10

11 **Abstract.** Over the eastern north Atlantic (ENA) ocean, a total of 20 non-precipitating single-layer
12 marine boundary layer (MBL) stratus and stratocumulus cloud cases are selected in order to investigate
13 the impacts of the environmental variables on the aerosol-cloud interaction (ACI_r) using the ground-
14 based measurements from the Department of Energy Atmospheric Radiation Measurement (ARM)
15 facility at the ENA site during the period 2016 – 2018. The ACI_r represents the relative change of cloud-
16 droplet effective radius r_e with respect to the relative change of cloud condensation nuclei (CCN) number
17 concentration at 0.2% supersaturation ($N_{CCN,0.2\%}$) in the water vapor stratified environment. The ACI_r
18 values vary from -0.004 to 0.207 with increasing precipitable water vapor (PWV) conditions, indicating
19 that r_e is more sensitive to the CCN loading under sufficient water vapor supply, owing to the combined
20 effect of enhanced condensational growth and coalescence processes associated with higher N_c and PWV.
21 The environmental effects on ACI_r are examined by stratifying the data into different lower tropospheric
22 stability (LTS) and vertical component of turbulence kinetic energy (TKE_w) regimes. The higher LTS
23 normally associates with a more adiabatic cloud layer and a lower boundary layer and thus results in
24 higher CCN to cloud droplet conversion and ACI_r . The ACI_r values under a range of PWV double from
25 low TKE_w to high TKE_w regime, indicating a strong impact of turbulence on the ACI_r . The stronger
26 boundary layer turbulence represented by higher TKE_w strengthens the connection and interaction
27 between cloud microphysical properties and the underneath CCN and moisture sources. With sufficient
28 water vapor and low CCN loading, the active coalescence process broadens the cloud droplet size
29 distribution spectra, and consequently results in an enlargement of r_e . The enhanced N_c conversion and
30 condensational growth induced by more intrusions of CCN effectively decrease r_e , which jointly presents
31 as the increased ACI_r . The TKE_w median value of $0.08 \text{ m}^2\text{s}^{-2}$ suggests a feasible way in distinguishing
32 the turbulence-enhanced aerosol-cloud interaction in non-precipitating MBL clouds.

33

34 1. Introduction

35 Clouds are one of the most important parts of the Earth's climate system. They can impact the global
36 climate by modulating the radiative balance in the atmosphere. Moreover, the radiative effects of cloud
37 adjustments due to aerosols remain as one of the largest uncertainties in climate modeling (IPCC, 2013).
38 Over the oceanic area, the lower troposphere is dominated by marine boundary layer (MBL) clouds.
39 MBL clouds can persistently reflect the solar radiation by their long-lasting nature maintained by cloud-
40 top radiative cooling, and therefore act as a major modulator of Earth radiative budget (Seinfeld et al.,
41 2016). The climatic importance of the MBL cloud radiative properties is primarily induced by the cloud
42 microphysical properties, namely the cloud-droplet number concentration (N_C) and effective radius (r_e),
43 has been intensively investigated by many researchers (Rosenfeld, 2007; Wood et al., 2015; Seinfeld et
44 al., 2016). These cloud microphysical properties can be influenced by the ambient aerosol conditions via
45 the aerosol-cloud interaction (ACI), where clouds under regions that have relatively higher below-cloud
46 aerosol concentrations exhibited reduced r_e , increased N_C , and enhanced both cloud liquid water contents
47 and optical depths than the clouds under relatively clean regions (McComiskey et al., 2009; Chen et al.,
48 2014). The MBL cloud microphysical properties changes induced by aerosols have been investigated
49 from previous studies using in-situ measurements, ground- and satellite-based observations, and model
50 simulations in multiple oceanic areas such as the eastern Pacific and eastern Atlantic (Twohy et al., 2005;
51 Lu et al., 2007; Hill et al., 2009; Costantino and Bréon, 2010; Mann et al., 2014; Dong et al., 2015;
52 Diamond et al., 2018; Wang et al., 2020).

53 The assessments of ACI, in particular using ground-based remote sensing, are found to vary in terms
54 of the quantitative values, which represent the different cloud susceptibilities to aerosol loadings. Owing
55 to the numerous approaches in assessing the ACI, such as the spatial and temporal scales, N_C and r_e
56 retrieval methods, and more importantly, the different aerosol proxies that used in the ACI quantification,
57 different ACI results could be achieved. For example, the studies using total aerosol number
58 concentration and aerosol scattering/extinction coefficients to represent the aerosol loadings would result
59 in relatively lower ACI values (Pandithurai et al., 2009; Liu et al., 2016). This is primarily attributed to
60 the inclusion of aerosol species with different abilities to activate, which is determined by their
61 physicochemical properties, and thus will cause non-negligible uncertainties in capturing the information
62 of aerosol intrusion to the cloud (Feingold et al. 2006; Logan et al., 2014). While some studies found
63 relatively higher ACI values using cloud condensation nuclei (CCN) number concentration (N_{CCN}),
64 presumably due to the fact that CCN represents the portion of aerosols that can be activated and possesses
65 the potential ability to further grow into cloud droplets, this favorably yields a more straightforward

66 assessment of ACI (McComiskey et al., 2009; Zheng et al., 2020). It is noteworthy that the ACI variations
67 have been found to have both increasing and decreasing trends in response to changing environmental
68 water availability (Martin et al., 2004; Kim et al., 2008; McComiskey et al., 2009; Pandithurai et al.,
69 2009; Martin et al., 2011; Liu et al., 2016; Zheng et al., 2020). Although these contradicting results have
70 been postulated due to multiple factors such as cloud adiabaticity, condensational growth, collision
71 coalescence, and atmospheric thermodynamics and dynamics, the underlying mechanisms in altering the
72 ACI and causing the uncertainties in the ACI assessments remain unclear, therefore, further studies are
73 necessary (Fan et al., 2016; Feingold and McComiskey, 2016; Seinfeld et al., 2016).

74 In terms of the aerosol influence on the cloud properties, the roles of meteorological factors on cloud
75 formation and development are not negligible and hence are being explored in this study. The large-scale
76 thermodynamic variables of the lower troposphere are widely used, such as the lower tropospheric
77 stability (LTS), where the higher LTS values are found to be associated with a relatively shallower and
78 well-mixed marine boundary layer, and is prone to stratiform cloud formations with higher cloud
79 fractions (Wood and Bretherton, 2006; Yue et al., 2011; Rosenfeld et al., 2019). In the cloud-topped
80 marine boundary layer maintained by cloud-top radiative cooling, the buoyancy generations contribute
81 most to the turbulence kinetic energy (TKE) production (Nicholls, 1984; Hogan et al., 2009), where the
82 intensity of turbulence denotes the coupling of MBL clouds to the below-cloud boundary layer. In terms
83 of the cloud droplet growing process, especially in a clean environment with low below-cloud N_{CCN} , the
84 cloud droplets at the cloud base experience rapid growth via the diffusion of water vapor, and
85 subsequently enter the regime of active coalescence process (Rosenfeld and Woodley, 2003; Martins et
86 al., 2011). The intensive turbulence is effectively modulating the cloud droplet growth by strengthening
87 the coalescence process and the cloud cycling (Feingold et al., 1996, 1999; Pawlowska et al., 2006). The
88 environmental effects on the MBL cloud formation and development processes and cloud microphysical
89 properties have been widely implemented and considered in climate modeling (Medeiros and Stevens,
90 2011; West et al., 2014; Zhang et al., 2016). Thus, it is important to provide observational constraints on
91 the environmental effects. The assessment of ACI from the ground-based perspective highly relies on
92 the sensitivities of cloud droplet number concentrations and size distribution spectra to the changing of
93 below-cloud CCN loadings. Hence, it is a nontrivial task to study the relationship between the
94 environmental effect and the MBL cloud microphysical responses.

