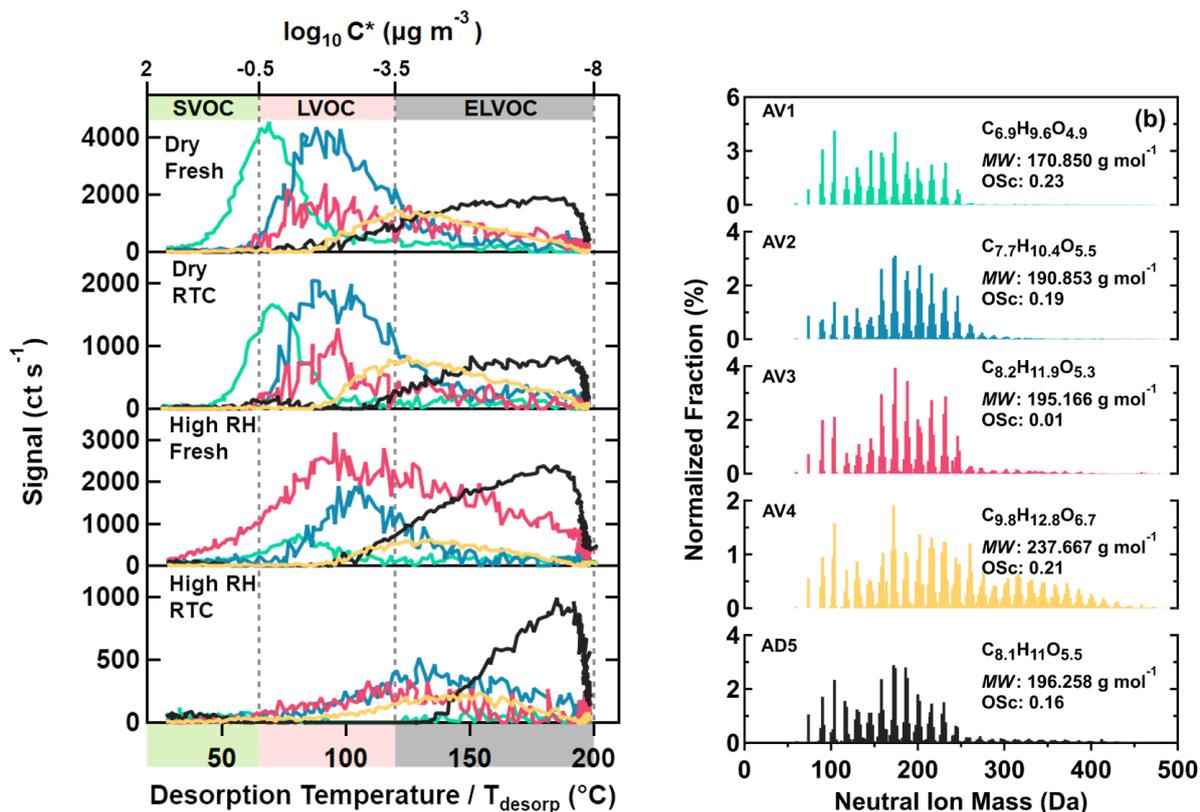

**Figure 1.** Evapograms for  $\alpha$ pin (turquoise) and SQTmix (orange) SOA particles under dry (<7%), intermediate RH (40% RH) and high RH (80% RH) conditions. The blue (fresh) and brown (RTC) areas indicate the corresponding sampling periods of FIGAERO-CIMS.

