21 Abstract

22 Black Carbon (BC) is a significant forcing agent in the Arctic, but substantial uncertainty remains
23 to quantify its climate effects due to the complexity of the different mechanisms involved, in particular
24 related to processes in the snowpack after deposition. In this study, we provide detailed and unique
25 information on the evolution and variability of BC content in the upper surface snow layer during the
26 spring period in Svalbard (Ny-Ålesund). Two different snow-sampling strategies were adopted during
27 spring 2014 and 2015, providing the *refractory* BC (rBC) mass concentration variability on a
28 seasonal/daily and daily/hourly time scales. The present work aims to identify which atmospheric
29 variables could interact and modify the mass concentration of BC in the upper snowpack, the snow layer
30 which BC particles affects the snow albedo. Atmospheric, meteorological, and snow-related physical-
31 chemical parameters were considered in a multiple linear regression model to identify the factors that
32 could explain the variations of BC mass concentrations during the observation period. Precipitation

33 events were the main drivers of the BC variability. Snow metamorphism and activation of local sources
34 during the snow melting periods appeared to play a non-negligible role (wind resuspension in specific
35 Arctic areas where coal mines were present). The statistical analysis **suggests that the BC content in the**
36 **snow is not directly associated to the atmospheric BC load.**

37 **1. Introduction**

38 In the last two decades, the Arctic region has been exposed to dramatic changes in terms of
39 atmospheric temperature rise, sea ice decrease, and increase of air mass transport from lower latitudes
40 bringing warmer and humid air masses containing pollutants and anthropogenic derived compounds (Law
41 and Stohl, 2007; Comiso et al., 2008; Screen and Simmonds, 2010; Eckhardt et al., 2013; Schmale et al.,
42 2018; Maturilli et al., 2019). Long-range transport and local emissions of combustion generating aerosols
43 like black carbon (BC) can influence the radiative budget of the Arctic atmosphere, especially the impacts
44 of atmospheric aging on the mixing state of BC particles (Eleftheriadis et al., 2009; Bond et al., 2013;
45 Zanatta et al., 2018). When deposited over snow, numerous aerosol species directly increase the quantity
46 of solar radiation absorbed by the snowpack, thus favouring snow aging processes and the decrease of the
47 snow albedo (Hansen and Nazarenko, 2004; Flanner et al., 2007; Hadley and Kirchstetter, 2012; Skiles et
48 al., 2018; Skiles and Painter, 2019).

49 Among these light-absorbing aerosols, *black carbon* (BC) particles are the most effective in
50 absorbing the visible and near infrared solar radiation. These primarily emitted, insoluble, refractory and
51 carbonaceous particles originate from natural and anthropogenic sources such as open fires or diesel
52 engine exhausts. Currently, the anthropogenic emissions are higher compared to the natural ones
53 (Moosmüller et al., 2009; Bond et al., 2013). In 2000, the energy production sector (including fossil fuels
54 and solid residential fuels combustion) generated approximately 59% of the total global BC emissions
55 while the remaining came from biomass burning (Bond et al., 2013). BC particles are characterized by a
56 mass size distribution peaking around 100-250 nm (or mass equivalent diameter), e.g. 240 nm in the
57 Svalbard area in spring (Bond et al., 2013; Laborde et al., 2013; Zanatta et al., 2016; Motos et al., 2019).
58 The impact of BC particles absorbing the incoming solar radiation has indeed a non-negligible role in the
59 Arctic region, which is already threatened by a two-fold temperature increase compared to the mid-
60 latitude areas, the so-called “Arctic Amplification” (Bond et al., 2013; Cohen et al., 2014; Serreze and
61 Barry, 2011). BC has an atmospheric lifetime of about seven days and has been directly targeted in
62 important international mitigation agreements (AMAP, 2015). Theoretical and experimental results
63 showed that the cryosphere is affected both by the BC-induced warming of the atmosphere and by direct
64 and indirect BC effects on the snow once deposited over it (Flanner, 2013),

65 Atmospheric BC measurements in the Arctic regions are still rare, despite an extraordinary effort
66 done by the international scientific community to evaluate the sources, transport paths, concentration, and
67 climate impact (Eleftheriadis et al., 2009; Pedersen et al., 2015; Ferrero et al., 2016; Ruppel et al., 2017;
68 Osmont et al., 2018; Zanatta et al., 2018; Laj et al., 2020). BC mass concentrations can be **directly**
69 measured by using incandescent or thermal techniques and indirectly, by absorption measurements using
70 an appropriate mass absorption cross-section (Petzold, 2013). Various terms such as refractory black
71 carbon (rBC) for incandescent measurements, elemental carbon (EC) using thermal techniques, or
72 equivalent black carbon (eBC) based on optical technique are used. Forsström et al. (2009) reported
73 measurements performed in Arctic snow in the past and new measurements of EC in snow surface using
74 filters and a thermo-optical method. The geographical and seasonal eBC variability was investigated in
75 the Arctic region by Doherty et al. (2010). Other BC measurement in snow samples from the Arctic
76 region can be found in Aamaas et al. (2011), Forsström et al. (2013), Pedersen et al. (2015), Gogoi et al.
77 (2016), Khan et al. (2017) and Mori et al. (2019). Intercomparison of different techniques agree within a
78 factor of 2 uncertainty at Alert (Sharma et al., 2017), Ny-Ålesund, and Barrow (Sinha et al., 2017).

79 A complex combination of processes are involved in the BC particles transfer from the
80 atmosphere to the surface snow. Via a modelling approach, Liu et al. (2011) found that approximately
81 50% of BC's total burden in the Arctic atmosphere is removed through wet deposition-related processes.
82 Yasunari et al. (2013) estimated the intensity of BC dry deposition on the Himalayan glaciers; they found
83 that the surface roughness and the surface wind speed are critical parameters in order to retrieve realistic
84 results. In a recent study, Jacobi et al. (2019) confirmed the previous estimates suggesting that
85 approximately 60% of the BC particles are deposited on the surface snow via wet deposition in spring in
86 the Svalbard Arctic area. Models are still not fully able to describe the actual deposition and transport
87 processes in Svalbard, resulting in underestimating the BC concentration in the snowpack (Eckhardt, S. et
88 al 2015, Stohl, A. et al. 2013). Although wet deposition is suggested to be the main driver of BC
89 concentration in the snow, little is known about other environmental processes potentially affecting the
90 BC particles concentration once deposited, i.e. physical post-depositional processes.