95 The Eastern North Atlantic (ENA) is a remote oceanic region that features persistent but diverse
96 subtropical MBL clouds, owing to complex meteorological influences from the semi-permanent Azores
97 High and prevailing large-scale subsidence (Wood et al., 2015). The ENA has become a favorable region
98 to study the aerosol indirect effects on MBL clouds under a relatively clean environment with occasional

99 intrusions of long-range transport of continental air mass (Logan et al., 2014; Wang et al., 2020). The
100 atmospheric radiation measurement (ARM) program established the ENA permanent observatory site on
101 the northern edge of Graciosa Island, Azores, in 2013, which continuously provides comprehensive
102 measurements of the atmosphere, radiation, cloud, and aerosol from ground-based observation
103 instruments. In this study, we target the non-precipitating single-layer MBL stratus and stratocumulus
104 clouds during the period between September 2016 and May 2018 and examine the role of
105 thermodynamical and dynamical variables on ACIs. This study aims to enhance the understanding of
106 ACI, particularly disentangling the environmental effect and reducing the uncertainty in quantifying the
107 ACI when modeling aerosol influences on MBL clouds. The ground-based observations and retrievals,
108 and the reanalysis are introduced in section 2. Section 3 describes the aerosol, cloud and meteorological
109 properties, and the variations of cloud microphysical properties under different environmental regimes.
110 Moreover, the ACIs under given water vapor conditions and the roles of environmental effect on ACI
111 are discussed in Section 3. The conclusion of the key findings and the future work are presented in section
112 4.

113

114 **2. Data and methods**

115 **2.1 Cloud and aerosol properties**

116 The cloud boundaries at the ARM ENA site are primarily determined by the ARM Active Remotely-
117 Sensed Cloud Locations (ARSCL) product, which is a combination of data detected by multiple active
118 remote-sensing instruments, including the Ka-band ARM Zenith Radar (KAZR) and laser ceilometer.
119 The KAZR has an operating frequency at 35 GHz and is sensitive in cloud detection with very minimum
120 attenuation up to the cloud top height (Widener et al., 2012). The temporal and vertical resolutions of
121 KAZR reflectivity are 4 seconds and 30 m, respectively. The ceilometer operates at 910 nm laser beam
122 and its attenuated backscatter data can be converted to the cloud base height up to 7.7 km with an
123 uncertainty of ~10 m (Morris, 2016). Combining both KAZR and ceilometer measurements, the cloud base
124 and top heights can be identified accordingly. The single-layer low cloud is defined as having a cloud
125 top height lower than 3 km, with no additional cloud layer in the atmosphere above (Xi et al., 2010).

126 The cloud microphysical properties are retrieved from a combination of ground-based observations,
127 including KAZR, ceilometer, and microwave radiometer. The detailed retrieval methods and procedures
128 are described in Wu et al. (2020a). The retrieved cloud microphysical properties, both in time series and
129 vertical profiles, have been validated using the collocated aircraft in-situ measurements during the
130 Aerosol and Cloud Experiments in the Eastern North Atlantic field campaign (ACE-ENA). The retrieval

131 uncertainties are estimated to be ~15% for cloud droplet effective radius (r_e) and ~35% for cloud droplet
132 number concentration (N_c) (Wu et al., 2020a).

133 The surface cloud condensation nuclei (CCN) number concentrations (N_{CCN}) are measured by the
134 CCN-100 (single-column) counter. Since the supersaturation (SS) levels are set to cycling between 0.10%
135 and 1.10% approximately within one hour, N_{CCN} under a relatively stable supersaturation level has to be
136 carefully calculated to rule out the impact of supersaturation on N_{CCN} . This study adopts the interpolation
137 method given by $N_{CCN} = cSS^k$ (Twomey, 1959), where parameters c and k are fitted by a power-law
138 function for every periodic cycle. In this study, the supersaturation level of 0.2% is used because it
139 represents typical supersaturation conditions of boundary-layer stratiform clouds (Hudson and Noble,
140 2013; Logan et al., 2014; Wood et al., 2015; Siebert et al., 2021), and N_{CCN} at 0.2% supersaturation
141 (hereafter $N_{CCN,0.2\%}$) is interpolated to 5-min temporal resolution.

142 2.2 Environmental conditions and cloud case selections

143 The integrated precipitable water vapor (PWV) is obtained from a 3-channel microwave radiometer
144 (MWR3C), which operates at three frequency channels of 23.834, 30, and 89 GHz. The uncertainty of
145 PWV is estimated to be ~0.03 cm (Cadeddu et al., 2013). The LTS parameter is used as a proxy of large-
146 scale thermodynamic structure and is defined as the difference between the potential temperature at 700
147 hPa and surface ($\theta_{700} - \theta_{sfc}$). The LTS values are calculated from European Centre for Medium-Range
148 Weather Forecasts (ECMWF) model outputs of potential temperature, by averaging over a grid box of
149 $0.56^\circ \times 0.56^\circ$ centered at the ENA site. To match the temporal resolutions of the other variables, the
150 original 1-hour LTS data are downsampled to 5-min under the assumption that the large-scale forcing
151 would not have significant changes within an hour.

152 As for the boundary layer dynamics, the higher-order moments of vertical velocity are widely used
153 in different model parameterization practices, such as higher-order turbulence closure and probability
154 density function methods (Lappen and Randall, 2001; Zhu and Zuidema, 2009; Ghate et al., 2010). The
155 vertical velocity variance can be used to represent the turbulence intensity in the below-cloud boundary
156 layer (Feingold et al., 1999). In this study, the mean vertical component of the turbulence kinetic energy
157 (TKE_w) are used, which is defined as:

$$158 \quad TKE_w = \frac{1}{2} \overline{(w')^2}, \quad (1)$$

159 where the $(w')^2$ is the variance of vertical velocity measured from Doppler lidar with the noise
160 correction applied to reduce the uncertainty to ~10% (Hogan et al., 2009; Pearson et al., 2009). The
161 original Doppler lidar vertical velocity has a temporal resolution of 10-min (Newson et al., 2019), and it
162 is further downsampled to 5-min for the temporal collocation purpose.

163 In this study, the non-precipitating cloud periods are determined when the KAZR reflectivity at the
164 ceilometer-detected cloud base height range does not exceed -37 dBZ (Wu et al., 2015, 2020b), which
165 extensively rules out the wet-scavenging depletion on below-cloud CCN (Wood, 2006) and ensures the
166 accuracy in capturing the below-cloud CCN loadings. Both retrieved cloud microphysical properties and
167 CCN data are available from September 2016 to May 2018 and confine this period in this study.

168

169 3. Result and Discussion

170 3.1 Aerosol, cloud, and meteorological properties of selected cloud cases

171 A total of 20 non-precipitating cloud cases are selected to conduct this study, with the detailed time
172 periods listed in Table 1, including 1143 samples in temporal resolution of 5-min, which corresponds to
173 ~95 hours. Among the selected cases, there are three, eight, five, and four cases for Spring, Summer,
174 Fall, and Winter seasons, respectively. MBL clouds often produce precipitation in the form of drizzle
175 (Wood 2012, Wu et al., 2015, 2020b). A recent study of the seasonal variation of the drizzling frequencies
176 (Wu et al., 2020b) showed that the MBL clouds in cold months (Oct-Mar) have the highest drizzling
177 frequency of the year (~70%), while the clouds in warm months (Apr-Sept) are found to have a lower
178 chance of drizzling (~45%). Therefore, the selection of a non-precipitating single-layer low cloud case
179 that lasts at least 2 hours is limited, with only 6 cases found in the cold months and 14 cases found during
180 the warm months.

