31   Abstract

32   Formaldehyde (HCHO) is one of the most abundant non-methane volatile organic compounds

33   (VOCs) emitted by fires. HCHO also undergoes chemical production and loss as a fire plume ages,

34   and it can be an important oxidant precursor. In this study, we disentangle the processes controlling

35   HCHO by examining its evolution in wildfire plumes sampled by the NASA DC-8 during the

36   FIREX-AQ field campaign. In nine of the twelve analyzed plumes, dilution-normalized HCHO

37   increases with physical age (range 1 – 6 h). The balance of HCHO loss (mainly via photolysis)

38   and production (via OH-initiated VOC oxidation) controls the sign and magnitude of this trend.

39   Plume-average OH concentrations, calculated from VOC decays, range from $-0.5\ (\pm 0.5) \times 10^{6}$

40   to $5.3\ (\pm 0.7) \times 10^{6}\ cm^{-3}$. Plume-to-plume variability in dilution-normalized secondary HCHO

41   production correlates with OH abundance rather than normalized OH reactivity, suggesting that

42   OH is the main driver of fire-to-fire variability in HCHO secondary production. Analysis suggests

43   an effective HCHO yield of 0.33 ($\pm$ 0.05) per VOC molecule oxidized for the 12 wildfire plumes.

44   This finding can help connect space-based HCHO observations to the oxidizing capacity of the

45   atmosphere.

47   1. Introduction

48   Wildfire biomass burning is a large source of trace gases and aerosols that affect regional

49   atmospheric chemistry, human health, air quality, radiative balance and climate. Wildfire

50   frequency and intensity are expected to increase with global warming under higher temperatures

51   and drier conditions in the future (Westerling et al., 2006). Wildfire emissions of volatile organic

52   compounds (VOCs) are a complex mixture spanning orders of magnitude in concentration,

53   reactivity, and volatility (Gilman et al., 2015; Koss et al., 2018). These VOCs contribute to

54   increased regional tropospheric ozone (Alvarado et al., 2010; Jaffe and Wigder, 2012; Mauzerall

55   et al., 1998; Wotawa and Trainer, 2000) and can deposit onto or evaporate from organic aerosols

56   in biomass burning air masses (Garofalo et al., 2019; Majdi et al., 2019; Palm et al., 2020).

57

58   Formaldehyde (HCHO) is one of the most abundant non-methane VOCs emitted by wildfires

59   (Akagi et al., 2011; Gilman et al., 2015; Simpson et al., 2011). HCHO emissions vary with total

60   carbon emissions, modified combustion efficiency (MCE) and fuel type. Emission factors of

61   HCHO decrease as MCE increases (e.g., Liu et al., 2017; Yokelson et al., 1999), indicating that

62   more HCHO is produced from smoldering fires than from flaming fires. HCHO emissions can

63   vary by more than a factor of 2 among tropical forest, savanna, boreal forest and temperate forest

64   biomes (Akagi et al., 2011). In addition to direct emissions, HCHO is formed in fire plumes via

65   VOC oxidation. Alvarado et al. (2020) used TROPOMI data to show that HCHO enhancements

66   in wildfire plumes persist for days downwind. HCHO also serves as an important source of peroxy

67   radicals (HO_2), thereby influencing the formation of ozone and other secondary pollutants

68   (Yokelson et al., 1999).

69

70

71 Few studies have investigated the photochemical evolution of HCHO in biomass burning plumes,

72 and these studies have reported both net HCHO production and loss. Mauzerall et al. (1998)

73 reported average HCHO enhancement (ΔHCHO/ΔCO) of 9.5 ppt/ppb for fresh plumes (less than

74 0.5 day), 1.8 ppt/ppb for recent plumes (less than 1 day), 2.3 ppt/ppb for aged plumes (< 5 days

75 old), and 0.9 ppt/ppb for old plumes (>5 days old). Trentmann et al. (2005) observed a potential

76 increasing trend of ΔHCHO/ΔCO from 20 ppt/ppb to over 30 ppt/ppb with limited data and

77 simulated a flat trend of ΔHCHO/ΔCO within 1 h age since emission from a Savanna fire plume

78 in Africa. Müller et al. (2016) also observed an increasing trend of ΔHCHO/ΔCO with an average

79 of 22.7 ppt/ppb and simulated a flat or slightly decreasing trend of ΔHCHO/ΔCO in a small fresh

80 agricultural biomass burning plume in Georgia, US. While such case studies are valuable, we lack

81 a general understanding of the drivers of plume trends and plume-to-plume variability in HCHO

82 evolution.

