26 **Abstract**

27 This work focuses on total organic carbon (TOC) and contributing species in cloud water over
28 Southeast Asia using a rare airborne dataset collected during NASA's Cloud, Aerosol and
29 Monsoon Processes Philippines Experiment (CAMP²Ex), in which a wide variety of maritime
30 clouds were studied, including cumulus congestus, altocumulus, altostratus, and cumulus.
31 Knowledge of TOC masses and their contributing species is needed for improved modeling of
32 cloud processing of organics and to understand how aerosols and gases impact and are impacted
33 by clouds. This work relies on 159 samples collected with an Axial Cyclone Cloud water
34 Collector at altitudes of 0.2 – 6.8 km that had sufficient volume for both TOC and speciated
35 organic composition analysis. Species included monocarboxylic acids (glycolate, acetate,
36 formate, and pyruvate), dicarboxylic acids (glutarate, adipate, succinate, maleate, and oxalate),
37 methanesulfonate (MSA), and dimethylamine (DMA). TOC values range between 0.018 – 13.66
38 ppm C with a mean of 0.902 ppm C. The highest TOC values are observed below 2 km with a
39 general reduction aloft. An exception is samples impacted by biomass burning for which TOC
40 remains enhanced as high as 6.5 km (7.048 ppm C). Estimated total organic matter derived from
41 TOC contributes a mean of 30.7% to total measured mass (inorganics + organics). Speciated
42 organics contribute (on carbon mass basis) an average of 30.0% to TOC in the study region, and
43 account for an average of 10.3% to total measured mass.

44 The order of the average contribution of species to TOC, in decreasing contribution of carbon
45 mass, is as follows (\pm one standard deviation): acetate ($14.7 \pm 20.5\%$), formate ($5.4 \pm 9.3\%$),
46 oxalate ($2.8 \pm 4.3\%$), DMA ($1.7 \pm 6.3\%$), succinate ($1.6 \pm 2.4\%$), pyruvate ($1.3 \pm 4.5\%$),
47 glycolate ($1.3 \pm 3.7\%$), adipate ($1.0 \pm 3.6\%$), MSA ($0.1 \pm 0.1\%$), glutarate ($0.1 \pm 0.2\%$), maleate
48 ($< 0.1 \pm 0.1\%$). Approximately 70% of TOC remains unaccounted for, thus highlighting the
49 complex nature of organics in the study region; samples collected in biomass burning plumes
50 have up to 95.6% of unaccounted TOC mass based on the species detected. Consistent with other
51 regions, monocarboxylic acids dominate the speciated organic mass (~75%) and are about four
52 times in greater abundance than dicarboxylic acids.

53 Samples are categorized into four cases based on back-trajectory history revealing source-
54 independent similarity between the bulk contributions of monocarboxylic and dicarboxylic acids
55 to TOC (16.03% – 23.66% and 3.70% – 8.75%, respectively). Furthermore, acetate, formate,
56 succinate, glutarate, pyruvate, oxalate, and MSA are especially enhanced during biomass burning
57 periods, attributed to peat emissions transported from Sumatra and Borneo. Lastly, dust (Ca^{2+})
58 and sea salt (Na^+/Cl^-) tracers exhibit strong correlations with speciated organics, thus supporting
59 how coarse aerosol surfaces interact with these water-soluble organics.

60

61 **1. Introduction**

62 The last two decades witnessed an acceleration of research to unravel the nature of the organic
63 fraction of airborne particles, including speciation (Hallquist et al., 2009; Kanakidou et al.,
64 2005), with implications for how particles impact air quality, public health, and the planet's
65 energy balance. However, there has been much less progress on organic research for cloud
66 droplets, owing largely to the inaccessibility of clouds as compared to particles that can be
67 measured more easily near the surface. Analyzing organic matter in cloud water will lead to
68 better understanding of secondary aerosol formation and the nature of cloud condensation nuclei
69 (CCN) that form droplets. The interaction of aerosol particles and clouds constitutes the
70 largest uncertainty in estimating total anthropogenic radiative forcing (IPCC, 2013), which
71 motivates using cloud composition as a tool to learn about these processes (MacDonald et al.,
72 2020). Characterizing cloud water composition is insightful for atmospheric chemical processes
73 such as the removal of gases that would otherwise participate in gas-phase reactions and for
74 aqueous reactions that yield products without an efficient gas-phase source (e.g., dicarboxylic
75 acids) (Ervens et al., 2013). While modeling of sulfate production in clouds is fairly mature
76 (Barth et al., 2000; Faloona, 2009; Kreidenweis et al., 2003; Liu et al., 2021), the formation and
77 evolution of organics in cloud water is much more poorly constrained (Ervens, 2015).

78 Advancing this research requires in situ measurements of cloud water composition. Among the
79 most common methods of characterizing the organic fraction of cloud water samples is total
80 organic carbon (TOC) analysis. Whether it is cloud water or fog water, most studies have shown
81 that (i) TOC is enhanced in air masses with higher anthropogenic influence (Collett Jr. et al.,
82 1998; Deguillaume et al., 2014; Herckes et al., 2013; Raja et al., 2009); (ii) ~40% – 85% of the
83 TOC is attributed to unidentified species (Benedict et al., 2012; Boris et al., 2016; Boris et al.,
84 2018; Herckes et al., 2002; Raja et al., 2008); (iii) organic acids usually account for \lesssim 15% of the
85 TOC (Deguillaume et al., 2014; Gioda et al., 2011; Straub et al., 2007); (iv) monocarboxylic
86 acids are more abundant than dicarboxylic acids (Löflund et al., 2002); and (v) acetic and formic
87 acids are the most dominant organic acids contributing to TOC (Collett Jr. et al., 2008; Gioda et
88 al., 2011). Most of the aforementioned studies focused on fog, therefore motivating a closer look
89 at cloud water, as solute concentrations depend on the type of aqueous medium (Fig. 1). More
90 specifically, TOC concentrations are reported to be higher in fog water relative to rain water
91 (Kim et al., 2020), while cloud water solute concentrations exceed those in rain water (Decesari
92 et al., 2005; Gioda et al., 2008).

93 Southeast Asia is an ideal laboratory to investigate the nature of TOC and its constituents as it is
94 impacted by a multitude of emissions sources in an environment with persistent cloud cover from
95 a variety of cloud types (e.g., shallow cumulus and cumulus congestus clouds) (Reid et al.,
96 2013). The complex meteorology of the region makes it very difficult to model (Wang et al.,
97 2013; Xian et al., 2013), but simultaneously provides a remarkable opportunity to learn more
98 about how aerosols impact (and are impacted by) tropical cloud systems. A knowledge gap exists
99 as there have been no studies of cloud composition in this region based on airborne
100 measurements. Analysis of fog water at Baengnyeong Island in the eastern Yellow Sea revealed
101 that organic acids accounted for 36 – 69% of TOC (Boris et al., 2016). The Acid Deposition

102 Monitoring Network in East Asia (<https://www.eanet.asia/>) provides data on wet deposition at
103 surface sites such as at the Manila Observatory (Metro Manila, Philippines) (Ma et al., 2021) and
104 is limited to inorganic ions. Previous studies such as the Seven South East Asian Studies
105 (7SEAS) (Reid et al., 2013) and the Cloud, Aerosol and Monsoon Processes Philippines
106 Experiment (CAMP²Ex) weathER and CompoSition Monitoring (CHECSM) were carried out in
107 this region; however, these campaigns were ground and ship-based, and focused mainly on
108 aerosol particles and not cloud composition (Hilario et al., 2020b; Reid et al., 2015; Reid et al.,
109 2016). It should also be noted that there have also been a handful of high elevation studies
110 carried out in Southeast Asia examining fog and cloud water organic acids (i.e., Decesari et al.,
111 2005; Li et al., 2017; Mochizuki et al., 2020).