181 The distributions of the aerosol and cloud properties, and the environmental conditions for the
182 selected cases are shown in Fig. 1. The $N_{CCN,0.2\%}$ presents a normal distribution with a mean value of
183 215 cm^{-3} and median value of 217 cm^{-3} . About 97% of the $N_{CCN,0.2\%}$ samples lay below 350 cm^{-3} and
184 represents a relatively clean environment (Logan et al., 2014, 2018). A few instances of aerosol
185 intrusions (~3%) with higher $N_{CCN,0.2\%}$ were likely a result of continental air mass transport from North
186 America (Logan et al., 2014; Wang et al., 2020). As for the cloud microphysical properties, the cloud-
187 layer mean N_c and r_e (Fig. 1b and 1c) are also both normally distributed with median values close to the
188 mean values. The majority of the N_c values (~91%) are lower than 125 cm^{-3} with a mean value of
189 86 cm^{-3} , and the r_e distribution peaks at 9 - 11 μm with a mean value of 10.1 μm . Both N_c and r_e values
190 fall in the typical ranges of the non-precipitating MBL cloud characteristics over the ENA site (Dong et
191 al., 2014; Wu et al., 2020b).

192 For all selected cases, the LTS, which represents the large-scale thermodynamic structure, is
193 distributed bimodally across the range from 14K to 23K with mean and median values of 19.1K in Fig.
194 1d. A higher LTS magnitude represents a relatively stable environment and is favorable to the formation

195 of marine stratocumulus (Medeiros and Stevens, 2011; Gryspeerd et al., 2016). Leveraging the
196 demarcation line at 19.1K may provide an opportunity to investigate the aerosol-cloud relationships
197 under contrasting thermodynamic regimes. As an indicator of the below-cloud boundary layer turbulence,
198 the TKE_w values present a gamma distribution that highly skewed to the right (Fig. 1e), with a mean
199 value of 0.11 and a median value of $0.08 \text{ m}^2\text{s}^{-2}$. About half of the cloud samples are under relatively
200 less turbulent environment, which suggests the weak connections between the cloud layer and the below-
201 cloud boundary layer. The other half of the cloud samples, with relatively higher TKE_w values up to 0.4
202 m^2/s^2 , imply tighter connections between cloud microphysical properties and below-cloud boundary
203 layer accompanied by intensive turbulent conditions, which is favorable to enhance cloud droplet growth
204 (Albrecht et al., 1995; Hogan et al., 2009; Ghate et al., 2010; West et al., 2014; Ghate and Cadettu,
205 2019).

206 It is noteworthy that PWV values exhibit a bimodal distribution with a median value of 2.4 cm (Fig.
207 1f). About 43% of the samples have their PWV values in the range of 1.0 - 2.0 cm with the first peak in
208 1.2 - 1.6 cm, and 56% of the samples have PWV values higher than 2.2 cm with a second peak in 2.4 -
209 2.8 cm, which may be due to the seasonal difference of the selected cases. Fig. S1 shows the seasonal
210 variation of the PWV from 2016 to 2018 when single-layer low clouds present. The monthly PWV values
211 are as low as ~ 1.7 mm and remain nearly invariant from January through March, then monotonically
212 increase up to ~ 3.4 cm (doubled) in August, and finally decrease dramatically to December. The selected
213 cloud cases are distributed across the seasons with $\sim 34\%$ of the samples occurring during the months
214 with the lowest mean PWV (Jan-Mar), while $\sim 43\%$ of the samples fall in the highest PWV months (Jun-
215 Sept). These two obvious PWV regions will provide a great opportunity for us to further examine the
216 ACI under different water vapor conditions.

217

218 3.2 Dependent of cloud microphysical properties on CCN and PWV

219 Figure 2 shows the cloud microphysical properties as a function of $N_{CCN,0.2\%}$ and PWV for the
220 samples from 20 selected cases. As illustrated in Fig. 2a, there is a statistically significant positive
221 correlation ($R^2=0.9$) between $\ln(N_c)$ and $\ln(N_{CCN,0.2\%})$. The linear fit of $\ln(N_c)$ to $\ln(N_{CCN,0.2\%})$ is then
222 mathematically transformed to a power-law fitting function of N_c to $N_{CCN,0.2\%}$, and plotted as dash lines
223 in Fig. 2a. The power-law fitting indicates that 90% of the variation in binned $\ln(N_c)$ can be explained
224 by the change in the binned $\ln(N_{CCN,0.2\%})$ and further suggests that with more available below-cloud
225 CCN, higher number concentrations are expected. The logarithmic ratio $\partial \ln(N_c) / \partial \ln(N_{CCN,0.2\%})$ is
226 computed to be 0.44 from our study. This ratio is very close to 0.48 found by McComiskey et al. (2009),

227 who also used ground-based measurements to study the marine stratus clouds over the California coast.
228 The logarithmic ratio (0.44) is also close to the result (0.458) of Lu et al. (2007) who used aircraft in-situ
229 measured cloud droplet and accumulation mode aerosol number concentration for the marine stratus and
230 stratocumulus clouds over the eastern Pacific Ocean. Our result agrees well with previous studies on the
231 relationship between cloud droplet and CCN in MBL clouds, which elaborate the bulk microphysical
232 responses of N_c to $N_{CCN,0.2\%}$ over different marine locations.

233 The PWV values are represented as blue circles (larger one for higher PWV) in Fig. 2a in order to
234 study the role of water vapor availability on the CCN- N_c conversion process. As demonstrated in Fig.
235 2a, the PWV values almost mimic the increasing $N_{CCN,0.2\%}$ trend, which is also governed by the seasonal
236 $N_{CCN,0.2\%}$ and the selected cloud cases. Fig. S2 shows the seasonal variation of $N_{CCN,0.2\%}$ from 2016 to
237 2018. It is noticeable that the monthly $N_{CCN,0.2\%}$ values, which mimic the monthly variation of PWV, are
238 much higher during warm months (May-Oct) than during cold months (Nov-Apr). This seasonal
239 $N_{CCN,0.2\%}$ variation is also found in recent studies of MBL aerosol composition and number concentration.
240 During the warm months, the below-cloud boundary layer is enriched by the accumulation mode of
241 sulfate and organic particles via local generation and long-range transport induced by the semi-permanent
242 Azores High, which are found to be hydrophilic and can be great CCN contributors (Wang et al., 2020;
243 Zawadowicz et al., 2020; Zheng et al., 2018, 2020). Therefore, the coincidence of high $N_{CCN,0.2\%}$ and
244 PWV does not necessarily imply a physical relationship, but instead is the result of their similar seasonal
245 trend. When taking the PWV into account, R^2 increases from 0.9 to 0.98, and this new relationship
246 suggests that the covariability between the binned $\ln(N_{CCN,0.2\%})$ and $\ln(\text{PWV})$ can explain 98% of the
247 change in binned $\ln(N_c)$. Intuitively, if the CCN- N_c relationship is primarily dominated by the diffusion
248 of water vapor, more CCN and higher PWV should result in a continuously increasing of N_c . However,
249 the rapid increase of N_c (37 to 92 cm^{-3}) in the first half of $N_{CCN,0.2\%}$ bins ($<250 \text{ cm}^{-3}$) does not happen
250 in the second half of the $N_{CCN,0.2\%}$ bins ($>250 \text{ cm}^{-3}$) where the slope of N_c increase (96 to 103 cm^{-3})
251 appears to be flattened for higher $N_{CCN,0.2\%}$ and PWV bins. Furthermore, the joint power-law fitting of
252 N_c (to $N_{CCN,0.2\%}$ and PWV) appears to be constantly lower than the single power-law fitting of N_c (to
253 $N_{CCN,0.2\%}$ solely) in each bin. The negative power of PWV in this relationship suggests that PWV might
254 play a stabilization role in the diffusional growth process, which will be further analyzed in the following
255 sections.