83

84 HCHO is also one of the few VOCs that can be observed from space, and the global coverage of

85 satellite observations has been leveraged to provide insights into a variety of atmospheric

86 chemistry questions. HCHO is correlated with organic aerosols in biomass burning air masses, and

87 this correlation might be exploited to estimate organic aerosol abundance from satellite HCHO

88 measurements (Liao et al., 2019). In regions with constant or very high OH reactivity, HCHO

89 variability is closely linked to OH variability (Valin et al., 2016; Wolfe et al., 2019) and may be

90 used to infer OH. Satellite HCHO columns have also been widely used to constrain emissions of

91 isoprene and other VOCs (Fu et al., 2007; Kaiser et al., 2018; Marais et al., 2014; Millet et al.,

92 2008; Stavrakou et al., 2009). Understanding the emissions, chemistry and trends of HCHO in

93 wildfires will facilitate the application of satellite HCHO towards broad-scale wildfire smoke

94 processes and impacts.

95

96 The Fire Influence on Regional to Global Environments and Air Quality experiment (FIREX-AQ)

97 deployed a comprehensive suite of instruments aboard the NASA DC-8 aircraft to study wildfires

98 and agricultural fires in the US. It provided a great opportunity to systematically study the

99 emissions and chemistry of HCHO in wildfire plumes. In the following, we describe the HCHO

100 dependence on plume age in wildfire plumes from FIREX-AQ, assess the drivers of HCHO trends,

101 and examine the factors controlling variability in secondary HCHO production.

102

103 2. Methods

104 2.1 FIREX-AQ field campaign and measurements description

105 During FIREX-AQ, a combination of four aircraft (the NASA DC-8, NASA ER-2, and two

106 NOAA Twin Otters) with a comprehensive suite of in situ and remote sensing instruments were

107 deployed to characterize fire emissions and chemistry with operational bases in Boise, ID and

108 Salina, KS from July to September 2019. This study focuses on wildfire plumes sampled by the

109 NASA DC-8 aircraft during FIREX-AQ.

110

111 In situ HCHO observations were acquired by several instruments onboard the DC-8; here we

112 primarily use measurements from the In Situ Airborne Formaldehyde (ISAF) instrument (Cazorla

113 et al., 2015). ISAF uses laser-induced fluorescence to detect HCHO. A tunable UV laser excites

114 HCHO molecules to an excited electronic state and the resulting fluorescence is detected with a

115 photon-counting photomultiplier tube. The laser wavelength is modulated on and off a rotational

Open Access
EGU

116   absorption feature (353.163 nm), and the difference between the "online" and "offline" signals is

117   proportional to the HCHO concentration.

118

119   ISAF was calibrated pre- and post-mission with a compressed-gas HCHO cylinder (584 ± 15 ppbv

120   in nitrogen, Air Liquide). Sensitivity typically varies by less than 5% between calibrations. Flow

121   meters for the standard dilution system were calibrated against a DryCal calibrator (Mesa Labs)

122   with an accuracy of < 1%. The HCHO standard concentration was calibrated before and after the

123   field deployment with an MKS Multigas 2031 Fourier transform infrared spectrometer. Gas

124   standard mixing ratios are typically reproducible to within 2% of the mean value measured over

125   multiple years. IR-determined mixing ratios are adjusted by a factor of 0.96 based on a separate

126   long-path UV absorption experiment (Cazorla et al., 2015). Thus, ISAF HCHO mixing ratios are

127   ultimately tied to the UV cross sections of Meller and Moortgat (2000) as recommended by the

128   JPL 2011 evaluation (Sander et al., 2011). The detection limit of ISAF was 30 pptv for 1-Hz data

129   at signal/noise = 1 and the accuracy of ISAF HCHO measurements was estimated as 10% + 10

130   pptv. The $1/e$ response time of ISAF during FIREX-AQ was about 300 ms, limited mainly by

131   flow through the sample cell.

132

133   During FIREX-AQ, ISAF HCHO measurements correlated with those from the Compact

134   Atmospheric Multispecies Spectrometer (CAMS) (Richter et al., 2015), with a correlation

135   coefficient r^2 of 0.99, a slope of 1.27 (CAMS vs. ISAF), and a near-zero intercept for 1-Hz average

136   wildfire data from equally weighted orthogonal distance regression (Fig. S1). The systematic bias

137   between the CAMS and ISAF measurements exceeds the combined stated uncertainty (10% for

138   ISAF, 6% for CAMS). Post-mission comparisons suggest this discrepancy is due to the absolute

139   calibration of compressed-gas HCHO standards, which are tied to literature-recommended UV

140   (ISAF) or IR (CAMS) cross sections; the source of this discrepancy is still under investigation.

141   Remotely-sensed HCHO column retrievals rely on the same UV cross sections (De Smedt et al.,

142   2018) that are used to calibrate the ISAF instrument. The HCHO enhancements in the plumes (Sect

143   3.1) and the estimated effective yield of HCHO from VOC oxidation by OH (Sect. 3.3) can have

144   a potential low bias of 27% due to the ISAF and CAMS HCHO measurement difference. This

145   uncertainty proportionally affects quantitative analysis results but does not alter qualitative

146   conclusions.