91 In this study we present two unique experiments performed in a clean area close to the town of
92 Ny-Ålesund (Svalbard) at the Gruebadet Aerosol Laboratory (78.91734 N, 11.89535 E, 40 m a.s.l.),
93 during spring 2014 and 2015. Daily and hourly time resolution samplings were performed on the snow
94 surface to investigate which atmospheric variables could directly or indirectly modify the BC mass
95 concentration in the surface snow once deposited. The daily sampling lasted for approximately 85 days to
96 assess the **intra-seasonal** variability covering the transition from a cold period (April) to the melting
97 period in late **June**. The hourly time resolution experiment was performed to investigate the existence of
98 potential processes affecting the BC concentration over the diurnal cycle.

100 2. Experimental Methods

101 2.1 Study Area

102 Both experiments were conducted in the proximity of the Ny-Ålesund research station (78.5526
103 N, 11.5519 E, 25 m a.s.l.), located on the Spitzbergen **Island** in Svalbard archipelago. Along the west
104 coast, Svalbard is characterized by a maritime climate with an annual average temperature of -3.9°C in
105 Ny-Ålesund (between 1994 and 2017) (Maturilli et al., 2019). On average, the snowpack starts building
106 up in September and melts away at the end of May (Førland et al. 2011). Ny-Ålesund has become one of
107 the reference locations for conducting Arctic climate studies focusing on atmospheric composition and
108 physics. Long-term monitoring of atmospheric aerosols is performed at the Gruvebadet station (Feltracco
109 et al., 2019, 2020, 2021a, 2021b; Moroni et al., 2018; Ferrero et al., 2016; Bazzano et al., 2015; Moroni et
110 al., 2015; Zangrando et al., 2013; Scalabrin et al., 2012, **Turetta et al., 2021**), and at the Zeppelin
111 observatory (475 m a.s.l.) (Eleftheriadis et al., 2009; Tunved et al., 2013; Lupi et al., 2016, and reference
112 therein).

113

114 2.2 Snow Sampling

115 There are no standardized methods for sampling, filtering and analytical protocols for detecting
116 atmospheric carbon deposited in snow, even if a few protocols have been developed (Ingersoll et al.,
117 2009; Gallet et al., 2018; Meinander et al., 2020). In the present work, two different sampling strategies
118 were adopted regarding the thickness of the sampled layer and the temporal sampling frequency.

119 Snow samples were collected during two field campaigns: The first campaign was carried out in
120 Spring 2014, from April 1st to June 24th for a total of 85 days, it consists of daily sampling and it is
121 referred hereafter as the “85-days experiment”. The second campaign was conducted in Spring 2015 from
122 April 28th to May 1st. During these three days, measurements were collected with hourly sampling. This
123 second campaign is hereafter referred as the “3-days experiment”. Snow samples were collected about 1
124 km North-West of Ny-Ålesund (Figure 1). The area is a dedicated clean site for aerosols and snow
125 sampling, with no fuel engine traffic. The wind at the site is usually blowing from east to west, and rarely
126 from North to South, minimizing the emission of the town reaching the sampling area. The main wind
127 pattern during the experiment is presented in Figures 1 and 2. The samples for both experiments were
128 kept frozen until the lab analyses. The samples were collected using neck nylon gloves to avoid any
129 contamination.

130 The two experiments aim to capture the rBC mass concentration on a daily basis in the surface
131 snow (upper 10 cm) during the seasonal change and on an hourly basis on a thinner surface snow layer
132 (upper 3 cm) during a daily cycle. Although wet and dry deposition are the main sources of BC in the

133 Artic snow, the aim of our experiments **was** to evaluate if other atmospheric parameters could contribute
134 to the snow surface rBC mass concentration variability.

135 In the 85-days experiment, the first 10 cm of surface snow were collected on a daily basis
136 (approximately at 11.00 am, GMT+2) in the same area, using a 5 cm diameter and 10 cm long Teflon
137 tube. The samples were collected following a straight line leaving about 15 cm between the sampling
138 points to minimize the spatial variability. The collected snow was homogenized in a pre-cleaned plastic
139 bag and then, without melting, 50 mL was transferred into vial (Falcon™ 50mL Conical Centrifuge
140 Tubes) for BC, coarse mode particles number (**mix of soil, mineral coarse mode and possibly coal coarse**
141 **mode**) concentration and electrical conductivity analyses. The 85-days experiment was designed with the
142 aim to investigate the BC presence in the upper snow layer, where most of the snow-radiation interaction
143 takes place and where BC particles' presence can decrease the snow albedo (Doherty et al., 2010). **Snow**
144 **albedos increased rapidly and asymptotically as the snow depth increased. Visible albedos reached 0.9 for**
145 **a snow depth of only 5 cm (Perovich et al. 2007).** Moreover, this sampling strategy allowed to evaluate
146 the variation of BC on a seasonal basis and to capture the impacts of wind, precipitation or melting.

147 During the 3-days experiment, the first 3 cm of surface snow were collected on an hourly basis in
148 pre-cleaned vials in a delimited area of 2 x 2 m using the same sampling tools as above (Spolaor et al.,
149 2019). In this case the samples were collected following a straight line leaving about 5 cm between the
150 sampling points. The aim of the 3-days experiment was to investigate the potential daily cycle of surface
151 BC concentration; therefore, we foresaw that small variations could derive from the impact of the daily
152 variation of **short-wave radiation (SWR)** and subsequent induced snow metamorphism at the surface of
153 the snowpack, often at cm scale. To avoid dilution of the signal, we reduced the vertical sampling
154 thickness to 3 cm to enhance our chances of observing variation in the rBC mass concentration, if such
155 variation exists.