112 Recent studies in Metro Manila, Philippines provide the following results of relevance to this
113 work: (i) a third to a half of the total aerosol particle mass is often unaccounted for after
114 considering water-soluble species (inorganic and organic acid ions and elements) and black
115 carbon (Cruz et al., 2019; Stahl et al., 2020); (ii) organic acids account for less than 1% of total
116 aerosol mass, with oxalate being the most abundant acid (Stahl et al., 2020); (iii) organic acid
117 concentrations are more enhanced during biomass burning periods (Hilario et al., 2020a),
118 especially succinate and oxalate (Braun et al., 2020; Stahl et al., 2020); and (iv) wet deposition
119 samples clearly show the influence of biomass burning tracer species on cloud composition (Ma
120 et al., 2021). Based on these points, we test two hypotheses: (i) the relative contribution of
121 organic acids to TOC will exceed what was observed at the surface layer over Metro Manila
122 owing to more aged air masses aloft as compared to the surface layer in Metro Manila exposed to
123 fresher emissions; and (ii) clouds impacted by biomass burning emissions will exhibit chemical
124 profiles shifted to higher TOC concentrations and with a greater portion of that TOC accounted
125 for by organic acids. To address these hypotheses in addition to characterizing the organic
126 fraction of cloud water, we utilized a rich set of cloud water samples collected around the
127 Philippines during CAMP²Ex between August and October in 2019. The subsequent results and
128 discussion focus on TOC concentrations in addition to the relative contribution and
129 interrelationships between a suite of organic species (organic acids, methanesulfonate,
130 dimethylamine) spatially, and as a function of altitude and air mass source origin. A unique
131 aspect of this dataset is the large sample number with both TOC and speciated organic acid
132 information from an airborne platform.

133

134 **2. Methods**

135 **2.1 Study overview**

136 A total of 159 cloud water samples were collected on the NASA P-3B Orion aircraft across 19
137 research flights (RF; 23 August – 5 October 2019) during CAMP²Ex that were measured for
138 ions, pH, and TOC. Flights were based out of Clark International Airport (15.189°N, 120.547°E)
139 and extended to regions around the island of Luzon (Fig. 2). Cloud water samples were collected
140 over a wide range of altitudes ranging from 0.2 – 6.8 km.

141

142 2.2 Cloud water collection and handling

143 Samples were collected using the Axial Cyclone Cloud water Collector (AC3), (Crosbie et al.,
144 2018), which efficiently (> 60% collection efficiency) collects cloud droplets with diameters >
145 20 μm . The size dependence of the collection efficiency may influence the measured properties
146 of the bulk cloud water in cases where there is a strong size-dependence in the droplet
147 composition. Sample water evaporation was identified to affect low liquid water content
148 environments and may increase aqueous concentrations. For this study the pipe position was set
149 to position 10, as described in Crosbie et al. (2018), and mounted to the fuselage pylon
150 approximately 300 mm from the skin. The AC3 has a shutter attached to a servo motor allowing
151 the collector to be closed when not in a cloud to prevent contamination. Samples were collected
152 between 10 seconds and 10 minutes depending on cloud availability and liquid water content
153 (i.e., shorter times possible with higher liquid water content). Cloud water was collected in
154 prewashed 15-mL plastic conical vials. Due to thorough prewashing of the plastic conical vials,
155 leaching of organics into samples was negligible. Additional laboratory tests also indicated that
156 there was no appreciable evidence that organics were adsorbing to the walls of the conical vials.
157 Before each flight, the collector was flushed with ~ 1 L of ultra-purified Milli-Q water (18.2
158 $\text{M}\Omega\text{-cm}$) prior to obtaining two blank samples. Blanks were also collected post-flight that were
159 similarly flushed prior to being collected. During flight, samples were collected and stored in a
160 cooler with sufficient ice packs to reduce possible decomposition. After flights, samples were
161 immediately taken to an onsite laboratory where sample volumes were recorded and analyzed for
162 ionic composition, TOC, and pH. A background was subtracted from the samples based on the
163 bottom 10th percentile of all blanks collected during the campaign (both pre- and post-flight).
164 The 10th percentile of the blanks was used instead of the mean as it is a compromise between
165 removing the influence of background contamination and conserving data points. Excess samples
166 were stored in a refrigerator for future analyses that are outside the scope of this study.

167

168 2.3 Cloud water analysis

169 2.3.1 Ion chromatography

170 Cloud water was speciated using ion chromatography (IC; Dionex ICS-2100) immediately after
171 each flight to reduce the possibility of degradation of the samples. Measured anionic species of
172 interest were glycolate, acetate, formate, methanesulfonate, pyruvate, glutarate, adipate,
173 succinate, maleate, oxalate, Cl^- , NO_2^- , Br^- , NO_3^- , and SO_4^{2-} . Measured cations were Na^+ , NH_4^+ ,
174 K^+ , dimethylamine (DMA), Mg^{2+} , and Ca^{2+} . A 23-minute instrument method was used for both
175 anion and cation columns with a 2-minute equilibration period, yielding a 25-minute sampling
176 period per sample. The instrument flow rate was 0.4 mL min^{-1} . The anions were measured using
177 a Dionex IonPac AS11-HC $2 \times 250 \text{ mm}$ column, a Dionex AERS 500e suppressor, and with
178 potassium hydroxide as the eluent. The cations were measured using a Dionex IonPac CS12A 2
179 $\times 250 \text{ mm}$ column, a Dionex CERS 500e suppressor, and using methanesulfonic acid (MSA) as
180 the eluent. The instrument methods used for analysis are as follows: (i) for anions the eluent
181 concentration started at 1 mM, ramped up to 4 mM between 0 – 10 minutes, ramped up to 6 mM
182 between 10 – 11 minutes, and finally ramped up to 7 mM between 11 – 23 minutes using a

183 suppressor current of 8 mA; (ii) for cations the eluent concentration started at 5 mM and
184 remained isocratic from 0 – 10 minutes, ramped up to 18 mM between 10 – 12 minutes, and
185 finally remained isocratic at 18 mM from 12 – 23 minutes using a suppressor current of 22 mA.
186 The limits of detection (LOD) for these species can be found in Table 1 and were calculated
187 using $3S_a b^{-1}$ where S_a is the standard deviation of the response and b is the slope of the
188 calibration curve for that species.

189

190 **2.3.2 Total organic carbon and pH**

191 Total organic carbon (TOC) was measured using a Sievers 800 Turbo TOC analyzer. Sample
192 aliquots were diluted to obtain the minimum volume needed by the instrument. The TOC
193 analyzer was operated in turbo mode and TOC values were averaged over a stable concentration
194 period. Milli-Q water was used as an internal reference and calibrations were performed before
195 and after each batch of samples was analyzed (i.e., one batch every ~3 – 4 flights) using a range
196 of different concentrations from an oxalate standard solution. A volume of approximately 10 mL
197 was used for each measurement and MQ water was used intermittently to flush the instrument
198 between each sample.

199 The pH of the cloud water samples was measured using an Orion StarTM A211 pH meter with an
200 OrionTM 8103BNUWP ROSS UltraTM pH electrode (precision of 0.01). A two-point calibration
201 (pH = 4 and pH = 7) was performed at the beginning of analyzing a particular flight's set of
202 samples.

203

204 **2.3.3 Units**

205 While many studies report concentrations in terms of air-equivalent concentrations, we instead
206 use the native liquid-phase concentrations. Aqueous concentrations of TOC and individual
207 molecular components are reported in units of ppb (i.e., parts per billion by mass). TOC
208 concentrations are specific to the mass of carbon atoms only, while molecules measured by IC
209 correspond to the specific mass of the species (unless noted otherwise). TOC was converted to
210 total organic matter (TOM) via multiplication by 1.8 (Zhang et al., 2005).

211 The choice to focus on aqueous- rather than air-equivalent concentrations was made for various
212 reasons. First, our analysis focuses heavily on relative amounts of species that were unaffected
213 by multiplying native aqueous units by cloud liquid water content. Second, the definition of
214 liquid water content applied by studies can vary widely based on the lower and upper bound of
215 what is considered a droplet. Third, relationships between solute concentrations in cloud water
216 and liquid water content, anticipated from nucleation scavenging, are ineffective when gases like
217 acetic and formic acids absorb directly into droplets rather than having been part of the initial
218 CCN activating into droplets (Khare et al., 1999; Marinoni et al., 2004). Lastly, many studies of
219 cloud water composition that our results can be contrasted with also use liquid units. The primary
220 liquid units reported for cloud water concentrations are ppm and ppb. However, it should be
221 noted that species concentrations in cloud water can be high simply due to the liquid water

222 content being low, or inversely the concentrations can be low due to being diluted by high liquid
223 water content.