147

148   We also use several supporting measurements in our analysis. CO was measured via mid-IR

149   wavelength modulation spectroscopy by the Differential Absorption Carbon Monoxide

150   Measurement (DACOM) instrument (Sachse et al., 1991). Photolysis rates were derived from the

151   Actinic flux measurements by the Charged-coupled device Actinic Flux Spectroradiometer (CAFS)

152   (Hall et al., 2018). Alkenes were measured by the NOAA Whole Air Sampler (iWAS) (Lerner et

153   al., 2017). Ozone (O_3) measurements were from the NOAA Chemiluminescence instrument

154   (Bourgeois et al., 2020). OH reactivity calculations used VOCs measurements from the NOAA

155   Proton-Transfer Reaction Time-of-Flight Mass Spectrometry (PTR-ToF-MS) (Yuan et al., 2016),

156   NCAR Trace Organic Gas Analyzer (TOGA) (Apel et al., 2015) outfitted with a Time-of-Flight

157   Mass Spectrometer, NOAA Airborne Cavity Enhanced Spectrometer (ACES) (Min et al., 2016),

158   and NOAA Iodide Ion Time-of-Flight (ToF) Chemical Ionization Mass Spectrometer (CIMS)

159   (Veres et al., 2020), listed in Table S1. Our analysis uses in situ measurements that are merged to

160   the iWAS sampling period, which ranged from 1-9 seconds per canister, such that multiple samples

161   were often acquired within a single plume crossing.

162

163   2.2 Normalized excess mixing ratio (NEMR) and physical age definitions

164   NEMR is defined as the difference between the concentration of species X in the plume and in the

165   background air outside of the plume, normalized by the difference between CO concentrations in

166   the plume and the background outside of the plume.

167    $NEMR = \frac{\Delta X}{\Delta CO}$ (1)

168   The background air outside of the plumes was manually selected and could be different or the

169   same for different transects of the same plume, depending on the availability of the iWAS data.

170   The HCHO NEMR is denoted by nHCHO below.

171

172   Physical age was estimated using a Lagrangian trajectory analysis (Holmes et al., in preparation)

173   and described briefly here. Fire source locations were pinpointed using the MODIS/ASTER

174   Airborne Simulator (MASTER) instrument data onboard the DC-8. Upwind trajectories from

175   aircraft locations were computed and the advection age was calculated from the time when a

176   trajectory was closest to the fire. Plume rise time from the surface to the trajectory initialization

177   altitude assumed a vertical wind speed of 7 m/s. The smoke age is the sum of advection age plus

178   rise age averaged over several meteorological models. The average uncertainty of the estimated

179   physical age for the analyzed wildfire plumes was 37% with an interquartile range of 20% based

180   on the range of ages derived from the High-Resolution Rapid Refresh (HRRR), North American

181   Mesoscale Forecast System (NAM) CONUS Nest, and Global Forecast System (GFS 0.25°)

182   meteorological datasets.

183

184   2.3 Plume selection

185   Details about the specific selected wildfire plumes among all sampled wildfire plumes during

186   FIREX-AQ are provided in Table S2. Wildfire plumes that meet the conditions listed below are

187   selected to study the evolution of HCHO in wildfires.

188   a) Lagrangian sampling patterns

189   Lagrangian sampling patterns are defined as flight tracks intercepted the plumes with flight leg

190   directions approximately perpendicular to the horizontal wind directions and more than three

191   transects downwind with different distances from the fire.

192   b) Enhanced HCHO mixing ratios above background

193   We selected the plumes with maximum 1-Hz HCHO mixing ratios > 600 ppt, which was close to

194   the ambient background HCHO mixing ratios. The North Hill plume on 29 July 2019 is the plume

195   with the lowest HCHO concentrations among the selected plumes.

196   c) Appropriate VOC decay for the period analyzed with sufficient data samples

197   We selected the plume samples where chemical age correlated with physical age. This was defined

198   by a correlation coefficient $r^2 \geq 0.57$ for a plot of ln(trans-2-butene/propene) or ln(cis-2-

199   butene/propene) vs physical age. We used 2-butenes/propene as chemical age tracers in this

200   analysis because these gases have comparable lifetimes to physical age for most of the analyzed

201   plumes. We filtered out plume data if the correlation coefficient of ln(trans-2-butene/propene) or

202   ln(cis-2-butene/propene) vs. physical age degraded at older physical ages. Figure S2 shows

203   ln(trans-2-butene/propene) and ln(cis-2-butene/propene) vs. physical age for the plumes that

204   satisfied conditions a) and b) and had iWAS data available. The threshold of $r^2 = 0.57$ is chosen