156 The temperature at the surface of the snowpack (at 7 cm for 85-days and at 3 cm for 3-days
157 experiment) was always measured. The daily/hourly snow accumulation was determined by measuring
158 the emerging part of 4 poles placed around the sampling area. The average standard deviation calculated
159 from the four poles provides us a reasonable estimate of the variability in snow accumulation\depletion
160 within the sampling area. The standard deviation obtained ranges from 2 to 4 cm for the entire periods,
161 indicating a limited spatial variability.

162

163 **2.3 Atmospheric Optical Measurements**

164 **2.3.1 Aethalometer (AE-31)**

165 In this study, the equivalent BC (eBC) concentration in the Boundary Layer (around 3 m a.s.l.)
166 was measured by an AE-31 aethalometer (Gundel et al., 1983), during the 3-day campaign. The device is

167 equipped with 7-wavelengths (370, 470, 520, 590, 660, 880, 950 nm). It determines the attenuation
168 coefficient by using the light attenuation ratio through a sensing spot and a referenced clean spot, both on
169 a quartz fiber filter substrate. The sampling and reference spots surface areas are 0.5 cm^2 , while the
170 volumetric flow rate is 4 L min^{-1} . The flow rate was calibrated with a TetraCal (BGI Instruments)
171 volumetric airflow before and after the field campaign. A 5 minutes temporal resolution was used for data
172 acquisition. However, due to the low background concentration in the Arctic, the signal/noise ratio is
173 high, so that data were hourly averaged. The data presented in this study were processed according to
174 Segura et al. (2014) methodology. For this purpose the multiple scattering and filter loading effect
175 (Weingartner et al., 2003) was corrected with new values of mass absorption cross section (MAC) and
176 multiple scattering factor ($C=3.1$), reported by Zanatta et al. (2018). The MAC value was derived using
177 observations and observationally constrained Mie calculations in spring at the Zeppelin Arctic station
178 (Svalbard, 78°N). Zanatta et al. (2018) estimated the MAC at 550 nm ($9.8 \text{ m}^2 \text{ g}^{-1}$) and at 880 nm (6.95 m^2
179 g^{-1}), which we used to estimate MAC at 520 nm ($10.2 \text{ m}^2 \text{ g}^{-1}$).

180

181 **2.3.2 Particle Soot Absorption Photometer (PSAP)**

182 During the 85-days sampling period the aerosol absorption coefficient was also measured by
183 means of a 3-wavelengths PSAP (this instrument was not available during the 3-days experiment period).
184 It measures the variation of light transmission through a filter where particles are continuously deposited
185 with constant airflow. A second filter identical to the first one remains clean and is used as a reference to
186 take into account possible variations of the light source, i.e. a 3-color LED (blue, green and red with
187 wavelength centred around 470, 530 and 670 nm, respectively). The correction developed by Bond et al.
188 (1999) was applied to consider the filter loading effect. The complete eBC mass concentration time series
189 for the 85-days experiment was retrieved using the Aethalometer (first period) and the PSAP (second
190 period), with an overlapping period with simultaneous measurements of 5 days. For the retrieved eBC
191 mass concentration from the two instruments to be equal during the overlapping period, the PSAP eBC
192 was calculated dividing the absorption measurements (at 530 nm) with a MAC equal to $7.25 \text{ m}^2 \text{ g}^{-1}$
193 (keeping the AE31 data as reference). Daily averages were calculated from the 1-minute data to compare
194 with the rBC daily data obtained from the snow.

195

196 **2.4 Surface Snow measurements**

197 **2.4.1 Coarse Mode Particles Number Concentration**

198 The snow samples were melted at room temperature before the on-line coarse-mode particles and
199 conductivity measurements (the water was pumped from the vials by a 12 channels peristaltic pump,
200 ISMATECH, type ISM942). Specifically, the number concentration of coarse mode particles in the

201 surface snow was measured with a Klotz Abakus laser sensor particle counter. This instrument optically
202 counts the total number of particles and measures each particle's size in a liquid constantly flowing
203 through a laser beam cavity (LDS 23/23). The measurements size range of the instrument is from 0.8 to
204 about 80 μm with 32 dimensional bins (Table SI 1), not overlapping with that of the SP2. Only the 32nd
205 bin has a dimensional range above 15.5 μm , i.e. of 80 μm . The data were recorded by a LabView® based
206 software obtaining a sufficient number of data points in order to have a **standard deviation less than 5% of**
207 **the mean value**. The particles number concentration was calculated using the constant water flow value.

208

209 **2.4.2 rBC Measurement – SP2**

210 The rBC mass concentration and mass size distribution were measured following the methods
211 described in Lim et al. (2014). The snow samples were melted at room temperature prior to the analyses.
212 The vials with the melted snow were sonicated for ten minutes at room temperature. The samples were
213 nebulized before the injection in the Apex-Q desolvation system (APEX-Q, Elemental Scientific Inc.,
214 Omaha, USA). The nebulization efficiency was evaluated daily by injecting Aquadag® solutions with
215 different mass concentrations, ranging from 0.1 to 100 ng g^{-1} , obtaining an average value of 61%, that
216 was used to correct all the BC mass concentrations reported in this manuscript. More details on the
217 method can be found in Lim et al. (2014) and in Wendl et al. (2014).

218 The SP2 data were analyzed using the IGOR based toolkit from M. Gysel (Laboratory of
219 Atmospheric Chemistry, Paul Scherrer Institute, Switzerland). The large amount of signals derived from
220 every single particle are elaborated achieving rBC mass and number concentrations and size distributions.

221

222 **2.5 Meteorological Parameters**

223 Meteorological parameters, in addition to the atmospheric and snow ancillary measurements,
224 were used in the statistical exercise to study the variability of rBC mass concentration in surface snow
225 samples as a function of the atmospheric conditions. BC particles are deposited on the snowpack
226 following a combination of wet and dry deposition. However, once deposited on/in the snowpack other
227 processes can potentially induced a significant variability in the surface BC content. The wind direction
228 and its velocity can modify the BC distribution in the upper snowpack due to snow-mobilization. The
229 solar radiation and relative humidity may enhance snow sublimation and surface hoar formation thus
230 modifying the relative BC concentration in the upper snow layer by removing or adding “water” mass to
231 the snow surface.