256 The relationship between τ_e and $N_{CCN,0.2\%}$ is shown in Fig. 2b where there is no significant
257 relationship between τ_e with $N_{CCN,0.2\%}$ solely, given a near-zero slope and the low correlation coefficient
258 (fitted line not plotted). However, after applying a multiple linear regression to the logarithmic form of

259 r_e , $N_{CCN,0.2\%}$ and PWV, a significant correlation among those three variables is found. The r_e is
260 negatively correlated with $N_{CCN,0.2\%}$ and positively correlated with PWV, and nearly 82% of the
261 variations in binned $\ln(r_e)$ can be explained by the joint changes of the binned $\ln(N_{CCN,0.2\%})$ and
262 $\ln(\text{PWV})$. This indicates that in the bulk part, the r_e decreases with increasing $N_{CCN,0.2\%}$ and enlarges
263 with increasing PWV. Notice that in lower $N_{CCN,0.2\%}$ bins ($<150 \text{ cm}^{-3}$) where the PWV values are the
264 lowest among all the bins (1.33 - 1.69 cm), the limitation of cloud droplet growth by competing for the
265 available water vapor is evident by the changes in N_c and r_e . For example, the $N_{CCN,0.2\%}$ changes from
266 47 to 128 cm^{-3} , the N_c increases from 37 to 71 cm^{-3} and r_e only increases from 9.30 to $9.74 \mu\text{m}$. In
267 other words, nearly tripling the CCN loading leads to roughly doubling N_c , while the r_e is only enlarged
268 by $0.44 \mu\text{m}$ (4.7%). In the relatively low available PWV regime, it is clear that even with more CCN
269 being converted into cloud droplets, the limited water vapor condition prohibits the further diffusional
270 growth of those cloud droplets. However, in the higher $N_{CCN,0.2\%}$ bins ($>150 \text{ cm}^{-3}$) with relatively
271 higher PWV, the binned r_e values fluctuate and decrease with increasing CCN bins under similar PWV
272 (i.e., the two $N_{CCN,0.2\%}$ ranges from 200-400 cm^{-3} , and from 400-500 cm^{-3}). Since r_e essentially
273 represents the area-weighted information of the cloud droplet size distribution (DSD), this sorting method
274 of r_e inevitably entangles multiple cloud droplet evolution processes and environmental effects that can
275 alter the DSD, especially under the condition of sufficient water supply. Therefore, the further assessment
276 of the r_e responses to the $N_{CCN,0.2\%}$ loading under the constraints of water vapor should be discussed in
277 order to untangle the impacts of different processes and environmental effects on r_e .

278

279 3.3 The role of adiabaticity in cloud microphysical variation

280 Following the discussion on the potential coalescence process in the last section, the cloud
281 adiabaticity conditions for the selected cases are investigated in this section. The profiles of cloud r_e and
282 LWC are plotted in normalized height from cloud base (z_b) to cloud top height (z_t) (Fig. 3), which is
283 given by $z_n = (z - z_b) / (z_t - z_b)$. The solid lines denote the mean values, and the shaded area
284 represents one standard deviation at each normalized height z_n . The normalized r_e increases from ~ 8.6
285 μm at the cloud base toward $\sim 11 \mu\text{m}$ near the upper part of the cloud where z_n is 0.7, primarily through
286 condensational growth and coalescence processes, and then decreases toward the cloud top due to cloud-
287 top entrainment. Profiles of retrieved LWC and calculated adiabatic LWC_{ad} (blue line) are presented in
288 Fig. 4b where $\text{LWC}_{ad(z)} = \Gamma_{ad}(z - z_b)$, and Γ_{ad} denotes the linear increase of LWC with height under
289 an ideal adiabatic condition (Wood, 2005). The LWC_{ad} is computed using an interpolated sounding,
290 following the method of Wu et al. (2020b), and the adiabaticity (f_{ad}) can be described as the ratio of

291 LWC to LWC_{ad} . As demonstrated in Fig. 3b, the f_{ad} values, which is the ratio of LWC to LWC_{ad} , reach
292 a maximum of 0.8 at the cloud base and a minimum of 0.38 at the cloud top. In the sub-adiabatic cloud
293 regime, the decrease of f_{ad} is largely due to the cloud-top entrainment and coalescence processes even
294 in the non-precipitating MBL clouds (Wood, 2012; Braun et al., 2018; Wu et al. 2020b). To better
295 understand the implication of cloud adiabaticity with respect to CCN- N_c conversion, all of the f_{ad}
296 samples are separated into two groups by the median value of the layer-mean f_{ad} (0.61). The N_c is
297 plotted against the binned $N_{CCN,0.2\%}$ (Fig. 4) for the near-adiabatic regime ($f_{ad} > 0.61$) and sub-adiabatic
298 regime ($f_{ad} < 0.61$). For the near-adiabatic regime, N_c increases from $\sim 60 \text{ cm}^{-3}$ to 119 cm^{-3} with
299 increased $N_{CCN,0.2\%}$ and PWV, and the $N_{CCN,0.2\%}$ and PWV appear to play equally important roles in
300 terms of the N_c increase. The result is as expected because the process of condensational growth is
301 predominant in the near-adiabatic cloud, that is, with increasing water vapor supply, the higher CCN
302 loading can effectively lead to more cloud droplets. However, in the sub-adiabatic cloud regime, N_c
303 increases with increased $N_{CCN,0.2\%}$ but possesses a negative correlation with PWV, which results in a
304 slow increase of N_c . The mean reduction of N_c in the sub-adiabatic regime is computed to be $\sim 33\%$
305 compared to that for the near-adiabatic cloud. As previously studied, the coalescence process contributes
306 significantly to N_c depletion, even in a non-precipitating marine boundary cloud (Feingold et al., 1996;
307 Wood, 2006). Thus, the lower N_c in the sub-adiabatic regime may be partly due to the combined effect
308 of coalescence and entrainment (Wood, 2006; Hill et al., 2009; Yum et al., 2015; Wang et al., 2020). The
309 impact of cloud adiabaticities on CCN- N_c conversions may shed light on interpreting the aerosol-cloud
310 interaction under different environmental effects.