205   by visual inspection of all VOC decay in Fig. S2. We also filtered out plumes with total number

206   of data points < 8 in the iWAS sample periods for an entire selected circuit of multiple plume

207   transects with good VOC decay. Due to the inhomogeneity of the plumes, too few data points can

10

208   introduce large bias.   In the analyzed plume periods, ln(trans-2-butene/propene) or ln(cis-2-

209   butene/propene) also has good correlations with the maleic anhydride/furan ratio (Fig. S3), another

210   tracer of chemical age in biomass burning plumes (personal communication with Carsten Warneke

211   and Matthew M. Coggon, 2021). The Mica and Lick Creek plume on 02 August 2019 is the plume

212   with the least number of data points among the selected plumes (N = 8).

213

214   The above filters, applied to a total of 26 fire plumes, yield 11 daytime plumes and 1 nighttime

215   plume that are suitable for our analysis (Table S2). One of the twelve plumes (Blackwater)

216   occurred in the southeast US and the rest eleven plumes were in the western US.

217

218   2.4 Estimating average OH concentrations in the plumes

219   Plume photochemical age is estimated based on the relative decay of primary emitted VOCs that

220   have different reaction rate coefficients with OH (e.g., Warneke et al., 2007). We can estimate the

221   average concentration of OH by combining the photochemical age with the trajectory-based air

222   mass age. Cis-2-butene/propene ratios and trans-2-butene/propene ratios are used to estimate OH

223   in this analysis because these gases have comparable lifetimes to physical age (2–6 h) for most of

224   the analyzed plumes. The lifetimes of propene, cis-2-butene, and trans-2-butene are approximately

225   4.5 h, 2.3 h, and 1.8 h, respectively, at OH concentrations of 2×10^6 molecules cm^{-3} (Atkinson et

226   al., 2006). Because both 2-butenes also differ from propene in O_3 reaction rate coefficients, the

227   reactions of these alkenes with O_3 are also considered when we estimate the OH concentrations.

228   We assume that the variability in the butenes–propene relationship is driven by OH and O_3 and

229   that there is negligible change in the relative emission ratios over the sampled plumes. These

230   reaction rate coefficients are those reported by Atkinson et al. (2006).

231 $\ln \frac{\text{butene}}{\text{propene}} = \ln \frac{\text{butene}_0}{\text{propene}_0} - \{(k_{\text{butene+OH}} - k_{\text{propene+OH}})[\text{OH}] + (k_{\text{butene}+O_3} - k_{\text{propene}+O_3})[O_3]\}t$

232 $\hspace{90mm}$ (2)

233 OH concentrations are derived from the slope of $\ln \frac{\text{butene}}{\text{propene}}$ vs. t (physical age), the measured ozone

234 concentrations and the reaction rate coefficients.

235 $[\text{OH}] = \dfrac{slope_{butene} + (k_{\text{butene}+O_3} - k_{\text{propene}+O_3})[O_3]}{k_{propene+OH} - k_{butene+OH}}$ $\hspace{40mm}$ (3)

236 The average ozone concentration of the entire circuit with multiple transects is used to represent

237 the integrated O_3 effect on alkene oxidation. The uncertainty due to O_3 variation and the

238 uncertainty in the slope of $\ln \frac{\text{butene}}{\text{propene}}$ vs. t are propagated to estimate the total uncertainty in plume-

239 average OH.

240

241 2.5 Calculating primary HCHO normalized mixing ratios and secondary HCHO production rates

242 To understand the relative importance of primary emission vs. secondary production of HCHO in

243 fire plumes downwind, we calculate primary and secondary HCHO as the plume ages. The primary

244 HCHO time profile is calculated by the following equation:

245 $\text{nHCHO}_{\text{primary}} = \text{nHCHO}_0 \exp(-(J_{HCHO} + k_{HCHO}[\text{OH}])t)$ $\hspace{30mm}$ (4)

246 where nHCHO_0 is equal to the fitted observed nHCHO (HCHO NEMR) closest to the fire source,

247 J_{HCHO} is the measured HCHO photolysis frequency in iWAS sample periods averaged and

248 interpreted in physical age space, k_{HCHO} is the reaction rate coefficient between HCHO and OH,

249 and t is the physical age. $\text{nHCHO}_{\text{secondary}}$ is calculated by subtracting $\text{nHCHO}_{\text{primary}}$ from the

250 measured nHCHO. Here we assumed the fitted observed nHCHO closest to the fire source is equal

251 to nHCHO at the emission source. This assumption will not impact the secondary nHCHO

252 production rate calculated below.

Atmospheric
Chemistry
and Physics
Discussions
Open Access
EGU

253

254 To characterize secondary HCHO production in wildfire plumes, we calculate the secondary

255 nHCHO production rate. The secondary nHCHO production rate is derived from the HCHO mass

256 balance equation.