232 Air temperature and relative humidity at 2 meter height have been retrieved from a meteorological station
233 located about 800 meters north of the sampling site, using a ventilated PT-100 thermo-couple by Thies
234 Clima and a HMT337 humicap sensor by Vaisala, respectively. Wind speed and direction at 10 meter

235 height were obtained from a Combined Wind Sensor Classic by Thies Clima (see Maturilli et al., 2013).
236 At about 50 m distance, the radiation measurements for the Baseline Surface Radiatio Network (BSRN)
237 provide among others the downward solar radiation detected by a Kipp&Zonen CMP22 pyranometer
238 (Maturilli et al., 2015). Both meteorological and surface radiation measurements are available in a 1-
239 minute time resolution via the PANGAEA data repository (Maturilli et al., 2020). The daily/hourly mean
240 values of the meteorological parameters were used in the statistical analyses of the 85-days/3-days
241 experiment and in **Figures 2 and 3** (the **physical**-chemical parameters from the snow samples are punctual
242 values).

243

244 **2.6 Parameters considered in the statistical analysis**

245 The **snowpack** evolution is primarily driven by meteorological parameters, which are responsible for
246 adding/removing mass to the annual **snowpack**. Wind can affect the snow pack evolution in several ways:
247 1) by snow redistribution, 2) favouring the ablation\sublimation, and 3) lifting particles from nearby
248 sources and areas. Surface snow and air temperatures are two fundamental parameters required to fully
249 understand the varying conditions of the snow pack. In our study, the temperature variables are proxies
250 for the melting episodes and for the presence of liquid water potentially affecting the concentration of
251 impurities. **The air and snow temperatures do not have a direct effect in the rBC concertation in surface**
252 **snow, but they are fundamental indicators to identify the spring warming events ($T > 0^{\circ}\text{C}$, called also the**
253 **Rain on Snow events - ROS) that yield the snow melting. Moreover, air and snow temperature could be**
254 **relevant to evaluate possible snow metamorphism and the response of the upper snowpack to the**
255 **meteorological conditions. Snow and air temperatures can be used during the 3-days experiment to**
256 **evaluate the daily scale frequency and be helpful to investigate the daily scale variability of rBC in the**
257 **surface snow.**

258 The **SWR** is not expected to be directly linked to the surface mass concentration of rBC, however the
259 surface process could affect it indirectly by favouring sublimation (water mass removal), as well as hoar
260 formation (water mass addition) during the colder parts of the day (night/early morning). The relative
261 humidity gives an idea of the amount of water present in the atmosphere and the high RH might favour
262 the deposition of BC suspended by the formation of water droplets through the cloud condensation nuclei.
263 **This parameter is especially significant for the selected sampling location, nearby to the shore. Indeed,**
264 **relative humidity values close or higher than 90% could be associated to fog or low cloud conditions and**
265 **not directly to wet or dry precipitations.** The last meteorological parameter considered is the precipitation
266 amount. **This aspect** is important to understand the wet deposition processes able to transfer BC particles
267 from the atmosphere to the snow surface.

268 The additional selected parameters are 1) the atmospheric eBC mass concentration, to investigate
269 the possible link between eBC particles present in the atmosphere and the rBC in snow surface, 2) the
270 coarse mode particles that could have a similar transport pathways to the black carbon and gives an idea
271 of the amount of total impurities deposition and 3) the total water conductivity, an indirect measurement
272 of the salinity content of the snow. It is important to note that the eBC and the rBC mass concentrations
273 are not the same physical quantities: the former is obtained from an absorption measurement assuming a
274 constant MAC, whereas the second is obtained via a laser-induced-incandescence method with an SP2
275 empirically calibrated with a reference material (Petzold et al., 2013). Considering the location of the
276 sampling site (<1 km from the coastline), the contribution of the ocean emissions to the snowpack
277 chemical composition is significant. We considered the total conductivity as an indication of sea spray
278 deposition, and to investigate common deposition patterns and/or similarities to the behaviour of BC
279 (although BC is not emitted from ocean surface). The conductivity was also considered to determine if
280 there was a large sea-spray aerosol event which could, potentially affecting the SP2 measurements (see
281 supplementary material).

282

283 2.7 Statistical Analysis

284 Multiple linear regression was carried out to evaluate the relationship between the observed
285 surface snow rBC mass concentration and the selected set of covariates consisting of the meteorological
286 and snow physical-chemical parameters that could have a direct effect on controlling snowpack dynamics
287 as well on the BC concentration as discussed in Section 2.6. All the atmospheric parameters described in
288 the previous section (wind, snow and air temperature, incoming solar radiation, relative humidity, and
289 snow precipitation amount) were initially considered as covariates to be included in the multiple linear
290 regression. However, wind speed and direction, as well as the atmospheric stability, expressed as vertical
291 wind speed, were removed because preliminary statistical analyses indicate that none of them is
292 associated with the observed variations in snow rBC mass concentrations. This does not mean that such
293 parameters do not play a role in controlling the BC concentration, but that no statistically significant
294 associations were found with the data collected in our study and thus these parameters were no longer
295 considered in the statistical analyses discussed below.

296 Multiple linear regression models were fitted on the logarithm scale because the distribution of rBC
297 concentrations in both experiments is characterized by a significant skewness. Coarse mode particles
298 number concentrations and conductivity were also log-transformed to linearize their relationships with
299 log(rBC). The regression model fitted on the two experiments is

300

$$\log(rBC) = \beta_0 + \beta_1 \log(dust) + \beta_2 eBC + \beta_3 temp + \beta_4 snow + \beta_5 swr + \beta_6 \log(cond) + \epsilon.$$

301
302 In the above model, ‘dust’ indicates coarse mode particles number concentrations, ‘temp’ is the snow
303 temperature at 7 cm depth for the 85-days experiment (daily resolution) and at 2 cm depth for the 3-days
304 experiment (hourly resolution), ‘snow’ is a binary indicator for the presence of solid precipitation, ‘swr’ is
305 solar incoming shortwave radiation, ‘cond’ is the conductivity and ε is a zero-mean normal error.
306 Graphical inspection of residuals plots and normal probability plots confirmed that after the logarithm
307 transformations, the regression models meet the assumptions of linearity, constant error variance (called
308 *homoscedasticity* in the statistical literature) and normal errors. The statistical analyses were performed
309 with the statistical language R (R Core Team, 2020).