311

312 3.4 Aerosol-cloud interaction under different PWV

313 As previously discussed above and suggested by earlier studies, the conditions of water vapor
314 supply have a substantial impact on various processes from CCN- N_c conversion to in-cloud droplet
315 condensational growth and coalescence, hence effectively altering the cloud DSD (Feingold et al., 2006;
316 McComiskey et al., 2009; Zheng et al., 2020). Moving forward to examine how r_e responds to the
317 changes of $N_{CCN,0.2\%}$ in the context of given water vapor availability, an index describing the aerosol-
318 cloud interaction process is introduced as follows:

$$319 \quad ACI_r = - \left. \frac{\partial \ln(r_e)}{\partial \ln(N_{CCN,0.2\%})} \right|_{PWV} . \quad (2)$$

320 The ACI_r represents the relative change of r_e with respect to the relative change of $N_{CCN,0.2\%}$, where
321 positive ACI_r denotes the decrease of r_e with increased $N_{CCN,0.2\%}$ under binned PWV. This assessment

322 of ACI_r focuses on the relative sensitivity of the cloud microphysics response in the water vapor stratified
323 environment (Twomey, 1977; Feingold et al., 2003; Garrett et al., 2004). Fig. 5 shows the variation of
324 ACI_r under different PWV bins, and illustrates the calculation of ACI_r in three different PWV ranges.
325 Note that in Fig. 5b, the regressions are derived from all points (statistically significant with a confidence
326 level of 95%) except for one point at $PWV=2.0$ cm. As shown in Fig. 5b, the ACI_r values range from
327 close-to-zero values (-0.004) to 0.207, with the mean value of 0.096 ± 0.026 . The ACI_r range of this
328 study agrees well with the previous studies of MBL cloud aerosol-cloud interactions (McComiskey et
329 al., 2009; Pandithurai et al., 2009; Liu et al., 2016). It is noteworthy that the variation of ACI_r with PWV
330 suggests two different relationships under separated PWV conditions, as discussed in the following two
331 paragraphs.

332 Under the relatively lower PWV condition (<2.0 cm), the low values of ACI_r (-0.004 - 0.074)
333 indicate that r_e is less sensitive to $N_{CCN,0.2\%}$, and the dependence on PWV is also insignificant given by
334 the flat regression line (green dash line) and low correlation coefficient of 0.17 (Fig. 5b). As discussed
335 in section 3.2, the limited water vapor can weaken the ability of condensational growth of the cloud
336 droplet converted from CCN, that is, the increase of CCN loading cannot be effectively reflected by a
337 decrease in r_e . For example, a near quadruple increase of $N_{CCN,0.2\%}$ only leads to a 41% decrease in r_e in
338 the PWV range of 1.2-1.4 cm as shown in Fig. 5a. So that in this regime, even with a slight PWV increase,
339 the lack of a sufficient amount of large cloud droplets is favorable to the predominant condensational
340 growth process, which effectively narrows the cloud DSD and, in turn, confines the variable range of r_e
341 with respect to $N_{CCN,0.2\%}$ (Pawlowska et al., 2006; Zheng et al., 2020). In this situation, the abilities of
342 CCN to cloud droplet conversion and the droplet condensational growth are limited by the insufficient
343 water vapor, rather than an influx of CCN.

344 However, under the relatively higher PWV regime (>2.2 cm), the ACI_r values become more positive
345 and express a significant increasing trend with PWV (correlation coefficient of 0.95), which indicates
346 that r_e is more susceptible to $N_{CCN,0.2\%}$ in this regime. On the one hand, due to the sufficient water vapor
347 supply, the enhanced condensational growth process allows more CCN to grow into cloud droplets, so
348 that the limiting factor of the droplet growth corresponds to the changes in CCN loading. On the other
349 hand, the increased N_c values associated with higher water vapor supply in the cloud effectively enhance
350 the coalescence process. This results in broadening the cloud DSD and increasing the variation range of
351 r_e in response to the changes of $N_{CCN,0.2\%}$. To test our hypothesis of active coalescence under higher
352 water vapor conditions, Table 2 lists the occurrence frequencies of large r_e values (> 12 and $14 \mu\text{m}$)
353 under the six high PWV bins (2.2 – 3.4 cm), because this range of 12-14 μm can serve as the critical

354 demarcation of an efficient coalescence process (Gerber, 1996; Freud and Rosenfeld, 2012; Rosenfeld et
355 al., 2012). As listed in Table 2, for the six high PWV bins, the occurrence frequencies of $r_e > 12 \mu\text{m}$ are
356 22.4%, 32.0%, 51.2%, 70.1%, 96.5% and 95.1%, and the occurrence frequencies of $r_e > 14 \mu\text{m}$ are 1.72%,
357 2.41%, 4.35%, 16.4%, 35.1% and 9.76%, respectively.

358 The increasing trends of large r_e occurrences mimic the trend of ACI_r and suggest that with
359 increased PWV, cloud droplets have a greater chance to grow via the effective coalescence process and
360 subsequently lead to an enlargement of ACI_r . Although previous studies have brought up the potential
361 impacts of cloud droplet coalescence process on ACI , it is rarely seen that the relationship among them
362 has been discussed in detail. Here we provide possible explanations on how the enhanced coalescence
363 process can enlarge ACI_r . Quantitatively, ACI_r is described by the log partial derivative ratio of r_e to
364 $N_{\text{CCN},0.2\%}$, thus a sharper decrease of r_e with respect to a given $N_{\text{CCN},0.2\%}$ range can result in a steeper
365 slope and in turn, larger ACI_r (i.e., a $N_{\text{CCN},0.2\%}$ increase of 49% leads to a r_e decrease of 41% in the 2.8-
366 3.0 cm bin in Fig. 5a). Physically, this relies on how the cloud droplet size distribution spectra would
367 change with different CCN loadings. Therefore, particularly in low CCN conditions, sufficient water
368 vapor availability allows cloud droplets to continuously grow via diffusion of water vapor (i.e.,
369 condensational growth), and enter the active cloud-droplet coalescence regime. In contrast, the increase
370 in cloud droplets can effectively reduce N_c via the process of large cloud droplets collecting small
371 droplets, and small droplets coalescing into large droplets. Consequently, the size distribution spectra are
372 effectively broadened toward the large tail by the coalescence, so that r_e is enlarged. With more CCN
373 available, the size distribution spectra are narrowed by the enhanced condensational growth and regress
374 toward the small tail by increasing the amount of newly converted cloud droplets and result in decreased
375 r_e . These interactions between CCNs and cloud droplets ultimately result in the broadened changeable
376 range of r_e , and in turn, the enlarged ACI_r .

377

378 **3.5 Impacts of meteorological factors on ACI**

379 **3.5.1 The role of lower tropospheric thermodynamics**

380 The LTS parameter is used to infer the large-scale thermodynamic structures for the selected
381 cases in order to examine their impacts on ACI . The samples are separated into two regimes: high LTS
382 and low LTS using the median LTS value (19.1K) as a threshold. The N_c values for the high LTS regime
383 are generally higher than those in the low LTS region (Fig. S3), though their difference is only 4.7%.
384 Since LTS is calculated by the difference between free tropospheric and surface potential temperatures,
385 a high LTS value represents a strong temperature inversion that caps the boundary layer, and implies a

386 thin entrainment zone that restricts the effectiveness of the cloud-top entrainment. Moreover, a more
387 stable lower troposphere is prone to boundary layer cloud formation with a lower cloud base height and
388 accompanies a well-mixed boundary layer that couple the surface moisture and aloft (Klein and
389 Hartmann, 1993; Wood and Bretherton, 2006; Wood, 2012). Thus, the high LTS values are often found
390 to be associated with clouds that more close to adiabatic (Kim et al., 2008), which results in more N_c
391 with less depletion.