257 $\frac{d\,HCHO}{dt} = P - L - D$ (5)

258 where P is chemical production, L is chemical loss, and D is dilution. The calculation of the

259 secondary nHCHO production rate is shown in eqn. 6. The derivation of eqn. 6 from eqn. 5 can be

260 found in the Appendix A.

261 $\frac{P}{\Delta CO}$ (or P_{nHCHO}) $= \frac{dnHCHO}{dt} + (J_{HCHO} + k_{HCHO}[OH])nHCHO.$ (6)

262 Here, $\frac{d\,nHCHO}{dt}$ is taken as the slope of measured nHCHO vs physical age and other parameters are

263 as defined above.

264

265 2.6 Impact of potential variation in HCHO emission ratios on nHCHO trend

266 In this analysis, we assume the variability in the HCHO/CO emission ratio (that is, nHCHO at the

267 source) is much smaller than the variability in nHCHO induced by chemistry for any single fire

268 plume. Emission factors of both HCHO and CO (that is, g of gas per kg of fuel burned) depend on

269 MCE, fuel type, and other factors (e.g., Liu et al., 2017; Yokelson et al., 1999). Normalizing

270 HCHO by CO removes the strong negative dependence of HCHO emission factors on MCE. A

271 small positive trend of nHCHO vs. MCE is due to higher nHCHO and MCE for the eastern US

272 wildfire plume than the western US wildfire plumes (Fig. S4). No clear trend of MCE in nHCHO

273 plume evolution was observed in FIREX-AQ data (Fig. S5). Emissions of CO_2 correlate with fire

274 radiative power (FRP) detected by satellite during FIREX-AQ, and the variability of FRP could

275 affect the variability of downwind concentrations (Wiggins et al., 2020). We found that HCHO

276   correlates with CO_2 (Fig. S6a) and thus likely also with FRP because the change of measured CO_2

277   correlates with the change of FRP (Wiggins et al., 2020). To account for emission variation and

278   dilution, which are main factors affecting the absolution concentrations of trace gases and aerosols

279   in the plumes, HCHO is normalized to CO to investigate the impact of photochemistry on HCHO

280   evolution in the plumes. Photochemistry takes place while emission varies. When normalized to

281   CO, nHCHO does not strongly depend on CO_2 (Fig. S6b and Fig. S7) or FRP. FRP and MCE do

282   not control the trends of nHCHO.

283

284   2.7 OH reactivity calculation

285   We calculate the observed OH reactivity using the Framework for 0-D Atmospheric Modeling

286   (F0AM v4) (Wolfe et al., 2016) with the Master Chemical Mechanism v3.3.1 (MCM; Jenkin et al.,

287   2015) and additional chemical reactions from recent publications of newly-observed biomass

288   burning species and reactions (Coggon et al., 2019; Decker et al., 2019). The VOC chemical

289   species included in the F0AM model are listed in Table S1. We calculate the OH-VOC reactivity

290   ($\sum k_i \, VOC_i$) by excluding OH reactions with NO_2 and CO.

291

292   3. Results and discussion

293   3.1 Trends of HCHO in wildfire plumes

294   nHCHO in wildfire plumes can increase or decrease as plumes age. The trends of measured

295   nHCHO vs. physical age and the corresponding quadratic polynomial regression for 12 selected

296   plumes are plotted in Fig. 1. Quadratic polynomial regression is used because it has suitable

297   degrees of freedom to capture the trends. Considering the CO measurement uncertainty of $\leq 7\%$

298   and HCHO measurement uncertainty of 10%, the uncertainty of nHCHO is estimated to be $\pm 12\%$

299   with a potential systematic low bias of as much as 27% (based on the difference between ISAF

300   and CAMS). Random error due to HCHO and CO measurement precision is negligible when

301   averaging over the iWAS integration time in high-concentration biomass burning plumes.

302

303   In the absence of secondary production, we expect nHCHO to decay with a time constant of a few

304   hours in the daytime. The blue curves in Fig. 1 show the predicted decay of initial nHCHO using

305   observed HCHO photolysis rates and measurement-derived OH concentrations. Because the

306   variability in nHCHO in one transect is significant, we use the start point of the observed nHCHO

307   fitted curve to represent the observed nHCHO closest to fire. HCHO photolysis frequencies are

308   averaged over each transect and linearly interpolated to determine continuous age-dependent

309   photolysis frequencies. The calculated nHCHO without production represents an upper limit of

310   primary (emitted) nHCHO because some HCHO production and loss had already occurred before

311   the closest transect.