310

311 **3. Results and Discussions**

312 **3.1 Seasonal BC variability in surface snow**

313 **3.1.1 Atmospheric eBC and atmospheric condition**

314 During the experimental period, the atmospheric eBC concentration ranged between from 80 ng m^{-3} to <
315 5 ng m^{-3} (Figure 2) with an average of $34 \pm 23 \text{ ng m}^{-3}$. The highest concentrations were measured at the
316 beginning of the campaign, especially from April 15th to 27th, followed by a general decreasing trend
317 characterized by the presence of several concentration peaks (on May 8th, 17th and 24th) potentially due to
318 Eurasian fires, as already suggested from Feltracco et al., 2020 (Figure S1). The ammonia daily
319 concentration time series (the only available biomass burning tracer for that period in the area) measured
320 at the Zeppelin station is plotted together with the Gruebadet atmospheric BC measurements in Figure
321 S3. Biomass burning is a significant source of atmospheric ammonia (Andreae and Merlet, 2001), often
322 affecting the Arctic region (Moroni et al. 2020). As shown in Figure S3, both time series have a similar
323 behaviour at the very beginning of the campaign, from April 3rd to 8th and during the period between May
324 7th and 21st. This suggests that the BC detected in the atmosphere could be originated from biomass
325 burning episodes during these two time periods. During the 85-days sampling period, wind was
326 characterized by the following median values (25th and 75th percentiles) for direction and speed: 205°
327 (152° , 257°) and 2.7 (1.9 , 3.7) m s^{-1} , respectively, therefore mostly coming from south-west (Figure 2).
328 Daily air temperature at 3 m increased during the campaign from -15°C to about $+5^\circ\text{C}$ (Figure 2)
329 following the seasonal variation of incoming solar energy: from 100 to 300 W m^{-2} with an average of 185
330 $\pm 75 \text{ W m}^{-2}$ (Figure 2, orange line). The snow precipitation episodes are presented as daily-accumulated
331 values (Figure 2, blue bars) ranging from zero to 12 cm.

332

333 **3.1.2 Surface Snow Conditions**

334 Over the 85 days experiment, the snow rBC mass concentration varies from 0.2 to 6 ng g⁻¹ (Figure 2),
335 with an average of 1.4 ± 1.3 ng g⁻¹, in agreement with results available in the literature (Mori et al., 2019;
336 Jacobi et al., 2019; Aamaas et al., 2011). An increasing trend can be observed for the rBC mass
337 concentration in the surface snow across the sampling period. The median of the rBC mass equivalent
338 diameter in the snow is 313 ± 35 nm (Figure 2), similar to what obtained in other studies (e.g. Schwarz et
339 al., 2013). The rBC mass equivalent diameter show high variability, ranging from 200 to 500 nm.
340 However, since the rBC concentrations were low, the evaluation of the **geometric mean of the** particles
341 diameter for the biggest sizes, above 300 to 400 nm, **has been considered** as qualitative information due to
342 the high signal noise.

343 **The number of coarse mode particles (Figure 2, blue line) shows a constant concentration in the first half**
344 **of the campaign (1st April - May 11th - average concentration of 3435±1824 # ml⁻¹) whereas it increases in**
345 **the second half (12th of May to 27th of June - average concentration of 7782±5683 # ml⁻¹), especially after**
346 **the 1st of June (1st of June to 27th of June - average concentration of 9352±6741 # ml⁻¹), in concomitance**
347 **with the onset of the snow melting period.** The conductivity (Figure 2, green line) **also** shows an
348 increasing trend at the end of the sampling campaign when snow is melting, with an overall average value
349 of 30 ± 8 μS. The spatial variability of **rBC**, calculated in the same manner as proposed by Spolaor et al.
350 (2019) for other species, was obtained from **six** surface snow samples collected in the four corners of the
351 sampling area and two **surface snow samples** in the centre right before the beginning of the experiment.
352 The following rBC mass concentrations were obtained: a) 3.95 ng g⁻¹; b) 4.92 ng g⁻¹ c) 4.20 ng g⁻¹ d) 3.10
353 ng g⁻¹ e) 3.82 ng g⁻¹ f) 3.58 ng g⁻¹, resulting in a rBC spatial variability of 16% in the surface snow **of** the
354 considered sampling area.

355

356 **3.1.3 Statistical Results**

357 **The fitted multiple linear regression model for the 85-days experiment data explains the 69% of**
358 **the variance of the logarithm of the snow rBC mass concentration ($R^2 = 0.69$). The fitted model indicates**
359 **the presence of strongly statistically significant associations of the (log transformed) snow rBC mass**
360 **concentration with the coarse-mode particles number concentration ($p < 0.001$) and the snow temperature**
361 **($p < 0.001$). A weaker association is found with the occurrence of snow precipitations ($p = 0.03$). The**
362 **statistical associations of rBC mass concentration with the other covariates considered in the model are**
363 **non-significant. See Table 1 for the estimated coefficients and the corresponding p-values.**

364 **In order to interpret the statistical results, the description of the 85-days campaign is split into two periods**
365 **identified as the transition from the “cold” to the “melting” state. The first period occurred before the end**
366 **of May: the rBC mass concentration often increases with snowfall episodes (April 9th/10th/11th and 17th,**

367 May 17th, 22nd and 27th/28th; June 1st) as suggested by previous studies, with exceptions for April 24th and
368 May 7th. Over the sampling period, a weakly statistically significant positive association ($p = 0.03$) was
369 found between snow rBC mass concentration in surface snow **and the occurrence of snow precipitations**.
370 BC wet deposition processes are estimated to remove 50% - 60% of the total atmospheric BC burden in
371 the Arctic (Liu et al., 2011; Jacobi et al., 2019). In our study, the wet deposition impacts could be partially
372 masked due to the sampling frequency and the wind snow. In Kongsfjord, a strong wind is often present
373 **during the precipitation events** (Figure 2). Consequently, the freshly deposited snow is frequently
374 removed from the surface before being able to sample it. Interestingly, our observations show that, on a
375 daily scale, the precipitation episodes are not clearly related to a decrease in the atmospheric eBC mass
376 concentration (Figure 2). A possible explanation is that the precipitation amounts were small so that the
377 precipitation events did not significantly alter the atmospheric BC reservoir.