224

225 **2.4 Aerosol Composition**

226 To complement the cloud water composition results, we use aerosol composition results from the
227 High-Resolution Time-of-Flight Aerosol Mass Spectrometer (AMS; Aerodyne, Inc.), which
228 reports non-refractory composition for the submicrometer range (DeCarlo et al., 2006). As
229 summarized by Hilario et al. (2021), the AMS deployed in CAMP²Ex functioned in 1 Hz Fast-
230 MS mode with data averaged to 30 s time resolution with the lower limit of detection (units of
231 $\mu\text{g m}^{-3}$) as follows for the measured species: organic (0.169), NH_4^+ (0.169), SO_4^{2-} (0.039), NO_3^-
232 (0.035), Cl^- (0.036). Negative mass concentrations were recorded owing to the difference method
233 used with the limits of detection. These negative values were included in the analyses to avoid
234 positive biases but were interpreted as zero concentrations. We also use data specifically for the
235 mass spectral marker representative of acid-like oxygenated organic species (m/z 44= COO^+)
236 (Aiken et al., 2008) and its mass relative to total organic mass (f_{44}). AMS data were omitted from
237 analysis if total mass of all detected species was $< 0.5 \mu\text{g m}^{-3}$. By convention for airborne
238 sampling, AMS data are reported at standard temperature and pressure (STP; 273 K, 1013 hPa).

239 AMS data were reported separately for cloud-free and cloudy conditions owing to the use of a
240 counterflow virtual impactor (CVI) inlet (Brechtel Manufacturing Inc.) (Shingler et al., 2012) in
241 clouds to isolate and dry droplets, leaving the residual particles for sampling by the AMS. Cloud-
242 free data involve sampling with a separate inlet designed by the University of Hawaii
243 (McNaughton et al., 2007). For cloud-free AMS results, data were selected 60 seconds before
244 and after each cloud water sample's start and end time, respectively, when the aircraft was not in
245 cloud. CVI-AMS data were reported for data collected within the period of cloud water
246 collection. It should be noted that cloud-free AMS data are missing for some cloud water
247 samples when the CVI was still in use for the 60 s before and after a sample's start and end time,
248 respectively.

249

250 **2.5 HYSPLIT**

251 Air mass origination was determined using 5-day back trajectories from the National Oceanic
252 and Atmospheric Administration (NOAA) Hybrid Single Particle Lagrangian Integrated
253 Trajectory model (HYSPLIT) (Rolph et al., 2017; Stein et al., 2015). Trajectories were generated
254 at 1-minute temporal resolution with meteorological inputs from the Global Forecast System
255 (GFS) reanalysis with a horizontal resolution of $0.25^\circ \times 0.25^\circ$ using the "model vertical velocity"
256 method.

257

258 **2.6 NAAPS**

259 The Navy Aerosol Analysis and Prediction System (NAAPS) global aerosol model was
260 implemented to assist in identifying biomass burning cases (Lynch et al., 2016)
261 (<https://www.nrlmry.navy.mil/aerosol/>). NAAPS relies on global meteorological fields from the
262 Navy Global Environmental Model (NAVGEM) (Hogan and Brody, 1993; Hogan and Rosmond,
263 1991) that analyzes and forecasts a $1^{\circ} \times 1^{\circ}$ grid with 6-hour intervals with 24 vertical levels. In
264 terms of identifying biomass burning cases, surface smoke concentrations were examined.
265

266 3. Cumulative Results

267 3.1 Concentration Statistics

268 TOC values ranged from 0.018 – 13.66 ppm C, with median and mean concentrations of 0.546
269 and 0.902 ppm C, respectively (Table 1). Samples in this study exhibited nearly the lowest mean
270 TOC value of all cloud water studies surveyed in Fig. 1, with the other lowest values being over
271 the Pacific Ocean west of San Diego, California (0.85 ppm C), (Straub et al., 2007) and East
272 Peak, Puerto Rico (0.90 ppm C), (Gioda et al., 2008; Gioda et al., 2011; Reyes-Rodríguez et al.,
273 2009). The CAMP²Ex dataset exhibited the lowest minimum TOC value of all shown studies.
274 For context, the highest mean and maximum TOC masses in cloud water studies were 34.5 and
275 51.7 ppm C, respectively, at Jeju Island, Korea, while the peak dissolved organic carbon (DOC)
276 mass in cloud water was 85.6 ppm C at Mt. Tai, China. For comparisons to published cloud
277 water measurements, DOC and TOC are assumed to be sufficiently similar in nature to directly
278 compare values. Differences in TOC between our study and others can partly be attributed to the
279 different types of clouds studied in the CAMP²Ex region (e.g., cumulus congestus, cumulus,
280 altocumulus, altostratus) and the higher collection altitudes being conducive to enhanced liquid
281 water contents and droplet sizes than stratocumulus clouds in regions like the northeastern
282 (Straub et al., 2007) and southeastern Pacific Ocean (Benedict et al., 2012). Previous studies
283 have primarily sampled stratocumulus or stratus clouds (Fig. 1). Also, some of our samples may
284 have included rain water, which naturally has lower concentrations of TOC than cloud water due
285 to dilution (Fig. 1). To illustrate the importance of this dilution effect, an average of the mean
286 values from the Fig. 1 studies shows the following (ppm C): Fog = 17.8, cloud = 6.4, rain = 0.6.
287 We further note that direct comparisons of our results to others need to factor that water
288 collectors have different transmission efficiency behavior as a function of droplet size, as well as
289 compositional differences across the droplet size spectrum (i.e., Boris et al., 2016; Collett Jr. et
290 al., 2008; Herckes et al., 2013).

291 The order of species is as follows in terms of decreasing average contribution of C mass relative
292 to total TOC (\pm one standard deviation): acetate ($14.7 \pm 20.5\%$), formate ($5.4 \pm 9.3\%$), oxalate
293 ($2.8 \pm 4.3\%$), DMA ($1.7 \pm 6.3\%$), succinate ($1.6 \pm 2.4\%$), pyruvate ($1.3 \pm 4.5\%$), glycolate ($1.3 \pm$
294 3.7%), adipate ($1.0 \pm 3.6\%$), MSA ($0.1 \pm 0.1\%$), glutarate ($0.1 \pm 0.2\%$), and maleate ($< 0.1 \pm$
295 0.1%). An average of 70.0% of TOC mass went unaccounted for. The predominant sources and
296 production pathways of these species are briefly explained here. Precursor emissions sources for
297 acetate and formate include plants, soil, vehicles, and biomass burning, with key production
298 routes including oxidation of isoprene, ozonolysis of olefins, and peroxy radical reactions (Khare
299 et al., 1999, and references therein). Pyruvate is considered the most abundant aqueous reaction
300 product of methylglyoxal, generated by the oxidation of gas-phase anthropogenic volatile

301 organic compounds (Boris et al., 2014; Carlton et al., 2006; Lim et al., 2013; Stefan et al., 1996;
302 Tan et al., 2010). Glycolate has been linked to aqueous processing of acetate and a precursor for
303 glyoxylate (Boris et al., 2014) and formed via oxidation of glycolaldehyde by hydroxide radicals
304 (Thomas et al., 2016). Oxalate is the most abundant dicarboxylic acid across different
305 environments (Cruz et al., 2019; Stahl et al., 2020; Yang et al., 2014; Ziemba et al., 2011) and
306 can be emitted directly by biogenic sources (Kawamura and Kaplan, 1987), combustion exhaust
307 (Kawamura and Kaplan, 1987; Kawamura and Yasui, 2005), and biomass burning (Narukawa et
308 al., 1999; Yang et al., 2014); however, it is also formed through the oxidation and degradation of
309 longer chain organic acids and acts as a notable tracer for cloud processing (Ervens et al., 2004;
310 Sorooshian et al., 2006). Saturated organics like glutarate, adipate, and succinate are linked to
311 fresh emissions and mainly from ozonolysis of cyclic alkenes (such as from vehicular emissions)
312 in the study region (Hatakeyama et al., 1985; Stahl et al., 2020). Maleate can be secondarily
313 formed from the photooxidation of benzene (Rogge et al., 1993) or from the primary emissions
314 of combustion engines (Kawamura and Kaplan, 1987). Alkyl amines (i.e., DMA) have numerous
315 sources such as biomass burning, vehicular emissions, industrial activity, animal husbandry,
316 waste treatment, and the ocean (Youn et al., 2015). Finally, MSA is formed via photooxidation
317 reactions involving dimethylsulfide (DMS) from oceanic emissions (Berresheim, 1987; Saltzman
318 et al., 1983) or dimethyl sulfoxide (DMSO) from anthropogenic emissions (Yuan et al., 2004), in
319 addition to being linked to agricultural emissions and biomass burning (Sorooshian et al., 2015).