312

313   We can also estimate the primary nHCHO (black dashed curves) and the fraction of primary

314   HCHO by assuming nHCHO and the loss rate of nHCHO were constant between emission and the

315   closest observation. The fraction of primary nHCHO to total nHCHO varies from plume to plume

316   and depends on secondary HCHO production rates and total HCHO loss rates. The primary HCHO

317   fraction could decay rapidly to be 60% in about 1 h of aging or it could decay slowly to still account

318   for 60% in about 5h of aging. The primary and secondary fractions of HCHO indicate the impact

319   of direct emission and photochemistry on the fire plume composition downwind. The average and

320   standard deviation of nHCHO production and loss rates for each plume are provided in Table S3.

321

322   HCHO production exceeds loss in 9 of the 12 selected plumes, indicated by positive trends of

323   nHCHO vs. physical age in Fig. 1. Plumes exhibiting negative nHCHO trends have higher nHCHO

324   loss rates than production rates (Table S3). This shows that fire-to-fire variability in the overall

325   nHCHO trend relates to the balance between loss (via photolysis) and production (via VOC

326   oxidation). HCHO loss by photolysis can be either higher or lower than the loss by reaction with

327   OH, but on average photolysis is faster. HCHO loss via photolysis accounts for $63 \pm 27\%$ of the

328   total HCHO loss in daytime plumes. The average HCHO lifetime by photolysis was 8.2 ($\pm$ 8.8) h

329   for the 11 daytime plumes, shorter than the average HCHO lifetime by OH oxidation of 23.5 ($\pm$

330   31.3) h. For some plume transects, there was significant variability in HCHO photolysis

331   frequencies over iWAS averaging intervals due to the aerosol radiative effects. Applying filters to

332   only analyze the data with relatively homogeneous in-plume HCHO photolysis rates does not alter

333   our conclusions. Plume-average OH is not well correlated with the HCHO photolysis frequency

334   (Fig. S8), likely due to inter-fire variability of OH sources and sinks.

335

336   3.2 OH concentration estimation

337   OH is the main oxidant that reacts with VOCs to produce HCHO in the daytime. As described in

338   Sect. 2.4, we estimate plume-average OH concentrations using the relative decays of 2-butenes to

339   propene via eqn. 3. The decay of the natural logarithm of the trans-2-butene to propene ratio and

340   the cis-2-butene to propene ratio with physical age are plotted in Fig. 2 with significant correlation

341   (r^2 = 0.57–0.99) for the 12 plumes. The lowest correlation coefficient occurs for the nighttime

342   plume on 12 August 2019 and the daytime plume on 29 July 2019. This indicates that the

343   photochemical age of the plumes is consistent with their physical age, and the oxidation chemistry

344   can be reasonably represented by average OH and O_3.

345

346   The estimated average OH concentrations for the 12 plumes are shown in Fig. 3. The uncertainties

347   in OH concentrations are based on the standard error in the slope of ln(butenes/propene) vs

348   physical age and the standard deviation of O_3 concentrations. The average and standard deviation

349   of O_3 concentrations and the uncertainty in OH estimation due to the impact of O_3 standard

350   deviation are listed in Table S4. The variation of OH concentrations derived from trans-2-butene

351   to propene ratios is generally consistent with that derived from cis-2-butene to propene ratios,

352   though OH concentrations from trans-2-butene have slightly higher (27% on average) values than

353   that from cis-2-butene to propene, which may be due to systematic bias in the reaction rate

354   coefficients at low temperature (276.9$\pm$3.9 K). The average OH concentrations from trans-2-

355   butene to propene and cis-2-butene to propene were used to represent the average OH

356   concentrations of the plumes. OH concentrations covered a large range, varying from $-0.5(\pm$

357    $0.5) \times 10^6$ (for a nighttime plume) to $5.3(\pm0.7) \times 10^6$ molecules cm^{-3}.

358

359   3.3 Controls on secondary HCHO formation

360   The average secondary nHCHO production rate correlates with the average OH concentration (r^2

361   = 0.69, Fig. 4a). The secondary production rates of nHCHO were calculated from the trends of

362   observed nHCHO ($\frac{dnHCHO}{dt}$), photolysis loss rate and OH (eqn. 6). The uncertainty in nHCHO

363   secondary production rates for each plume is estimated from the standard deviation of the

364   calculated nHCHO secondary production rates along the physical age of the plume. The

365   uncertainty in estimated OH is determined by the propagated uncertainties of OH from trans-2-

366   butene to propene ratios and cis-2-butene to propene ratios. The good correlations (r^2= 0.69)

367   between the secondary production rate of nHCHO and average OH indicate that the variability in

368   OH is a key driver of the secondary production rate of nHCHO. Figure 4a is color-coded with

369   normalized OH-VOC reactivity calculated from measured VOCs (Sect. 2.7). Plume-average

370   normalized OH-VOC reactivity ranges from 11 to 31 s^{-1} (ppm CO)$^{-1}$, is about 20% lower than total

371   OH reactivity across the analyzed plumes, and does not exhibit a clear relationship with OH. This

372   demonstrates that variability in OH, as well as secondary nHCHO production, likely depends

373   principally on variability in OH sources (e.g., photolysis of HONO and conversion of HO_2 by NO)

374   (Peng et al., 2020) rather than sinks. Because nHCHO trend, OH concentration, and normalized

375   OH-VOC reactivity all depend on physical age, in addition to the different properties of the plumes,

376   the difference in physical age among these plumes also has an impact on the average values.