378 In the second period, from the beginning of June, the atmospheric temperature increases, causing the
379 snow-melting season's onset. At the beginning of June, the snow rBC mass concentration increases up to
380 approximately 5 ng g^{-1} , and a simultaneous increase was detected in the coarse mode particles number
381 concentration (peaks between June 4th and 7th). As suggested in previous studies, the surface melting
382 process could explain the observed increase in **rBC** and **coarse mode** particles concentrations. **However,**
383 **we also have to consider that rBC can be dry deposited, as it has been recently suggested (up to 50-60%;**
384 **Liu et al., 2011; Jacobi et al., 2019).** Very few field validation data exist for estimating the amount of dry
385 **deposition** at the snow surface, and this process is often used as an ancillary information since most
386 models underestimate the BC in the Arctic snowpack compared to field measurements.

387 Our data support the hypothesis related to local sources' activation in enhancing the dry deposition
388 impacts in an old mining town as Ny-Alesund. Especially during poor snow cover conditions, as during
389 the snow-melting season, **coarse mode** particles as residuals of carbon extraction mining activities are
390 available for wind lift\suspension (**Vecchiato et al. 2018**). The possible effect of local sources' activation
391 is further supported by a recent analysis of the Brøggerbreen glacier and Ny-Ålesund annual **snowpack**.
392 This analysis shows the presence of retene (an organic compound frequently used to track the presence of
393 coal), most likely due to local sources (Vecchiato et al., 2018).

394 The simultaneous increase of rBC mass and coarse mode particle number concentrations during the
395 second part of the experiment (e.g. visible between June 3rd and **June 7th-8th**) could be explained via
396 similar post-depositional processes: snow melting and sublimation. The episodes of snow surface melting
397 can significantly affect the snow particulate content and we hypothesize that the hydrophobicity of pure
398 BC particles, and of several species in the coarse mode particles, might affect its physical location in the

399 snowpack (in the literature, the response of the BC particles is still debated): the hydrophobicity of the
400 particles can cause the surface concentration to increase while losing water mass through percolation.
401 This could lead into a positive feedback process: the increase of BC concentration can thus enhance snow
402 sublimation (water evaporation) resulting in a further increase of BC concentration in surface snow, and
403 so on.

404 In this study, the estimated statistical association between snow rBC mass concentration and the daily
405 snow temperature is negative and strongly significant ($p < 0.001$). During the 85-days experiment, we can
406 distinguish two events where the temperature appeared to play a role in the BC concentration. Both of
407 them show an increase in rBC mass concentration during melting/refreezing episodes, in agreement with
408 other studies (Aamaas et al., 2011; Xu et al., 2006; Doherty et al., 2013; Doherty et al. 2016). The first
409 event occurred between May 5th to May 12th and the second event after May 20th, when the proper snow
410 melting began (Figure 2). The first event was characterized by a rapid rise of the daily air temperature
411 (from -6°C to -1°C) in concomitance to a snow precipitation event, followed by a rapid temperature
412 decrease to -6°C . The surface snow (10 cm) mirrored this behaviour, first rising from -6°C to 0°C , and
413 then cooling down to -6°C . During this warm event, the upper snow strata underwent a melting episode
414 with surface water percolation (although limited), making the surface BC concentration to increase. The
415 second event started approximately on May 20th and lasted until the end of the experiment (Figure 2).
416 During this period, the atmospheric temperature increased constantly, and the snowpack started to melt
417 consequently. Moreover, surface BC concentration increased almost continuously from May 25th to its
418 maximum observed on June 6th. Afterward, the upper snow rBC mass concentration tended to decrease
419 following the rapid snowpack decline.

420

421 **3.2 Diurnal variation of rBC in surface snow**

422 **3.2.1 Surface Snow/Atmospheric Aerosol Content and Atmospheric Conditions**

423 The 3-days experiment was performed at the end of April 2015, during the Arctic spring. The
424 samples were collected on an hourly basis over 3 days achieving a high-resolution sampling frequency.
425 The atmospheric concentration of eBC ranged from 2 to 50 ng m^{-3} , decreasing during the sampling period
426 and not showing any particular diurnal pattern (Figure 3). The mean value of the atmospheric eBC mass
427 concentration is $34 \pm 23\text{ ng m}^{-3}$, similar to the average of the 85-days experiment.

428 The surface snow rBC mass concentration undergoes to daily time scale change of surface
429 concentration showing up to 2-fold hourly increases (Figure 3, bottom panel, smoothed dark blue line).
430 rBC mass concentrations of approximately 15 ng g^{-1} were measured in the snow samples from the
431 beginning of the sampling to the end of the second day. Later, from the beginning of the third day until

432 the end of experiment, rBC mass concentrations show an average concentration of about 5 ng g^{-1} (Figure
433 3). The average value over the whole sampling period is $9 \pm 5 \text{ ng g}^{-1}$ (approximately 6 times higher than
434 during the 85-days experiment). The rBC mass size distribution was characterized by a **median value of**
435 **the geometric means** of about $230 \pm 32 \text{ nm}$, significantly lower than that which was measured during the
436 85-days, and still in agreement with previous studies (Sinha et al., 2018; Schwarz et al., 2013). The
437 concentrations of EC and OC measured in parallel snow samples (not of the same volume) are reported
438 and described in Figure S4; the interpretation of the differences between the rBC and the EC
439 measurements in snow samples was beyond this manuscript's objectives.