392 To examine the impact of LTS on the water constrained ACI_r , the samples are further separated by
393 the median PWV (2.4 cm) and median LTS, so each regime has ~25% of the total samples. As shown in
394 Fig. 6, where the regression lines for the four regimes are fitted to the 95% confidence interval, the ACI_r
395 differences between low and high PWV regimes are still retained. In the low PWV regime, the ACI_r
396 values are limited to 0.03 and 0.053 for low and high LTS regimes, respectively. In the high PWV regime,
397 the ACI_r values are 0.154 and 0.171 for low and high LTS regimes, respectively, which is about 3-5 times
398 greater than those in low PWV regime. It appears that PWV plays a more important role in ACI_r than
399 LTS since the LTS is mostly capturing the large-scale thermodynamical structures, and is obtained from
400 a coarser temporal resolution. Thus, the LTS does not essentially have strict correspondence to the
401 strength of boundary layer turbulence (which more directly interferes with the cloud processes). LTS
402 may not effectively represent the connection between cloud layer and boundary layer CCN and moisture
403 in terms of both spatial and temporal scales, and thus induces limitations in assessing the role of
404 thermodynamics on the ACI_r .

405

406 3.5.2 The role of boundary layer turbulence

407 To examine the role of the dynamical factors on ACI , the TKE_w parameter is used to represent
408 the intensity of below-cloud boundary layer turbulence. The median TKE_w ($0.08 \text{ m}^2\text{s}^{-2}$) is used to
409 separate the N_c variation with $N_{CCN,0.2\%}$ for low and high TKE_w regimes (Fig. S4). The N_c values are
410 higher (with a mean increase of 20%) under high TKE_w environments than those under lower TKE_w ,
411 across all CCN bins. The higher logarithmic ratios of N_c to PWV for high TKE_w regime suggest a more
412 sensitive N_c response to CCN with an increased water vapor supply. This is mainly due to a closer
413 connection between the CCN below and the cloud layer loft, accompanied by stronger boundary layer
414 turbulence, so that more CCN can be converted into cloud droplets. When using the mean values of 215
415 cm^{-3} for $N_{CCN,0.2\%}$ and 2.2 cm for PWV as an example, the calculated N_c values from the multiple
416 regressions are 83 and 68 cm^{-3} for high and low TKE_w regimes, respectively. Thus, under the condition

417 at given $N_{CCN,0.2\%}$ and PWV, the boundary layer with strengthened turbulence would be favorable for
418 more cloud droplets to be converted from CCN by water vapor condensation.

419 Similar to the aforementioned data separation method, the samples are further separated into four
420 regimes demarcated by PWV and TKE_w in Fig. 7. Similar to the results in Fig. 6, the ACI_r values in the
421 higher PWV regime are also much higher than those in the lower PWV no matter low or high TKE_w
422 regimes, whereas TKE_w plays a more important role in ACI_r than LTS because the ACI_r values in the
423 high TKE_w regime are double those in the low TKE_w regime. In the regimes of higher TKE_w and PWV,
424 r_e is highly sensitive to the CCN loading with the highest ACI_r of 0.252. The sufficient water vapor
425 availability allows CCN to be converted into cloud droplets more effectively, while the relatively higher
426 TKE_w indicates stronger turbulence in the below-cloud boundary layer. The CCN and moisture below-
427 cloud layer are efficiently transported and mixed aloft via the ascending branch of the eddies (Nicholls,
428 1984; Hogan et al., 2009), hence effectively connected to the cloud layer. Therefore, under the lower
429 CCN loading condition, the active coalescence process results in the depletion of small cloud droplets
430 and broadening of cloud DSD (Chandrakar et al., 2016), which leads to further enlarged r_e . However,
431 with higher CCN intrusion into the cloud layer, the enhanced cloud droplet conversion and the
432 subsequential condensational growth behave contradictorily to narrows the DSD (Pinsky and Khain,
433 2002; Pawlowska et al., 2006), which leads to decreased r_e . Therefore, the MBL clouds are distinctly
434 susceptible to CCN loading under the environments of sufficient water vapor and strong turbulence in
435 which the ACI_r is enlarged.

436 Under high PWV but low TKE_w conditions, the mean ACI_r reduces to 0.125 (~ 50% of that under
437 high TKE_w). The weaker turbulence loosens the connection between cloud layer and the underlying
438 boundary layer, results in a less effective conversion of CCN into cloud droplets, and then diminishes
439 the r_e sensitivity to CCN. Although the constraints of insufficient water vapor on the ACI_r are still
440 evident, the ACI_r value is doubled from 0.017 in low TKE_w regime to 0.035 in high TKE_w regime. The
441 ACI_r differences between the two TKE_w regimes attest that ACI_r strongly depends on the connection
442 between the cloud layer and the boundary layer CCN and moisture, that is, strong turbulence can enhance
443 the susceptibility of r_e to CCN. Given the significant increase of ACI_r , the TKE_w demarcation line of
444 $0.08 \text{ m}^2 \text{ s}^{-2}$, which corresponds to the mean vertical velocity variation of $0.16 \text{ m}^2 \text{ s}^{-2}$, may be a feasible
445 way to distinguish the impact of turbulence effect on the cloud microphysical responses to the change in
446 CCN loadings.

447 In this study, the relationship between turbulence and ACI is found to be valid in non-precipitating
448 marine boundary-layer clouds. Theoretically, the effect of turbulence on ACI_r would appear to be

449 artificially amplified, if in the presence of precipitation. The intensive turbulence can enhance the
450 coalescence process and accelerate the CCN-cloud cycling, and subsequently, the CCN depletion due to
451 precipitation and coalescence scavenging would result in quantitatively enlarged ACI_r (Feingold et al.,
452 1996, 1999; Duong et al., 2011; Braun et al., 2018). Though it is beyond the scope of this study, it would
453 be of interest to perform such analysis on the aerosol-cloud-precipitation interaction using ground-based
454 remote sensing in the future study.

455

456 **4. Summaries and Conclusions**

457 Over the ARM-ENA site, a total of 20 non-precipitating single-layer MBL stratus and stratocumulus
458 cloud cases are selected in order to investigate the aerosol-cloud interaction (ACI). The distributions of
459 CCN and cloud properties for selected cases represent the typical characteristics of non-precipitating
460 MBL clouds in the relatively clean environment over the remote oceanic area. The impact of different
461 environmental effects on ACI is analyzed.

462 The overall variations of N_c with $N_{CCN,0.2\%}$ show an increasing trend, regardless of the water vapor
463 condition, while the sufficient PWV appears to stabilize the CCN- N_c conversion process. The water
464 vapor limitation on cloud droplet growth is evident in the lower $N_{CCN,0.2\%}$ up to 150 cm^{-3} with low PWV
465 values, where a near tripling of CCN loading leads to a near doubling of N_c but only 4.7% increase in r_e .
466 When $N_{CCN,0.2\%}$ is greater than 250 cm^{-3} and PWV values are also relatively high, r_e appears to
467 decrease with increasing $N_{CCN,0.2\%}$ under similar water vapor conditions. In a more adiabatic cloud
468 vertical structure, the cloud droplet is dominated by condensational growth, so N_c responses to increased
469 $N_{CCN,0.2\%}$ and PWV are strengthened. When the cloud layer become more sub-adiabatic, the effect of
470 coalescence leads to the depletion of N_c and thus, the competition between the condensational growth
471 and coalescence processes has a strong impact on the variations of cloud microphysics to CCN loading.

472 The ACI_r values vary from -0.004 to 0.207 for different PWV conditions where the ACI_r appears to
473 be diminished under limited water vapor availability due to the limited droplet activation and
474 condensational growth process. While under relatively sufficient water supply condition, r_e shows more
475 sensitive responses to the changes of $N_{CCN,0.2\%}$, due to the combined effect of condensational growth and
476 coalescence processes accompanying the higher N_c and PWV. The coalescence process further enlarges
477 r_e , particularly in low CCN loading, while the enhanced condensational growth narrows the cloud DSD
478 and decreases r_e , so that a broader variable range of r_e with respect to $N_{CCN,0.2\%}$ change results in a
479 higher ACI_r value.