320 Measured organic species were further grouped into categories: monocarboxylic acids (MCA;
321 glycolate, acetate, formate, pyruvate), dicarboxylic acids (DCA; glutarate, adipate, succinate,
322 maleate, oxalate), and measured organics (MO = sum of MCA, DCA, MSA, DMA). Total MCA
323 concentrations accounted on average for ~75% of MO and were approximately four times larger
324 than those of DCAs. MO values ranged from 29.46 – 10820 ppb, accounting for an average of
325 30.0% (median 23.8%) of TOC when masses were converted to just the C masses of the
326 measured species (Table 1). Examples of other undetected organics include tricarboxylic acids,
327 aromatics, alcohols, sugars, carbohydrates, and aldehydes. Previous studies reported undetected
328 species accounting for ~45% (Boris et al., 2016) and 82.9% (Boris et al., 2018) of organics.
329 Interestingly, the ionic charge balance for the 159 samples show an anion deficit (Fig. S1), with a
330 slope of 0.95 (i.e., anion charge on y-axis). This strong charge balance suggests that detected
331 organic species were balanced by cations detected via IC analysis. Species contributing to the
332 anion deficit likely include a mix of unspciated organic and inorganic anions.

333 TOC was converted to total organic matter (TOM) by multiplying it by 1.8 (Zhang et al., 2005),
334 as in other cloud water studies (Boris et al., 2016; Boris et al., 2018), in order to compare it to
335 total measured mass (i.e., sum of TOM, Na^+ , NH_4^+ , K^+ , Mg^{2+} , Ca^{2+} , Cl^- , NO_2^- , Br^- , NO_3^- , SO_4^{2-}).
336 We caution that using a fixed 1.8 conversion value yields uncertainty as samples were collected
337 in a range of air masses, but 1.8 is a value fairly intermediate to those reported in the literature:
338 1.6 ± 0.2 for urban aerosols (Turpin and Lim, 2001), 2.07 ± 0.05 in nonurban areas (Yao et al.,
339 2016), and values for biomass burning organic aerosols ranging from 1.56 – 2.0 (Aiken et al.,
340 2008; Turpin and Lim, 2001) based on fuel type and combustion condition (Aiken et al., 2008).
341 Higher values are expected for more oxidized organics. Estimated TOM accounted for a median
342 and mean of 23.2% and 30.7%, respectively, of total measured mass, with the maximum for a

343 single sample being 95.1%. The median and mean ratios of MO to TOM were 38.1% and 46.4%,
344 respectively. Furthermore, the median and mean ratios of MO to total measured mass were 7.2%
345 and 10.3%, respectively, with a maximum of 57.6%. On average, chloride, sulfate, and nitrate
346 were the most abundant species ($\geq 12.6\%$), with the median and mean ratio of total inorganic
347 mass to TOM being 3.3 and 5.8, respectively. The pH of the cloud water with TOC
348 measurements ranged from 3.79 – 5.93 and averaged 5.04 ± 0.51 . The lowest pH values all
349 occurred over the ocean.

350 Our calculated percentages of MO relative to total measured mass are in contrast to results from
351 a surface site in Metro Manila (Stahl et al., 2020), where most of the same organic species
352 (adipate, succinate, maleate, oxalate, MSA) accounted for $\sim 1.3\%$ of total aerosol mass, excluding
353 black carbon. Therefore, the first hypothesis of this study holds true that the contributions of
354 measured organic species account for a greater portion of total measured mass in cloud water as
355 compared to surface particulate matter.

356 Gravimetry was used to measure total mass in the surface measurements whereas in cloud water,
357 total measured mass was more restrictive in terms of being based on measurable species, thus
358 qualifying our percentages as an upper bound. However, the measured ions in cloud water should
359 contribute relatively more to total measured mass in cloud water owing to their hygroscopic
360 nature (e.g., sea salt) and greater ease to become associated with cloud water as compared to
361 more hydrophobic species (Chang et al., 2017; Dalirian et al., 2018; Pringle et al., 2010) like
362 black carbon that contribute significantly to total aerosol mass in the boundary layer of Metro
363 Manila (Cruz et al., 2019). For example, black carbon accounted for 78.1% and 51.8% of the
364 total mass between $0.10 - 0.18 \mu\text{m}$ and $0.18 - 0.32 \mu\text{m}$ in Metro Manila surface aerosol particles
365 (Cruz et al., 2019), respectively, size ranges of which are highly relevant to droplet activation.
366 Air masses aloft in the CAMP²Ex region, and especially those processed by clouds, are likely
367 more aged and oxidized compared to fresh organic emissions (e.g., automobiles, industry,
368 burning) in the surface layer over Metro Manila, which is the most populated urban area within
369 the CAMP²Ex flight domain. Recent work has shown that cloud processing of isoprene oxidation
370 products (a key fraction of organic precursor vapors involved with organic aerosol generation) is
371 the main source of secondary organic aerosol (SOA) in the mid-troposphere (4 – 6 km)
372 (Lamkaddam et al., 2021). This motivates examining vertical TOC and organic species
373 characteristics in more detail, which is discussed next.

374

375 **3.2 Vertical Profiles**

376 The vertical profile of TOC masses were of interest as it relates to general vertical distribution of
377 organic matter in the troposphere. Measurements off the coast of Japan approximately two
378 decades ago during the ACE-Asia campaign revealed unexpectedly high organic aerosol
379 concentrations in the free troposphere due to presumed SOA formation (Heald et al., 2005).
380 During that campaign, organic aerosol concentrations in the boundary layer and free troposphere,
381 and their relative contribution to total non-refractory aerosol mass (organic, SO_4^{2-} , NO_3^- , NH_4^+),
382 were amongst the highest of various global regions examined (Heald et al., 2011). Therefore, it is

383 of interest to examine such types of vertical profiles farther south in the CAMP²Ex region where
384 data are more scarce, with the unique aspect of this work being the focus on cloud water
385 composition.

386 The highest TOC masses were observed in the bottom two kilometers, with a general reduction
387 above that altitude (Fig. 3). The decrease of TOC concentration with respect to altitude could be
388 attributed to more dilution in larger droplet sizes; results of cloud microphysical data will be the
389 focus of forthcoming work. Four data points influenced by biomass burning were singled out in
390 red markers (Fig. 3a) owing to having systematically higher TOC masses than other points.
391 Those points will be discussed in more detail in Sect. 4, and it is noteworthy that clouds were
392 impacted by biomass burning across a wide range of altitudes up to almost 7 km.

393 Focusing on the non-biomass burning (non-BB) data, there was considerable variation in the
394 bottom 2 km in TOC, with concentrations as low as 0.144 ppm C and as high as 3.362 ppm C.
395 Interestingly, cloud water collected above 5 km tended to still show enhanced TOC masses,
396 reaching up to 1.530 ppm C (6.1 km) among the non-BB points. The composition contributing to
397 TOC was similar with altitude in non-BB and biomass burning (BB) conditions, with ~75% of
398 TOC mass unaccounted for by the measured species, and MCAs dominating the measured
399 organic mass (Fig. 3b). The exception to that was the high-altitude BB point where 95.6% of
400 TOC was unassigned. Fig. 3c-d show that there was some qualitative agreement in the vertical
401 profile of AMS organic and m/z 44 for data collected immediately adjacent to the cloud water
402 samples in cloud-free air; more specifically, the highest concentrations of AMS organic, m/z 44,
403 and TOC were in the bottom 2 km. However, some interesting differences exist as they related to
404 specific air mass types as will be discussed in Sect. 4. Some differences could be rooted in how
405 AMS data represent submicrometer particles whereas cloud water data encompass a wider range
406 of particle sizes that activated into cloud droplets (including supermicrometer dust and sea salt
407 particles) and also gases partitioning to cloud water.