377

378   Figure 4b shows nHCHO production vs. the product of OH and dilution-normalized observed OH-

379   VOC reactivity (averaged for each plume). The latter is a lower limit for the total average OH

380   loss/production rate as observations do not include all OH sinks. The correlation is slightly higher

381   than that in Fig. 4a because variability in normalized OH-VOC reactivity plays a smaller role than

382   OH in affecting P_{nHCHO}. The slope of this relationship, 0.33 ± 0.05, is a metric for the effective

383   yield of HCHO from OH-initiated VOC oxidation. Assuming that reaction of OH with a VOC is

384   the rate-limiting step and ignoring non-OH sources, integrated HCHO production can be written

385   as in eqn. 7.

386    $$P_{HCHO} = \sum \alpha_i k_i [OH][X_i] = \alpha_{eff} k'_{OH}[OH] \qquad (7)$$

387   Where α_i is the yield of HCHO from OH oxidation of any VOC reactant X_i and depends on both

388   the structure of X and the fate of reactive intermediates like peroxy radicals, k_i is the reaction rate

389   coefficient for VOC_i + OH, k'_{OH} represents VOC-OH reactivity, and α_{eff} is the effective yield

390   weighted over OH-VOC reactions. If all OH reactivity (including reactions with CO and NO_2)

Atmospheric
Chemistry
and Physics
Discussions
Open Access
EGU

391   instead of OH-VOC reactivity is considered, α_{eff} will be about 20% smaller. As discussed by Valin

392   et al. (2016), α_{eff} from all OH reactivity is expected to range from 0.2 to 0.4 depending on the

393   magnitude of NO_x and the magnitude and speciation of VOC. The yield reported here (0.28 for all

394   OH reactivity) is on the low end of this range, implying that HCHO production in the plume is not

395   very efficient due to the nature of the emitted VOC and/or the balance of RO_2 reactions with NO,

396   HO_2, and other RO_2. High α_{eff} values reported by Valin et al. (2016) occur in high isoprene

397   emission regions, implying the emitted VOCs in wildfires are not as efficient as isoprene in

398   producing HCHO. Our α_{eff} of 0.28, when considered all OH reactivity, is higher than the value of

399   0.20 (± 0.01) derived by Wolfe et al. (2019) for total-column HCHO in the remote troposphere,

400   where methane oxidation is the primary HCHO source. The potential low bias in observed HCHO

401   could lead to a proportional (27%) low bias in in α_{eff}. We used PTRMS CH_3CHO measurements,

402   which had more complete data coverage than TOGA, and can be more easily integrated over the

403   iWAS sampling time than the TOGA CH_3CHO, which had a sampling duration between 12-33s

404   during FIREX-AQ, and was not always aligned with the iWAS time step. This could also lead to

405   slightly high bias (~5%) in the calculated OH reactivity and a low bias in the α_{eff}. This indicates

406   that besides the potential missing VOCs, the uncertainties in measured VOCs concentrations also

407   contribute to the uncertainties in OH reactivity and α_{eff}. The α_{eff} for the eastern US wildfire plume

408   seems to be higher than western US wildfire plumes but the uncertainties are large. Higher

409   NO_x/VOC ratio in the eastern than western US wildfire plumes may contribute to the higher α_{eff}

410   because more NO_x generally means more radical turnover and a larger fraction of RO_2 + NO, both

411   of which favor HCHO production.

412

413   3.4 Implications for interpretation of satellite observations

414   The quantification of the evolution of HCHO in wildfire plumes can be leveraged to enhance

415   interpretations of satellite remote sensing observations. The good correlation of dilution-corrected

416   secondary HCHO production and oxidant levels suggests the use of satellite HCHO data to

417   estimate oxidant levels in biomass burning plumes. Similar to the studies of NO_2 lifetime from

418   satellite NO_2 data (e.g., Laughner and Cohen, 2019; Liu et al., 2016), with parameterized

419   production rates of HCHO as a function of OH from this study, the effective lifetime of HCHO

420   and OH concentrations in the wildfire plumes could potentially be derived from remote sensing

421   HCHO and CO data if the photolysis rates can be properly parameterized. Satellite HCHO

422   retrievals in biomass burning plumes remain challenging, and information about vertical

423   distributions of trace gases and aerosols from airborne measurements are likely needed to improve

424   satellite retrievals in biomass burning plumes. The effective yield of HCHO from this analysis

425   indicates that the biomass burning VOCs could be less efficient than isoprene in producing HCHO,

426   although other factors such as balance of RO_2 reactions with NO, HO_2, and other RO_2 can play a

427   role. This information may be useful for estimating VOC emissions from satellite HCHO data.