480 To investigate the impacts of environmental effect on the ACI_r , the LTS parameter is used as a proxy
481 of the thermodynamic structure. A higher LTS regime is favorable to the adiabatic cloud with lower
482 cloud base height, accompanied by a well-mixed boundary layer, which likely enhances the cloud
483 microphysical responses to CCN loadings. However, the ACI_r in different LTS regimes cannot be
484 distinctly differentiated, partly due to the competing effect of adiabaticities and turbulence characteristics
485 on the cloud droplet development processes.

486 In contrast, the intensity of boundary layer turbulence, which is represented by TKE_w , plays a more
487 important role in ACI_r than LTS. The N_c shows more sensitive response to CCN with increased water
488 vapor supply for the higher TKE_w regime, which may be due to enhanced CCN to cloud droplet
489 conversion induced by intensive boundary layer turbulence. As for ACI_r , assessments in different TKE_w
490 and PWV regimes, the constraints of insufficient water vapor on the ACI_r are still evident, but in both
491 PWV regimes the ACI_r values increase more than double when going from low TKE_w to high TKE_w
492 regimes. Noticeably, the ACI_r increases from 0.125 in low TKE_w regime to 0.252 in high TKE_w regime,
493 under high PWV conditions. The intensive below-cloud boundary layer turbulence strengthens the
494 connection between the cloud layer and below-cloud CCN and moisture. So that with sufficient water
495 vapor, an active coalescence leads to further enlarged r_e , particularly for low CCN loading condition,
496 while the enhanced N_c from condensational growth induced by increased $N_{CCN,0.2\%}$ can effectively
497 decrease r_e . Combining these processes together, the enlarged ACI_r is presented.

498 In this study, the non-precipitating MBL clouds are found to be most susceptible to the below-cloud
499 CCN loading under environments with sufficient water vapor and stronger turbulence. And the TKE_w
500 demarcation line of $0.08 \text{ m}^2\text{s}^{-2}$ might be feasible in distinguishing the turbulence-enhanced aerosol-
501 cloud interaction. Future studies will be focusing on exploring the role of environmental effects on the
502 aerosol-cloud-precipitation interactions in MBL stratocumulus through an integrative analysis of
503 observations and model simulations.

16	20180130	1030	20180131	0500	152
17	20180203	1930	20180204	0500	72
18	20180324	0210	20180324	0600	46
19	20180508	0730	20180508	1110	42
20	20180513	2130	20180514	1200	139

Table 2. Occurrence frequencies of large in-cloud r_e^* under high PWV conditions

PWV (cm)	2.2- 2.4	2.4- 2.6	2.6- 2.8	2.8- 3.0	3.0- 3.2	3.2- 3.4
$r_e > 12 \mu\text{m}$ (%)	22.4	32.0	51.2	70.1	96.5	95.1
$r_e > 14 \mu\text{m}$ (%)	1.72	2.41	4.35	16.4	35.1	9.76

*The occurrence of large r_e is defined when the r_e is found to be larger than $12 \mu\text{m}$ or $14 \mu\text{m}$ using the retrieved in-cloud vertical profiles.

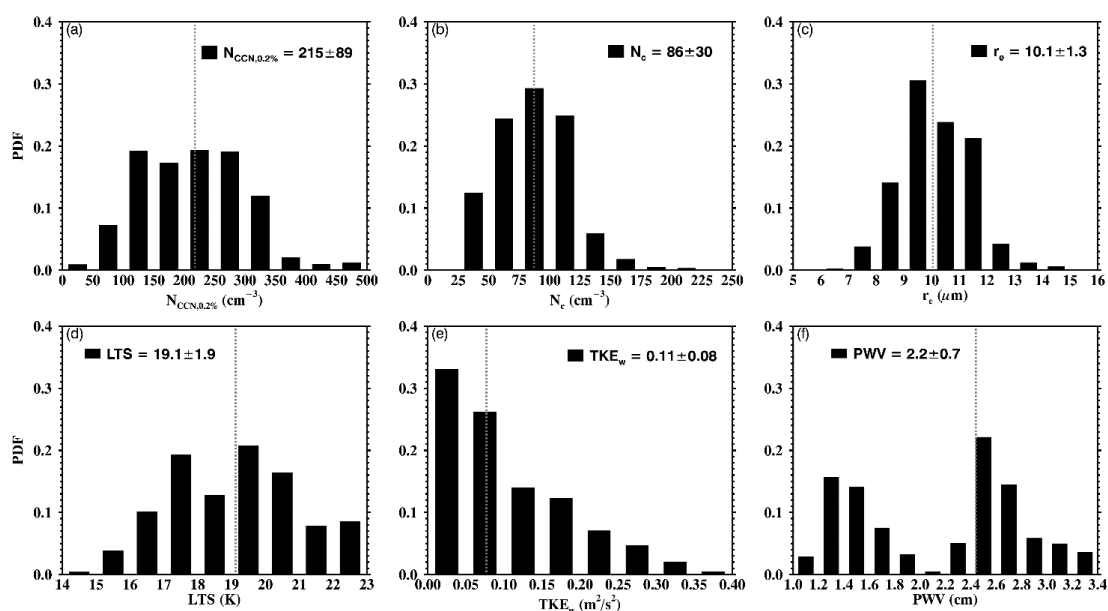

Figure 1. Probability distribution functions (PDFs), mean, standard deviation and median values (dash lines) of aerosol, cloud and meteorological properties for 20 selected non-precipitating cloud cases at the DOE ENA site during the period 2016-2018. (a) Cloud condensation nuclei (CCN) number concentration at 0.2% supersaturation ($N_{CCN,0.2\%}$), (b) cloud-droplet number concentration (N_c), (c) cloud-droplet effective radius (r_e), (d) lower tropospheric stability (LTS), (e) mean vertical component of turbulence kinetic energy (TKE_w), and (f) precipitable water vapor (PWV).

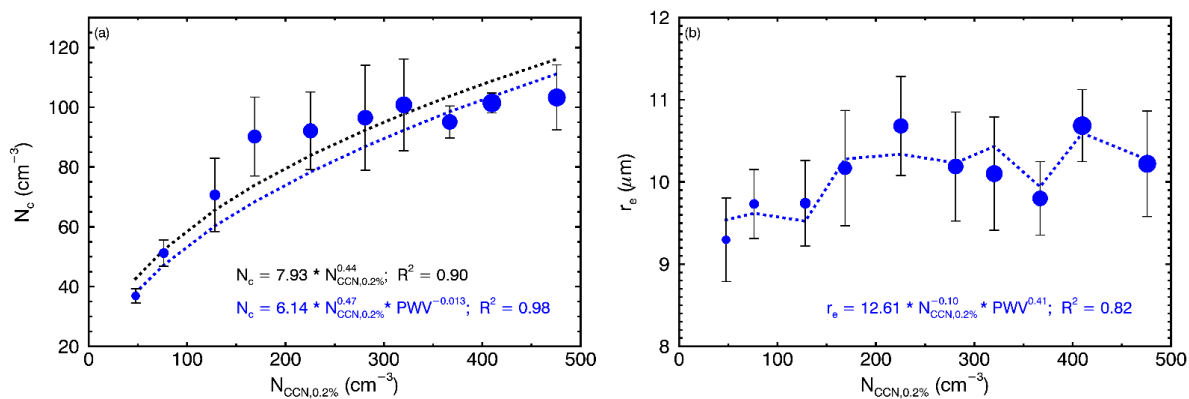

Figure 2. (a) N_c and (b) r_e as a function of $N_{CCN,0.2\%}$ (x-axis) and PWV (blue filled circles) for all selected samples. The larger blue circles represent relatively higher PWV values. Whiskers denote one standard deviation for each bin.