408 Vertical profiles of ratios representative of the relative amount of oxidized organics are shown in
409 Fig. 4. The MO:TOC ratio was quite variable with altitude ranging from 0.16 to 0.32 based on
410 the locally averaged curve shown; individual sample values ranged from 0.01 to 0.92. Vertically-
411 resolved ratio values for f_{44} in cloud-free air and in cloud (downstream CVI) ranged on average
412 between 0 to 0.35 and 0.13 to 0.35, respectively. While mass concentrations decreased with
413 altitude (Fig. 3), ratios relevant to the degree of organic aerosol oxidation and make-up of the
414 organic component of cloud water did not exhibit a clear change with altitude.

415

416 **4. Case Studies**

417 Four subsets of samples are examined here to probe how the organic nature of cloud water varies
418 for distinct air masses. Sources of the air masses are visually shown in Fig. 5 based on 5-day
419 HYSPLIT back-trajectories: (i) “North” (RF11, $n = 20$) collected off the northern coast of Luzon
420 with influence from East Asia, the Korean Peninsula, and Japan; (ii) “East” (RF13, $n = 11$)
421 collected off the eastern coast of Luzon with back-trajectories traced to southern China with
422 subsequent passage across Luzon before arriving to the area of sample collection; (iii) “Biomass

423 Burning” (RF09, n = 4) collected to the southwest of Luzon above the Sulu Sea with influence
424 from biomass burning plumes from Borneo and Sumatra primarily consisting of peat as the fuel
425 type (Field and Shen, 2008; Levine, 1999; Page et al., 2002; Stockwell et al., 2016; Xian et al.,
426 2013); and (iv) “Clark” (RF04, RF06, RF07, RF09, RF10, and RF11, n = 25) collected around
427 the operational area over Luzon, approximately ~90 km northwest of Metro Manila, with back-
428 trajectories extending to the west and southwest of Luzon.

429 Biomass burning samples were identified based on the following criteria: flight scientist notes,
430 elevated surface smoke concentrations and aerosol optical depth (AOD) from the NAAPS model,
431 and the remarkable enhancement in chemical concentrations in cloud water. TOC, K⁺, SO₄²⁻, and
432 NH₄⁺ in particular were enhanced in these samples with concentrations exceeding 4 ppm C, 0.13
433 ppm, 2.3 ppm, and 2.5 ppm, respectively.

434 Vertical profile results shown previously (Figs. 3-4) show markers corresponding to these four
435 case studies. With the exception of one BB sample collected at 6.5 km, samples in the four cases
436 were obtained below 3.3 km.

437 **4.1 North**

438 This category of samples was unique in that the mean MO (527.5 ± 301.6 ppb) and TOC (636.1
439 ± 230.4 ppb C) concentrations were the lowest of all four cases (Table 2). The largest three
440 organic contributors to TOC (\pm one standard deviation) were acetate (177.8 ± 72.96 ppb C; 11.5
441 $\pm 4.0\%$), oxalate (148.7 ± 81.47 ppb C; $6.0 \pm 1.3\%$), and formate (83.16 ± 79.65 ppb C; $3.0 \pm$
442 2.2%). Maleate and DMA were not detected for this case and 73.3% of the TOC went
443 unaccounted for. Samples in this category were collected between 1.2 and 2.9 km, without any
444 pronounced organic chemical trends with altitude (Figs. 3-4).

445 This case exhibited a few distinct features worth noting. First, it had the highest sea salt presence
446 based on the highest case-wide concentrations of Na⁺ (3238 ± 2861 ppb), Cl⁻ (5277 ± 4333 ppb),
447 Mg²⁺ (347.1 ± 328.3 ppb), and Br⁻ (15.56 ± 8.036 ppb), the latter of which is a trace component
448 of sea salt (Seinfeld and Pandis, 2016). MSA originates partly from marine emissions of DMS,
449 but its concentration was among the lowest of all species for all four cases with a mass
450 contribution to total TOC (based on C mass) of only $0.17 \pm 0.05\%$ in the North category (Table
451 3). In their analysis of aerosol data in the surface layer of Metro Manila, Stahl et al. (2020)
452 showed lower overall organic acid aerosol concentrations in the northeast monsoon season where
453 northeasterly air masses originated predominantly from East Asia; Stahl et al. (2020) also
454 showed those air masses were characterized by an enhancement in organic acid masses in the
455 supermicrometer size range owing to adsorption to coarse particle types such as sea salt and dust,
456 but with a preference for dust (Mochida et al., 2003; Rinaldi et al., 2011; Sullivan and Prather,
457 2007; Turekian et al., 2003). As there was no direct evidence of dust in this case as the Ca²⁺:Na⁺
458 ratio was on average (0.04) nearly the same as sea salt (0.038) (Seinfeld and Pandis, 2016),
459 organic acids could have interacted with sea salt. There were strong correlations between sea salt
460 constituents, TOC, and almost all detected organics (Table S1).

461 The second notable feature of this case was limited air mass aging characteristics based on
462 speciated ratios. The acetate:formate ratio is often used to indicate the relative influence of fresh

463 emissions (higher ratios) as compared to secondary production (lower ratios) (Talbot et al., 1988;
464 Wang et al., 2007). In at least one study, fresh emissions were linked to cloud water ratios above
465 1.5 and aged samples having values below 1 (Coggon et al., 2014). The mean acetate:formate
466 ratio for this air mass category was 4.21 ± 3.26 , which was the highest of all four categories in
467 Table 2, suggestive of fresh emissions and low aging. This was consistent with the $\text{Cl}^-:\text{Na}^+$ ratio
468 (1.70 ± 0.13) being the close to sea water (1.81); our use of this ratio in the study assumes these
469 species originate primarily from sea salt. Lower $\text{Cl}^-:\text{Na}^+$ values in the study region coincide with
470 sea salt reactions with acids such as sulfuric, nitric, and organic acids (AzadiAghdam et al.,
471 2019). This was one of the two cases that had adipate present, with this category exhibiting the
472 highest mean concentration (5.146 ± 6.266 ppb). This suggests there was influence from cyclic
473 organics possibly originating from combustion sources, among others, during the transport to the
474 sample region. Adipate exhibited negative correlations with almost all other organic species in
475 this case ($r: -0.48 - -0.72$), suggestive of limited aging to form shorter chain carboxylic acids via
476 photochemical reactions (Table S1). With the exception of adipate, interrelationships between
477 the other organics detected in this case exhibited positive and significant correlations with one
478 another suggestive of common precursors and/or production mechanisms. Therefore, the results
479 of the North case point to influences from marine emissions and limited aging signatures based
480 on speciated ratios.

481

482 **4.2 East**

483 The dominant organic contributors to TOC (1051 ± 330.6 ppb C) in the East case were the same
484 as the North case with the difference being the order after acetate (\pm one standard deviation):
485 acetate (359.0 ± 40.71 ppb; $14.9 \pm 3.1\%$), formate (258.2 ± 122.2 ppb; $7.2 \pm 3.8\%$), and oxalate
486 (153.6 ± 81.06 ppb; $3.8 \pm 1.2\%$). The percentage of TOC unaccounted for by the speciated
487 measurements (69.4%) was the lowest out of all of the cases. This case resembled the North one
488 in that there was marine influence, but with differences being more pronounced dust influence
489 and greater evidence of aging based on chemical ratios. Marine signatures come from the second
490 highest concentrations of Na^+ , Cl^- , and Mg^{2+} after North, with high correlations between these
491 species (Table S2).