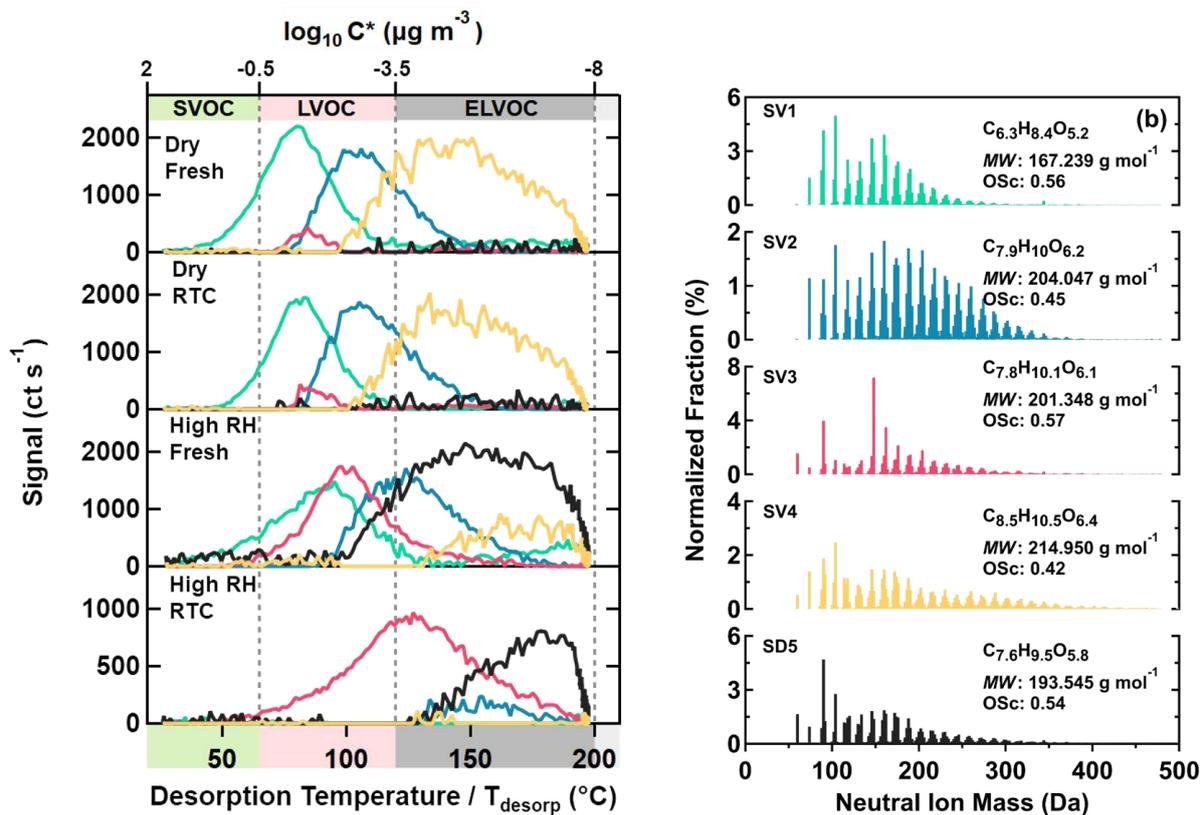

**Figure 2.** Sum thermograms (STG) (a, b), average volume fraction remaining ( $\text{VFR}_{\text{avg}}$ ) (c), and median desorption temperature ( $T_{50}$ ) (c) for apin (turquoise) and SQTmix (orange) SOA particles, for dry ( $\text{RH} < 7\%$ ; (a)) and high RH ( $\text{RH} 80\%$ ; (b)) conditions. Shaded areas indicate the ranges of STG(T) for RTC stages after accounting for changes and uncertainties in average molecular weight and particle density (i.e.,  $\alpha_{\text{MW}_{\text{avg}}}$  and  $\beta_{\rho_{\text{avg}}}$  in Eq. (2)). Volatility classes (a, b) are derived from  $T_{\text{max}} - C^*$  calibrations using a set of PEG compounds (Ylissirio et al., 2021). They are indicated by different background colors using the classification according to Donahue et al. (2012).