Figure 3. Normalized in-cloud vertical profiles of retrieved (a) r_e and (b) LWC (black) and calculated adiabatic LWC_{ad} (blue) for all selected cloud cases, 0 is cloud base and 1 is cloud top. Solid dotted lines denote mean values and shaded area denote one standard deviation at each height.

Figure 4. N_c as a function of $N_{CCN,0.2\%}$ (x-axis) and PWV (dots) for high adiabaticity f_{ad} (red) and low f_{ad} (black) regimes. The larger circles represent relatively higher PWV values. Whiskers denote one standard deviation for each bin.

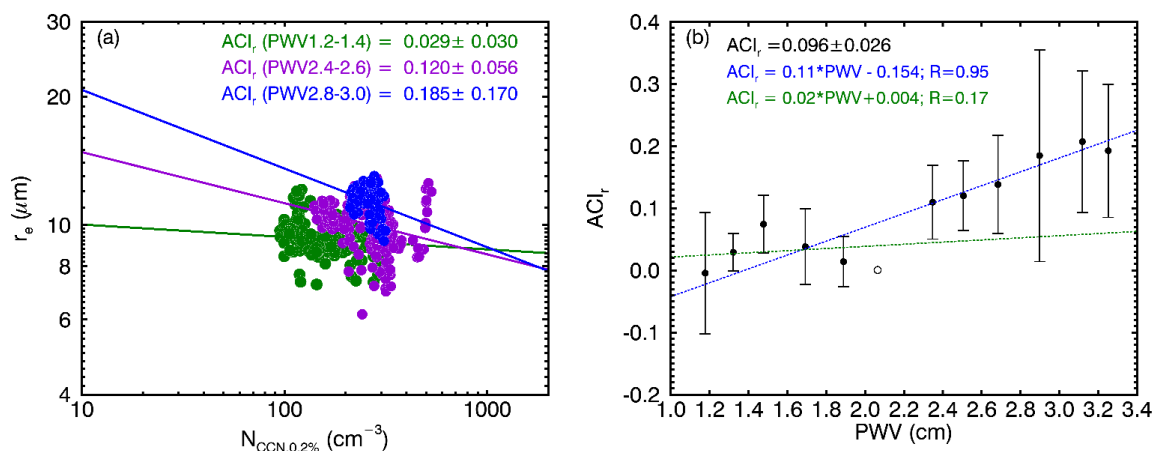

Figure 5. ACI_r derived from (a) r_e to $N_{CCN,0.2\%}$ in following three PWV bins: 1.2-1.4 cm (green), 2.4-2.6 cm (purple), 2.8-3.0 cm (blue) and (b) Relationship of ACI_r (dots) to binned PWV. Whiskers denote one standard deviation for each bin. Linear regressions are performed in relatively low PWV regime (< 2.0 cm, green) and high PWV regime (> 2.2 cm). Bin that does not pass the significant test in 95% confidence level is denoted by a hollow circle and is excluded from the regressions. ACI_r represents the relative change of r_e with respect to the relative change of $N_{CCN,0.2\%}$, where positive ACI_r denotes the decrease of r_e with increased $N_{CCN,0.2\%}$ under binned PWV.

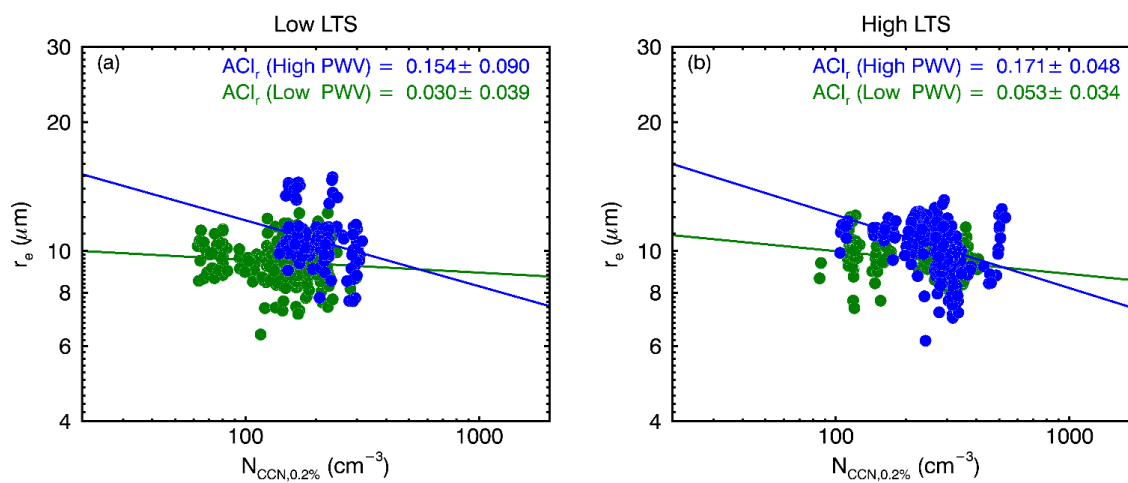

Figure 6. ACI_r derived from r_e to $N_{CCN,0.2\%}$ for (a) low LTS and (b) high LTS regimes. Samples in the low PWV regime are plotted in green, and samples in the high PWV regime are plotted in blue.

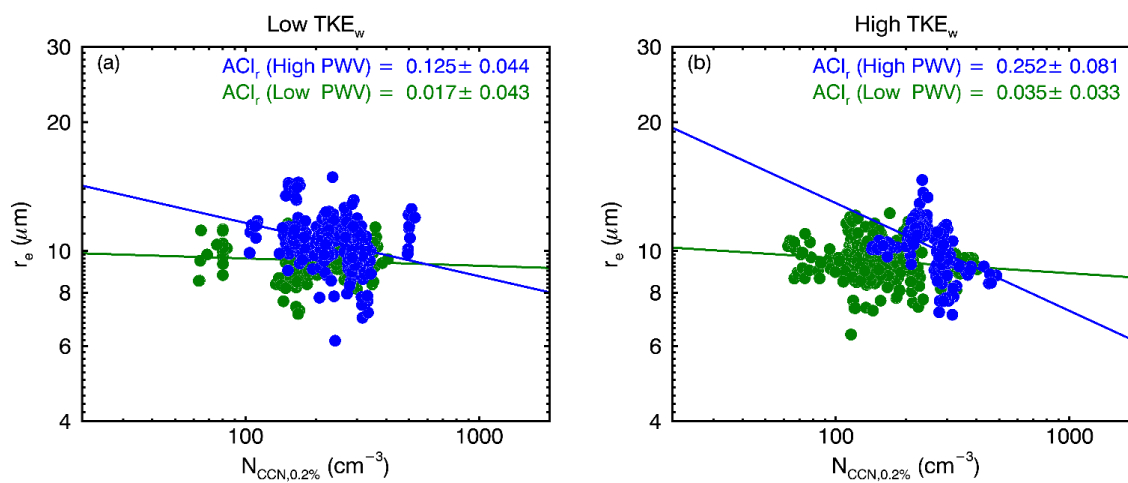

Figure 7. ACI_r derived from r_e to $N_{CCN,0.2\%}$ for (a) low TKE_w and (b) high TKE_w regimes. Samples in the low PWV regime are plotted in green, and samples in the high PWV regime are plotted in blue.