492 Unlike the previous case, the $\text{Ca}^{2+}:\text{Na}^+$ ratio (0.10) was elevated from that of typical sea salt
493 (0.038). Wang et al. (2018) showed that East Asian dust can get lofted up during dust storms,
494 which could contribute to the transport to the Philippines. Previous studies have shown that
495 organic acids adsorb more readily to dust as compared to sea salt due to dust's more alkaline
496 nature (Stahl et al., 2020; Sullivan and Prather, 2007). While Ca^{2+} was correlated to six of the 11
497 organic species for this case ($r: 0.70 - 0.96$; Table S2), the magnitude of the correlations was
498 very similar to those between either Na^+ or Cl^- and the speciated organics. TOC also exhibited
499 similar correlations with Na^+ , Cl^- , and Ca^{2+} ($r: 0.83 - 0.87$). Therefore, it is too difficult with the
500 given data to assert whether (if at all) the organic acids had a preference towards either salt or
501 dust aerosol particles; of note though is that oxalate exhibited the strongest correlation with
502 either Na^+ , Cl^- , and Ca^{2+} ($r: 0.96 - 0.99$) among all species and also TOC. Additionally, Park et
503 al. (2004) showed enhanced Ca^{2+} and NO_3^- in the coarse mode owing to continental Asian dust.

504 In the East case, speciated organics were fairly well correlated to NO_3^- (r : 0.68 – 0.99), which
505 has been associated with adsorption onto coarse aerosol types like dust and sea salt (e.g.,
506 Maudlin et al., 2015; Stahl et al., 2020). Nitrate was especially well correlated with Na^+ , Cl^- , and
507 Ca^{2+} (r : 0.98 – 1.00), which exceeded correlations of other common inorganic ions such as SO_4^{2-}
508 and NH_4^+ .

509 The vertical profiles show clearly the systematically higher TOC masses relative to the North
510 case across roughly the same altitude range (1.3 – 3.3 km), but in contrast the AMS organic and
511 m/z 44 values (although sparse) were more comparable, which again can simply be due to the
512 differences in what is being measured with AMS not accounting for the supermicrometer
513 particles types (i.e., dust and sea salt) that likely were more influential in the cloud water in the
514 East case. However, the importance of droplet uptake of water-soluble organic gases should also
515 be considered as they can influence TOC mass.

516 Evidence of greater aging as compared to the North case comes from a few ratios of interest. The
517 $\text{Cl}^-:\text{Na}^+$ ratio for this case (1.40 ± 0.06) was lower than the North case, suggestive of more sea
518 salt reactivity aided by presumed aging. Furthermore, the acetate:formate ratio (1.93 ± 1.51) was
519 less than half the value from the North case. More broadly, the overall contribution of MCAs and
520 DCAs to TOC were very similar between the North and East cases and also the next two cases:
521 $\text{MCA}:\text{TOC} = 16.03\% - 23.66\%$, and $\text{DCA}:\text{TOC} = 3.70\% - 8.75\%$ (Table 3). In contrast to the
522 North case, this category of samples had weaker interrelationships between organic species
523 presumed to be due to the mixture of sources impacting this case including dust, marine
524 particles, and likely other anthropogenic and biogenic sources over land.

525

526 **4.3 Biomass Burning**

527 The BB category samples exhibited the highest concentrations of TOC (8342 ± 3730 ppb C) and
528 almost every organic with the dominant contributors to TOC (\pm one standard deviation) being
529 formate (2178 ± 1589 ppb; $7.0 \pm 4.5\%$), acetate (1845 ± 1668 ppb; $8.4 \pm 5.6\%$), and succinate
530 (557.0 ± 575.6 ppb; $2.4 \pm 1.7\%$). As acetate and formate were so abundant, the relative
531 enhancement of MCA mass was much larger than DCA mass as compared to the three other
532 cases examined (Table 2). While the correlation matrix for this case was quite sparse in terms of
533 significant values owing partly to such few points ($n = 4$), TOC and K^+ were highly correlated (r :
534 0.99), which demonstrates the strong linkage between TOC and biomass burning emissions
535 (Table S3) as also shown by others (Cook et al., 2017). For context, Desyaterik et al. (2013)
536 reported cloud water TOC masses of 100.6 ppm C in a biomass burning airmass at Mt. Tai in
537 eastern China that was eight times higher than typical values in the absence of agricultural
538 burning. Cook et al. (2017) observed significant higher cloud water TOC masses during wildfire
539 periods at Whiteface Mountain, New York (16.6 ppm C) than biogenic (2.16 ppm C) or urban
540 (2.11 ppm C) periods.

541 In our BB samples, mean values of succinate (557.0 ± 575.6 ppb), glutarate (150.4 ± 82.20 ppb),
542 and pyruvate (125.9 ± 126.1 ppb) were significantly elevated above the other cases. Stahl et al.
543 (2020) recently showed that succinate, oxalate, and MSA were especially enhanced in aerosol

544 samples collected in the study region during BB periods in the 2018 southwest monsoon season.
545 Study-wide peak concentrations of succinate (1372 ppb), oxalate (1135 ppb), and MSA (24.79
546 ppb) were found in this case reinforcing those findings (Stahl et al., 2020). Unlike the previous
547 two cases, maleate was detected in BB samples (5.583 ± 6.456 ppb). Although maleate is
548 associated with combustion sources (Kawamura and Kaplan, 1987; Rogge et al., 1993), such as
549 from extensive ship traffic around the sampling area, other studies have shown enhancements of
550 maleate in BB air masses (i.e., Mardi et al., 2019; Tsai et al., 2013). The percentage of mass
551 contributing to TOC that was unaccounted for was 78.7%, with the highest sample at 6.5 km
552 having 95.6% undetected, which was surprisingly large based on the prevalence of organic acids
553 in biomass burning emissions (Reid et al., 1998). Therefore, the second hypothesis posed in this
554 study is partly true in that the BB case exhibited much higher TOC values; however, these
555 samples did not exhibit a greater contribution by organic acids to TOC since the North and East
556 cases actually had a greater contribution from such species. This motivates more attention to
557 organic chemical speciation in clouds impacted by biomass burning emissions as such a large
558 portion of the TOC mass went unaccounted for in this study.

559 While absolute concentrations of most organics were greatly enhanced in BB, the relative
560 contributions of individual organics within the MCA and DCA subsets of species also varied.
561 Most notably in the MCA category, formate was greatly enhanced with a mass contribution to
562 total MCA mass being 46.40% versus 16.54% – 29.09% for other cases. In the DCA population
563 of species, glutarate and succinate accounted for higher mass fractions (17.15% and 41.95%)
564 than other cases (0.65% – 4.02% and 20.82% – 38.52%, respectively).

565 The $\text{Cl}^-:\text{Na}^+$ ratio was 1.30 ± 0.06 and suggestive of Cl^- depletion, which has been observed in
566 other regions with biomass burning and linked to high concentrations of inorganic and organic
567 acids (Braun et al., 2017, and references therein). This is supported by how the values of MO ,
568 SO_4^{2-} , and NO_3^- were the highest in this case (Table 2). The acetate:formate ratio was $0.69 \pm$
569 0.30 , but it is unclear as to how effective this and other ratios are as aging indicators when
570 biomass burning is present and especially as fuel type varies between regions. Talbot et al.
571 (1988) and Wang et al. (2007) both report that the acetate:formate ratio is substantially larger in
572 biomass burning samples, which is contradictory to the ratios that are reported for this case
573 ranging from 0.32 – 1.03. This could be due to the fuel type or due to aging of the biomass
574 burning plume, however this is speculative and should be examined more extensively.

575

576 **4.4 Clark**

577 Samples in this category were collected during ascents after takeoff and descents during
578 approaches to the airfield, which allowed for sample collection closer to the surface than the
579 other categories (altitude range: 0.2 – 2.9 km). Clark International Airport is located within the
580 Clark Freeport Zone, which is part of both the Pampanga and Tarlac provinces and consists of
581 five cities and municipalities: Angeles City, Mabalacat City, Porac, Capas, and Bamban. This
582 gives the Clark area a population of approximately 996,000 with a population density of ~ 3100
583 km^{-2} , which is low in comparison to the most populated city in the Philippines, Quezon City in

584 Metro Manila, with 2.94 million people and a population density of $\sim 17000 \text{ km}^{-2}$ (PSA, 2016). In
585 addition to Metro Manila just to the southeast ($\sim 90 \text{ km}$), Clark lies between Mt. Pinatubo to the
586 west and Mt. Arayat to the east, which are active and potentially active volcanoes, respectively.