440 The number concentration of coarse mode particles remains stable in the first half of the
441 experiment, until the end of April, and shows an average value over the three days of $26642 \pm 9261 \text{ # mL}^{-1}$
442 ³. The water conductivity shows a similar behaviour, and it is characterized by an average of $39 \pm 9 \text{ }\mu\text{S}$
443 (30% higher than during the 85-days experiment).

444 **All the measured snow impurities show** two common features (see supplementary material and
445 **Figure S4**): first, a decrease in the absolute values detected between 4 and 8 a.m. of April 30th, despite the
446 absence of precipitations **or any other particular** meteorological episode (Figure 3); second, the impact of
447 the snow precipitation event from approximately 4 p.m. to midnight of the April 30th, where the
448 concentrations of aerosols in the snow slightly increased at the very beginning whereas decreasing at the
449 end of the event. Only the BC core diameter remained above the average when the other aerosol snow
450 content decreased (up to approximately 400 nm of mass equivalent diameter), consequently returning to
451 the average value. The spatial variability of BC, calculated as proposed by Spolaor et al. (2019) for other
452 species, was obtained by the analysis of 5 surface snow samples, collected in the four corners of the
453 sampling area and one in the centre obtaining the following concentrations: a) 10.17 ng g^{-1} , b) 10.64 ng g^{-1} ,
454 c) 7.04 ng g^{-1} , d) 11.98 ng g^{-1} , and e) 11.91 ng g^{-1} , thus resulting in a spatial variability of 19%. Clear
455 sky conditions were observed for the duration of the sampling period except for the snowfall occurred at
456 the end of the third day.

457

458 **3.2.2 Statistical Results**

459 **The multiple linear regression model for the 3-days experiment explains the 78% of the snow**
460 **rBC mass concentration variance, a percentage higher than the 85-days experiment, likely due to the more**
461 **stable atmospheric conditions and the greater interaction with the atmosphere of the upper 3 cm of the**
462 **snow pack compared with the depth resolution used during the seasonal experiment. Similar for the 85-**
463 **days experiment we evaluate (Figure S4) the 10 days back-trajectory during the 3 days of the experiment.**
464 The result suggests that the air mass arriving in Ny-Ålesund during the experiment were mainly
465 originated from the Arctic Ocean.

466 The fitted multiple linear regression model indicates a statistically significant association between
467 the logarithm of the rBC mass concentration in the snow and the logarithm of the conductivity ($p <$
468 0.001), the logarithm of the number concentration of coarse-mode particles ($p < 0.001$) and the
469 occurrence of snow precipitations ($p < 0.001$). The estimated coefficients of the covariates are reported in
470 Table 1. In Figure 4 are displayed the 95% and 90% confidence intervals for the estimated coefficients of
471 regression models fitted to two experiments (85-days and the 3-days). Since the covariates considered in
472 the two experiments have quite different unit scales, Figure 4 shows the confidence intervals for the
473 standardized covariates. The standardization simplifies the comparison among the estimated effects of the
474 different covariates and between the two experiments, in this way allowing a visual comparison of the
475 estimated statistical associations between the logarithm of the snow rBC mass concentration and the
476 considered parameters.

477 The association between the logarithm of the coarse-mode particles number concentration and the
478 logarithm of the snow rBC mass concentration is positive and strongly significant ($p < 0.001$), similarly to
479 what observed for the 85-days experiment, confirming the similar behaviour of these types of particles
480 also in the surface snow pack (3 cm). The association between the logarithm of conductivity and the
481 logarithm of the snow rBC mass concentration is positive and strongly significant ($p < 0.001$). Snow
482 conductivity is mostly influenced by the presence of sea salt ions (mainly coming from sea spray aerosol
483 considering the location of the experimental site) in the snow samples. Sea spray aerosol is not considered
484 a source of rBC and a direct effect of the sea spray emission on the rBC snow concentration is here
485 consider negligible. However the positive association between rBC and conductivity can be explained by
486 the fact that both sea spray aerosol and BC particles (as well dust) undergoes to similar dry deposition
487 process (when concentration increase) favoured by the stable atmospheric condition occurred during the
488 experiment (with the exception of the snow event during the third day) as well from similar physical
489 removal process (concentration decrease) from the snow surface. Considering we are exploring the rBC
490 concentration change in the upper 3 cm, we explore the possible existence of a daily cycle. The BC
491 particles are known to be non-volatile and not photo-chemically active, therefore the decrease/increase in
492 their concentration observed during the experiment can only be driven by physical process such as wind
493 erosion and snow deposition. However and additional process that might drive the rBC concentration
494 change in the upper snow pack is the condensation of water vapour on the top of the snow crystals and the
495 formation of surface hoar as well the sublimation. The formation of surface hoar has the effect to adding
496 “water” mass without BC particles in the snow surface causing a relative rBC dilution, while sublimation
497 has the effect remove “water” mass causing a relative concentration increase. Surface hoar and
498 sublimation are depending mainly by the temperature and solar radiation, two parameters that exhibits the
499 diurnal cycle (Figure 4). From the statistical analysis no associations were found on rBC with the

500 incoming solar radiation (at hour resolution) and the snow temperature during the sampling period. These
501 results indicate that the rBC mass concentration in the surface snow does not undergo to diurnal changes
502 and this process are negligible in controlling the rBC snow surface concentration.

503 The occurrence of snow precipitations is negatively associated with the logarithm of the rBC
504 mass concentration in the snow ($p < 0.001$). As previously remarked, the aerosol scavenging intensity is
505 not measurable with snow sampling strategies based on the sampling of a constant snow thickness from
506 the surface (3 cm in this case). We tentatively explain the negative relation observed in this study with the
507 high frequency sampling, being able to follow the evolution of the BC particles scavenged during a snow
508 episode (from 3 to 12 p.m. of the 30th April 2015). The beginning of the precipitation episodes appeared
509 to remove the highest amount of BC particles, leaving the atmosphere cleaner as reflected by the lower
510 BC mass concentration revealed in subsequent samples. The snow collected at 18:00 of April 30 showed
511 a higher amount of rBC as well as the highest coarse mode particles number concentration and
512 conductivity. In the next few hours, from 9 to 12 p.m., the snow precipitations were depleted in terms of
513 aerosol content and rBC mass concentration.