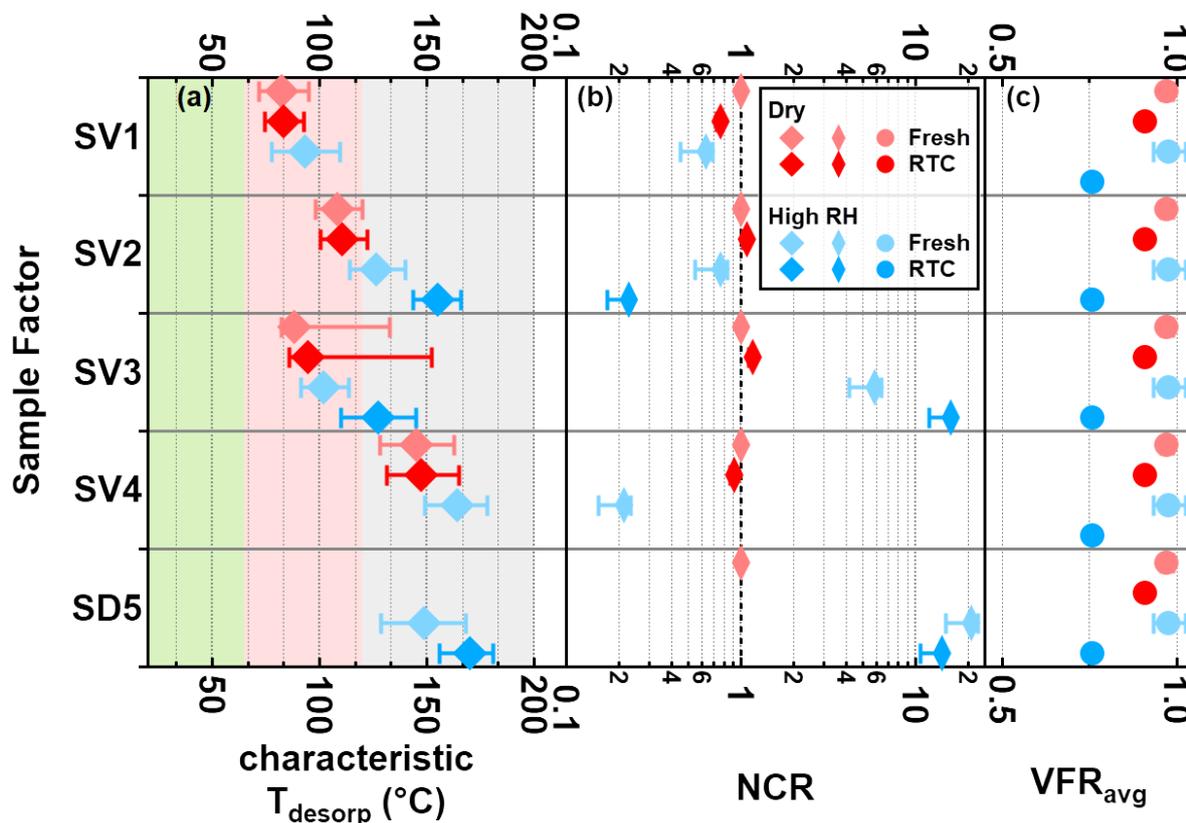

**Figure 3.** Five main sample factors from an eight-factor PMF solution for apin SOA particles. On the panel (a), factor thermograms are shown with color bands on the abscissa indicating volatility classes. On the panel (b), normalized factor mass spectrums are presented with average molecular composition, molecular weight, and oxidation state. The color code is identical for both panels.