587 The average TOC for this case ($1181 \pm 920.2 \text{ ppb C}$) was most similar to the East case and
588 exhibited the most variability relative to the mean TOC value of all four cases, which we
589 attribute to numerous sources impacting these samples including local and regional emissions,
590 time of day variability, local spatial variability, and number of flights. This case exhibited the
591 highest percentage of TOC mass unaccounted for by speciated organics (79.5%) with the three
592 largest measured contributors (\pm one standard deviation) consisting of acetate (296.7 ± 325.8
593 ppb ; $9.6 \pm 9.5\%$), formate ($266.1 \pm 316.8 \text{ ppb}$; $4.8 \pm 3.3\%$), and oxalate ($88.33 \pm 103.9 \text{ ppb}$; 1.7
594 $\pm 1.0\%$). A few notable features are mentioned specific to this case. This was the only case that
595 had DMA present ($6.454 \pm 15.89 \text{ ppb}$) albeit with a low mass contribution to total TOC ($0.43 \pm$
596 1.17%). This case exhibited the highest mass fractions of maleate ($3.20 \pm 5.93\%$) and adipate
597 ($16.05 \pm 21.48\%$) relative to DCA mass, suggestive of greater anthropogenic emission influence
598 and processed aromatic compounds. DMA was only correlated with maleate ($r: 0.67$) among the
599 organic species suggestive of a similar source (Table S4). Stahl et al. (2020) showed increased
600 aerosol concentrations of freshly emitted organics (i.e., phthalate, maleate) owing to the vast
601 sources of combustion engines to the southeast of the Clark area. Clark is situated near a major
602 highway that could also contribute to the high combustion sources, though commercial aircraft
603 emissions could also have a significant role.

604 Because succinate peaked in concentration for this case (498.50 ppb) and back-trajectories
605 originated from Borneo and Sumatra, there may have been some influence from biomass burning
606 (Fig. 5). The $\text{K}^+:\text{Na}^+$ ratio was elevated (0.25) above that of sea salt (0.036) (Seinfeld and Pandis,
607 2016), and even higher than the Biomass Burning case (0.15), suggestive of local and/or regional
608 biomass burning influence. This case exhibited the highest mean $\text{Ca}^{2+}:\text{Na}^+$ ratio (0.99) that was
609 well above the sea salt value (0.038), which we presume could be linked largely to resuspended
610 and/or transported dust. Cruz et al. (2019) showed for Metro Manila that resuspended dust,
611 especially linked to vehicular traffic, is an important source of dust in the study region. Stahl et
612 al. (2020) showed that adipate is most influenced by crustal sources in the study region and was
613 unique among the studied organics in this work in that it exhibited a prominent peak in the
614 supermicrometer range based on surface aerosol measurements in Metro Manila. Consistent with
615 that work, Ca^{2+} was only correlated with adipate in the Clark samples ($r: 0.71$) among the studied
616 organics (Table S4), adding support for how organic acids like adipate can partition to dust with
617 the novelty here being that the signature was observed in cloud water.

618

619 **5. Conclusion**

620 This work analyzed 159 cloud water samples collected over a 2-month period as part of the
621 CAMP²Ex airborne campaign around the Philippines. TOC and a total of eleven organic
622 compounds comprised of four MCAs (glycolate, acetate, formate, and pyruvate), five DCAs
623 (glutarate, adipate, succinate, maleate, and oxalate), MSA, and DMA were measured. The

624 measured organics were then compared to TOC to determine the percentage of organic species
625 measured compared to the total organic composition. Notable results are summarized below
626 including responses to the two hypotheses proposed at the end of Sect. 1.

- 627 • TOC masses ranged widely between 0.018 – 13.66 ppm C between 0.2 – 6.8 km, with a
628 mean value of 0.902 ppm C. The contribution (in C mass) of the 11 measured species to
629 total TOC was on average 30%. Using a conversion factor of 1.8 for organic matter
630 relative to organic carbon, the mean amount of total organic matter (TOM) accounted for
631 by our measured 11 species was 46.4%. Furthermore, the mean contribution of TOM and
632 speciated organics to total mass (inorganics + organics) was 30.7% (maximum = 95.1%)
633 and 10.3% (maximum = 57.6%), respectively. The mean ratio of inorganic to TOM was
634 5.8. The study's first hypothesis holds true that the measured organic species account for
635 a higher mass fraction relative to total mass as compared to surface layer aerosol
636 measurements over Luzon, excluding black carbon (~1.3%), (Stahl et al., 2020). This is
637 likely owing to more processed air masses aloft and the reduced influence of black
638 carbon that is so abundant in areas like Metro Manila (Cruz et al., 2019; Hilario et al.,
639 2020a). The uptake of water-soluble gases can also attribute to greater organic mass
640 contributions.
- 641 • In terms of the chemical profile of the speciated organics, the order in decreasing
642 contribution of C mass relative to TOC was as follows (\pm one standard deviation): acetate
643 ($14.7 \pm 20.5\%$), formate ($5.4 \pm 9.3\%$), oxalate ($2.8 \pm 4.3\%$), DMA ($1.7 \pm 6.3\%$), succinate
644 ($1.6 \pm 2.4\%$), pyruvate ($1.3 \pm 4.5\%$), glycolate ($1.3 \pm 3.7\%$), adipate ($1.0 \pm 3.6\%$), MSA
645 ($0.1 \pm 0.1\%$), glutarate ($0.1 \pm 0.2\%$), maleate ($< 0.1 \pm 0.1\%$). Approximately 70.0% of
646 TOC went unaccounted for pointing to the complexity and difficulty of organic
647 speciation in the study region, with this value fairly similar to other regions too (Benedict
648 et al., 2012; Boris et al., 2016; Boris et al., 2018; Herckes et al., 2002; Raja et al., 2008).
649 Monocarboxylic acids dominated the speciated organic mass (~75%) and were about four
650 times more abundant than dicarboxylic acids, suggestive of higher abundance of gaseous
651 species and precursors. It should also be noted that MCAs have a higher volatility than
652 DCAs, which could contribute to the higher organic mass. Additionally, the MCAs
653 measured in this study were predominately short chain organics that have naturally higher
654 volatilities (Chebbi and Carlier, 1996; Wang et al., 2007).
- 655 • Vertical profiles of TOC revealed higher concentrations in the bottom 2 km with a
656 reduction above that. Samples impacted by biomass burning emissions were substantially
657 enhanced in TOC and most speciated organic masses, ranging in altitude from as low as
658 1.3 km to as high as 6.5 km. While vertical profiles of AMS organic and m/z 44 mass
659 concentrations qualitatively resembled that of TOC with reductions above 2 km, the
660 vertical behavior of chemical ratios relevant to the composition of the cloud (ratio of C
661 mass from measured organics to TOC) and aerosol organics (f_{44}) did not reveal any clear
662 trend. For both non-BB and BB samples, monocarboxylic acids uniformly dominated C
663 mass with ~75% of TOC mass unaccounted for across the range of altitudes studied.
- 664 • The second hypothesis in this study proved to be partly true as clouds impacted by
665 biomass burning exhibited markedly higher values of TOC (4.974 – 13.66 ppm C) and

666 masses of most all other species detected as compared to the other three categories of
667 samples in Sect. 4 (North, East, Clark). However, the part of the hypothesis about
668 speciated organic acids contributing more to BB samples did not hold true as total
669 measured organics accounted on average for 21.25% of the TOC, which was lower than
670 two of the other categories of samples (North [26.72%] and East [30.61%]). Interestingly,
671 the highest BB sample (6.5 km) had 95.6% of the C mass unaccounted for by speciated
672 organics. This motivates increased attention to organic speciation in clouds impacted by
673 biomass burning.