514

515 **4. Conclusions and Future Perspectives**

516 The seasonal and daily experiments (85- and 3-days long, respectively) suggest that the rBC
517 concentration in the upper snow layer is not only driven by a cumulative process, as it happens when the
518 entire annual snow pack is evaluated, but it is a rather more complex process involving atmospheric,
519 meteorological and snowpack conditions. Our results based on a multiple linear regression models
520 suggest that the amount of BC in the surface snow is not associated to the BC atmospheric load. This
521 finding suggests that, despite the potentially high atmospheric BC concentrations (as in the case of long-
522 range transport of biomass burning plumes), this parameter does not seem to be the primary driver of the
523 variations in the surface snow rBC over the experiment periods. In both experiments, the coarse mode
524 particles are positively associated with the snow BC mass concentration, suggesting that the BC and
525 coarse mode particles deposition undergo similar deposition and, in case, to post-depositional processes in
526 the upper snowpack. Specifically, before the beginning of the melting season, the wet deposition episodes
527 appeared to have major impacts, whereas the activation of common local sources favour the wind
528 suspension from uncovered areas enhancing the intensity of dry deposition processes, might lead to an
529 accelerated snow melting.

530 Our results also suggest that in order to explain the observed BC mass concentration variability
531 during seasonal and diurnal time ranges other processes than wet and dry depositions should be
532 considered. Surface melting episodes enrich the BC content in the surface layer not because of an
533 enhanced deposition but mainly because of water mass loss. In particular, the snow mass loss is stronger

534 during the snow-melting season, where an increase in the rBC concentration could significantly alter the
535 snow albedo and further enhance the radiative absorption, hence promoting a positive feedback. **The**
536 **proposed processes and the rBC concentration determined in Ny-Ålesund could be influenced by local**
537 **emission in particular at the beginning and at the end of the snow season when the snowpack does not cover**
538 **homogeneously the surface. However, the process described by our results could occur in other Arctic**
539 **sites although with different magnitudes and impacts.**

540 **The remarkable diurnal and daily variability, as well as the complex interdependent mechanisms**
541 **affecting the rBC mass concentration in the Arctic surface** snow, makes the results of albedo-based
542 radiative impact model of the active layer a potential source of erroneous conclusions: the impacts of long
543 distance biomass burning episodes might be overestimated, whereas the impact of local sources and dry
544 deposited impurities during the melting season **might be underestimated. Additional empirical** studies are
545 therefore necessary in order to improve our understanding of the involved physical mechanisms and to
546 better constrain modelling studies.

547

548 **Acknowledgements**

549 This work was part of the PhD (in “Science and Management of Climate Change”) of Michele Bertò at
550 the Ca’ Foscari University of Venice that was partly funded with the Early Human Impact ERC project.
551 Thanks to Giuseppe Pellegrino for helping collecting the samples. Thanks to Jacopo Gabrieli and the
552 technicians of the Ca’Foscari University of Venice for the precious help in building up the **coarse mode**
553 **particles** and conductivity measurement apparatus. We acknowledge the use of data and imagery from
554 LANCE FIRMS operated by the NASA/GSFC/Earth Science Data and Information System (ESDIS) with
555 funding provided by NASA/HQ. We want to thank Paolo Laj and the LGGE (Grenoble, France) for
556 lending us the SP2 and Marco Zanatta for transferring the SP2 know-how on instrumental functioning and
557 data analyses. Thanks to Martin Gysel-Beer, PSI, for the IGOR based SP2 Toolkit for SP2 data analyses.
558 We thank Marion Maturilli and AWI for providing us with the meteorological data. Thanks to Giorgio
559 Bertò for checking and correcting the language of this manuscript. This paper is an output of the AMIS
560 project in the framework of “Project MIUR – Dipartimenti di Eccellenza 2018-2022”. This project has
561 received funding from the European Union's Horizon 2020 research and innovation programme under
562 grant agreement No 689443 via project iCUPE (Integrative and Comprehensive Understanding on Polar
563 Environments).

565

566

567 **Data Availability**

568 **Meteorological** and surface radiation data are available at the PANGAEA database (Maturilli, 2015a;
569 2015b; 2015c; 2016a; 2016b; 2018a; 2018b; 2018c; 2018d; 2018e). The data for precipitation amount at
570 Ny-Ålesund can be accessed via the eKlima database of MET Norway. The BC data are available upon
571 request.

572

573 **Author Contributions**

574 Author contributions. AS, EB, DC and MB conceived the experiments; AS, EB, DC, and LP collected the
575 samples; MB measured the samples; KM and MMaz provided the atmospheric eBC concentrations; SC
576 and DC provided the back-trajectories analyses; CV performed the statistical analyses with inputs from
577 MB and AS. MB prepared the manuscript mainly with inputs from AS, J-C. G and DC (in the methods
578 section from AS, KM, MMaz) and all co-authors contributed to the interpretation of the results as well as
579 manuscript review and editing.

632

633 **Figure 4.** Estimated coefficients of the standardized covariates of the multiple linear regression models
634 fitted to the 3 days and 85 days experiments. The segments correspond to 95% confidence intervals about
635 the corresponding estimated coefficients. The internal thicker segments correspond to 90% confidence
636 intervals. Intervals, that do not include the zero, correspond to statistically significant covariates. If a
637 confidence interval consists of positive values, then there is a significant positive association between the
638 corresponding covariate and the logarithm of the snow rBC mass concentration given the remaining
639 covariates. Vice versa, if the confidence interval consists of negative values, then the association is
640 negative. The abbreviations used in the plot are: “log(cond)” – logarithm of the water conductivity time
641 series, “log(dust)” – logarithm of the coarse mode particles number concentration time series, “eBC” –
642 equivalent black carbon atmospheric concentration, “snow” – presence of snow precipitation episodes,
643 “swr” – short wave radiation, “temp” – the snow temperature. The plot is produced with the R package (R
644 Core Team, 2020) jtools (Long, 2020).