428

429

430   4. Conclusions

431   We studied the chemical evolution of HCHO in wildfire plumes during FIREX-AQ. Twelve well-

432   developed plumes with consistent chemical and physical age 1–6 h downwind were selected

433   among 26 wildfire plumes sampled. During plume transport and aging, dilution-corrected HCHO

434   increased in smoke from nine wildfires and decreased in three, depending on the balance of HCHO

435   production and loss processes. Secondary nHCHO production tracks average OH concentrations,

436   indicating that the variability in OH rather than the variability in the reactive VOC pool drives the

437   production of nHCHO in these wildfire plumes. The effective HCHO yield from OH-initiated

438   VOC oxidation is estimated to be 0.33 (± 0.05), which is about in the middle of previous studies

439   of isoprene-rich, urban VOC-dominated and remote atmospheric background regions.

440

441

442
443

444

445 Appendix A. Derivation of secondary nHCHO production rate from mass balance equation

446 Change of HCHO concentration with time can be obtained from mass balance equation (eqn. A1)

447 $\frac{d\,HCHO}{dt} = P - L - D$ (A1)

448 where P is the HCHO chemical production term; L is the HCHO chemical loss term; and D is the
449 dilution term.

450 Considering the HCHO normalized excess mixing ratio ($nHCHO = \frac{HCHO - HCHO_{bkg}}{CO - CO_{bkg}}$) and

451 assuming that the HCHO background change is relatively small ($\frac{d\,HCHO\,bkg}{dt} \approx 0$), $\frac{d\,HCHO}{dt}$ can be

452 written as

453 $\frac{d\,HCHO}{dt} = \Delta CO \frac{d\,nHCHO}{dt} + nHCHO \frac{d\,\Delta CO}{dt}$. (A2)

454 Because L, D and P terms are as

455 $L = (J_{HCHO} + k_{HCHO}[OH])HCHO$. (A3)

456 $D = -kdil\,(HCHO - HCHO_{bkg}) = -\frac{1}{\Delta CO}\frac{d\,\Delta CO}{dt}HCHO$.

457   (A4)

458 $P = \frac{d\,HCHO}{dt} + L + D = \Delta CO \frac{d\,nHCHO}{dt} + nHCHO \frac{d\,\Delta CO}{dt} + (J_{HCHO} + k_{HCHO}[OH])HCHO -$

459 $\frac{1}{\Delta CO}\frac{d\,\Delta CO}{dt}HCHO$. (A5)

460 By assuming HCHO >> HCHO bkg, $\frac{P}{\Delta CO}$ can be written as

461 $\frac{P}{\Delta CO} = \frac{dnHCHO}{dt} + (J_{HCHO} + k_{HCHO}[OH])nHCHO$. (A6)

462 Where $\frac{d\,nHCHO}{dt}$ can be derived from measured HCHO and CO vs physical age; J_{HCHO} is the HCHO

463 photolysis coefficient, derived from in-situ actinic flux measurements; OH is calculated from

464 VOCs ratios (Sect.2.4); k_{HCHO} is the reaction rate coefficient of HCHO and OH.

467   Data and code availability:

468   Data are publicly available at https://www-air.larc.nasa.gov/missions/firex-aq/index.html with a

469   dataset doi: FIREX-AQ DOI: 10.5067/SUBORBITAL/FIREXAQ2019/DATA001. F0AM is

470   available at https://github.com/AirChem/F0AM. Model setup scripts for this study are available

471   from the contact author upon request.

472

473   Author contribution:

474   GMW and TFH directed the research direction. JL analyzed the data and discussed the results with

475   GMW. JL wrote the manuscript. TFH, GMW, JMS, JL, and RAH made ISAF HCHO

476   measurements. JBG, AL, and VS made iWAS measurements. GSD, JBN, HSH, JPG made

477   DACOM CO measurements. SRH and KU made CAFS photolysis frequencies measurements.

478   CDH, CHF, and AA provided the trajectories-based plume physical age. HSH provided MCE

479   calculation. TBR, JP, and IB made O_3 measurements. CW, MMC, GIG, and KS made PTR-ToF-

480   MS VOC measurements. AF, DR, and PW made CAMS HCHO measurements. ECA and RSH

481   made TOGA VOC measurements. SSB, CCW, MAR, and RAW made ACES measurements. PRV

482   and JAN made CIMS measurements. All authors reviewed and commented on the manuscript.