750

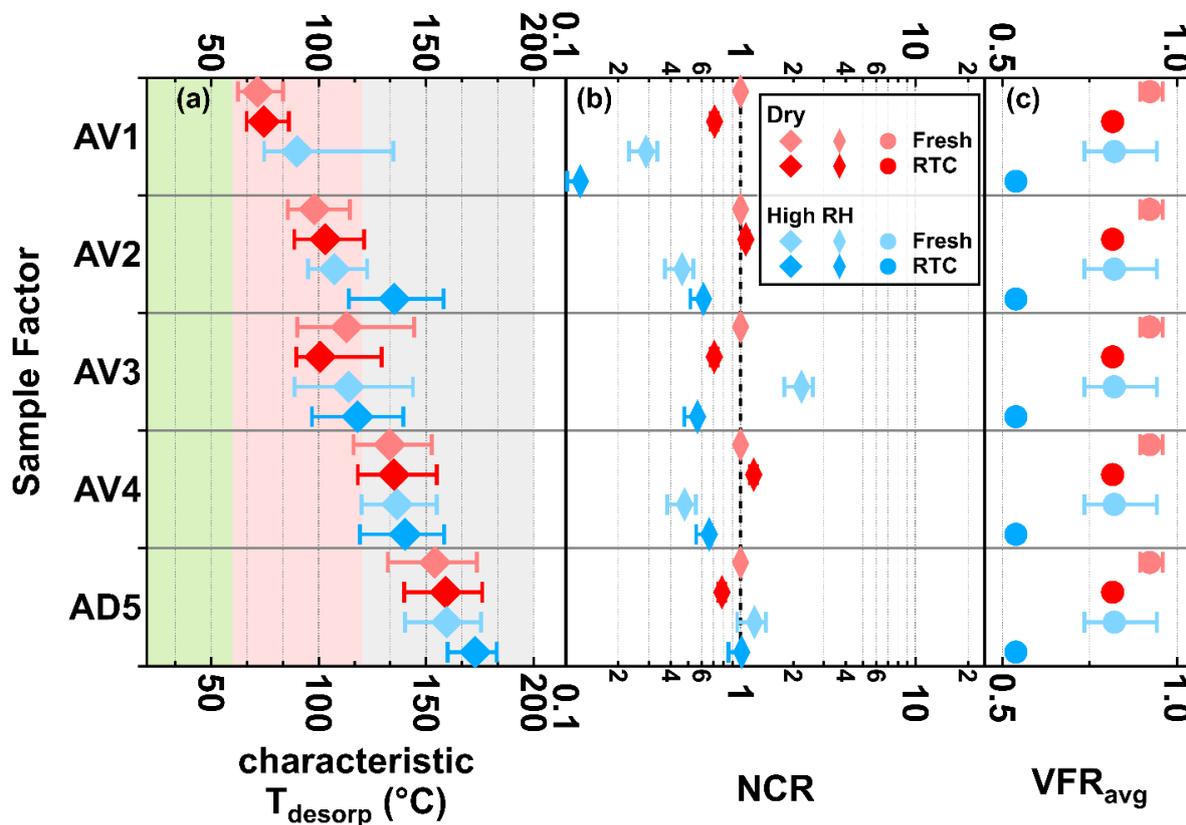

**Figure 4.** Five main sample factors from a ten-factor PMF solution for SQTmix SOA particles. On the panel (a), factor thermograms are shown with color bands on the abscissa indicating volatility classes. On the panel (b), normalized factor mass spectrums are presented with average molecular composition, molecular weight, and oxidation state. The color code is identical for both panels.

755

**Figure 5.** Characteristic desorption temperature (characteristic  $T_{\text{desorp}}$  with 25<sup>th</sup>, 50<sup>th</sup> and 75<sup>th</sup> percentiles, a), net change ratio (NCR, b) of main sample factors and mean values of volume fraction remaining ( $VFR_{\text{avg}}$ , c) of SQTmix SOA particles at fresh (avg.  $t_{\text{R}} = 0.25$  h) and RTC (avg.  $t_{\text{R}} = 4.25$  h) evaporation stages under dry (red) and high RH (blue) conditions. Background colors in the panel (a) indicate the volatility categories derived from  $T_{\text{max}} - C^*$  calibrations (green – SVOC; red – LVOC; and grey – ELVOC). Note that values of  $VFR_{\text{avg}}$  are identical in each row of panel (c). The error bars of NCR represent values accounting for changes in molecular weight and particle density, while those of  $VFR_{\text{avg}}$  indicates the minimum and maximum values during the FIGAERO sampling time. If the factor thermogram does not exhibit the shape as expected for type V/D factors because its signal is significantly low, corresponding values of characteristic  $T_{\text{desorp}}$  and NCR are not presented above.

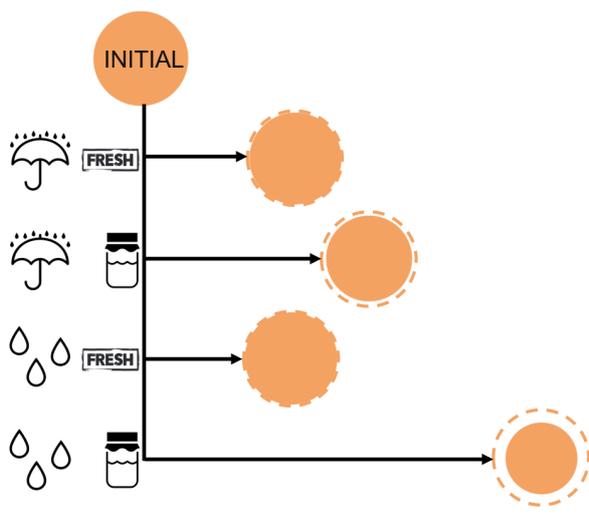

**Figure 6.** Characteristic desorption temperature (characteristic  $T_{\text{desorp}}$  with 25<sup>th</sup>, 50<sup>th</sup> and 75<sup>th</sup> percentiles, a), net change ratio (NCR, b) of main sample factors and mean values of volume fraction remaining ( $VFR_{\text{avg}}$ , c) of  $\alpha$ pin SOA particles at fresh (avg.  $t_R = 0.25$  h) and RTC (avg.  $t_R = 4.25$  h) evaporation stages under dry (red) and high RH (blue) conditions. Background colors in the panel (a) indicate the volatility categories derived from  $T_{\text{max}} - C^*$  calibrations (green – SVOC; red – LVOC; and grey – ELVOC). Note that values of  $VFR_{\text{avg}}$  are identical in each row of panel (c). The error bars of NCR represent values accounting for changes in molecular weight and particle density, while those of  $VFR_{\text{avg}}$  indicates the minimum and maximum values during the FIGAERO sampling time. If the factor thermogram does not exhibit the shape as expected for type V/D factors because its signal is significantly low, corresponding values of characteristic  $T_{\text{desorp}}$  and NCR are not presented above.