674 • Four categories of samples with different air mass history characteristics were compared
675 revealing a few notable features: (i) while speciated concentrations and TOC masses
676 varied considerably between the four cases, the contributions of MCAs and DCAs (based
677 on C mass) to TOC were remarkably similar with little variation (MCA:TOC = 16.03% –
678 23.66%, DCA:TOC and 3.70% – 8.75%); (ii) dust and sea salt tracer species were
679 strongly correlated to most all speciated organics for the North and East cases suggestive
680 of interactions between such species and coarse aerosol surfaces as supported by past
681 work (Stahl et al., 2020; Sullivan and Prather, 2007); (iii) for samples with limited aging
682 (North case) based on selected chemical ratio values, adipate was more abundant and
683 negatively correlated to smaller carboxylic acids; (iv) BB samples exhibited the highest
684 TOC concentrations (8342 ± 3730 ppb C) as well as significant elevations in individual
685 organics such as acetate, formate, succinate, glutarate, pyruvate, oxalate, and MSA; and
686 (v) the Clark case had a higher variability of TOC (1181 ± 920.2 ppb C) compared to the
687 North and East cases presumably owing to a greater mix of influential sources such as
688 fresh anthropogenic emissions (e.g., enhanced maleate), but also transport of biomass
689 burning plumes from Borneo and Sumatra (e.g., enhanced succinate), dust, as well as
690 spatial and temporal variances across different flights. Related to dust, Ca^{2+} was only
691 correlated to adipate in the Clark samples, consistent with a recent study in Metro Manila
692 (Stahl et al., 2020) showing that adipate uniquely exhibits a prominent supermicrometer
693 peak among organic acids attributed to interactions with dust.

694

695 **Data availability**

696 All data used can be found on the NASA data repository at
697 DOI:10.5067/Suborbital/CAMP2EX2018/DATA001.

698

699 **Author contributions**

700 EC, RAB, CS, ABM, and AS designed the experiment. All coauthors carried out various aspects
701 of the data collection. EC, CS, and AS conducted analysis and interpretation of the data. CS and
702 AS prepared the manuscript with contributions from the coauthors.

1120

1121 **Table 1:** Mass concentration limits of detection (LOD), minimum, maximum, mean, one
 1122 standard deviation, and median values (ppb; left), in addition to mass fraction (%; right) for the
 1123 159 CAMP²Ex cloud water samples with TOC data; note that mass fraction values depend on the
 1124 C mass of each organic species shown. Total measured mass is defined as the sum of TOM, Na⁺,
 1125 NH₄⁺, K⁺, Mg²⁺, Ca²⁺, Cl⁻, NO₂⁻, Br⁻, NO₃⁻, and SO₄²⁻. MCA – monocarboxylic acids, DCA –
 1126 dicarboxylic acids, MSA – methanesulfonate, DMA – dimethylamine, MO – measured organics,
 1127 TOM – total organic matter, DL – detection limit.

1131 **Table 3:** Average organic composition for each case study where the first, second, and third
 1132 group of rows show percentage contribution (%) of individual components to monocarboxylic
 1133 acids (MCA), dicarboxylic acids (DCA), and total organic carbon (TOC), respectively.

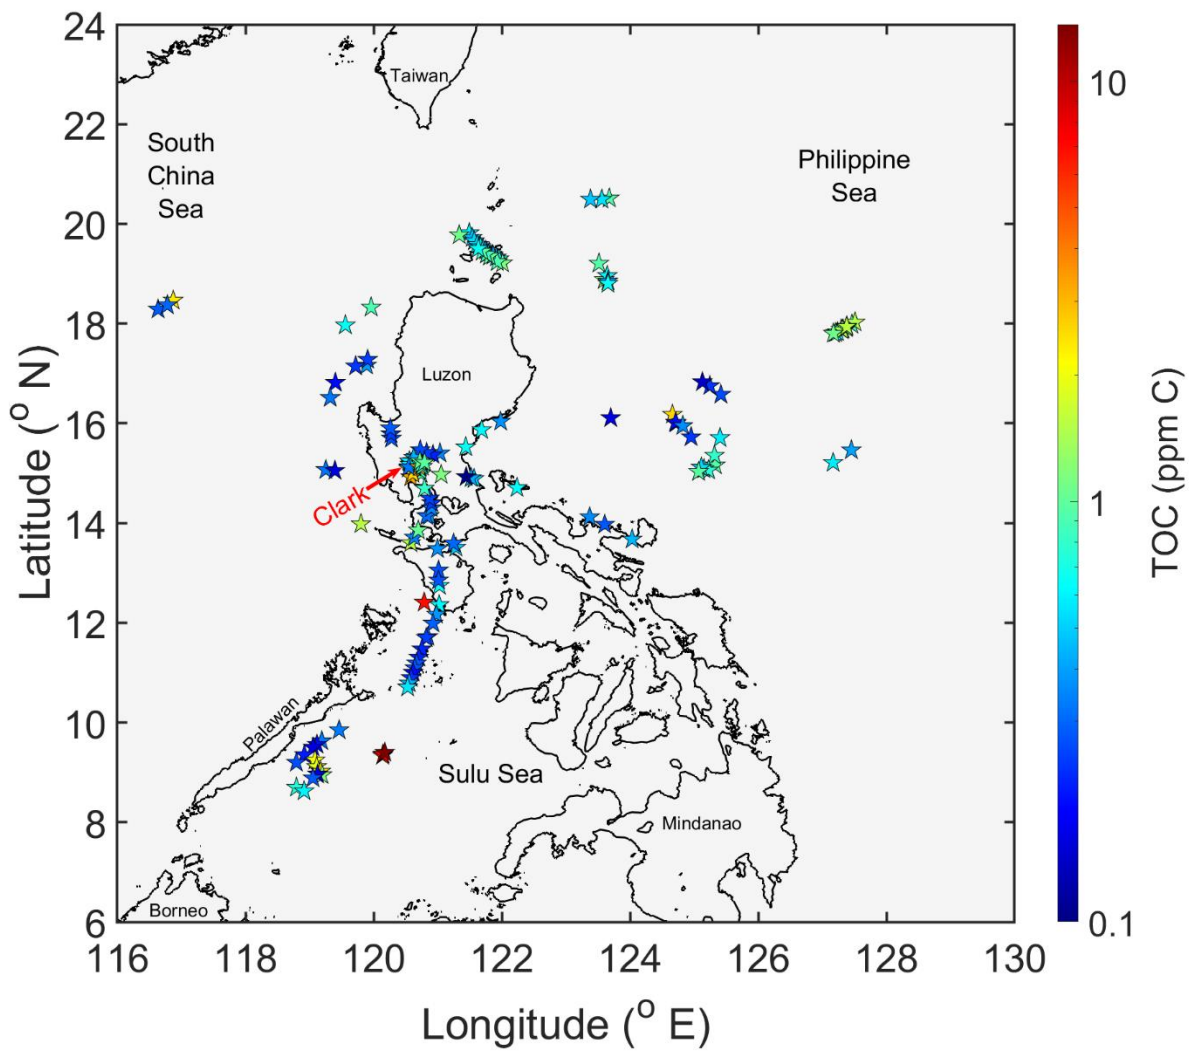

Group	Species (%)	North (n = 20)		East (n = 11)		BB (n = 4)		Clark (n = 25)	
		Mean	Stdev	Mean	Stdev	Mean	Stdev	Mean	Stdev
MCA	Glycolate	7.20	9.20	1.84	0.81	5.09	9.87	17.65	29.05
	Acetate	64.03	17.74	64.20	10.85	45.86	14.07	46.35	23.98
	Formate	16.54	9.83	28.62	10.35	46.40	7.24	29.09	11.72
	Pyruvate	12.23	6.90	5.33	2.87	2.65	1.87	6.91	4.90
DCA	Glutarate	0.65	1.00	2.91	1.41	17.15	9.28	4.02	5.02
	Adipate	8.04	9.47	0	0	0	0	16.05	21.48
	Succinate	20.82	20.08	38.52	12.15	41.95	25.27	26.53	25.39
	Maleate	0	0	0	0	0.75	0.88	3.20	5.93
	Oxalate	70.49	12.29	58.57	11.52	40.16	16.50	50.20	17.42

1134

1135

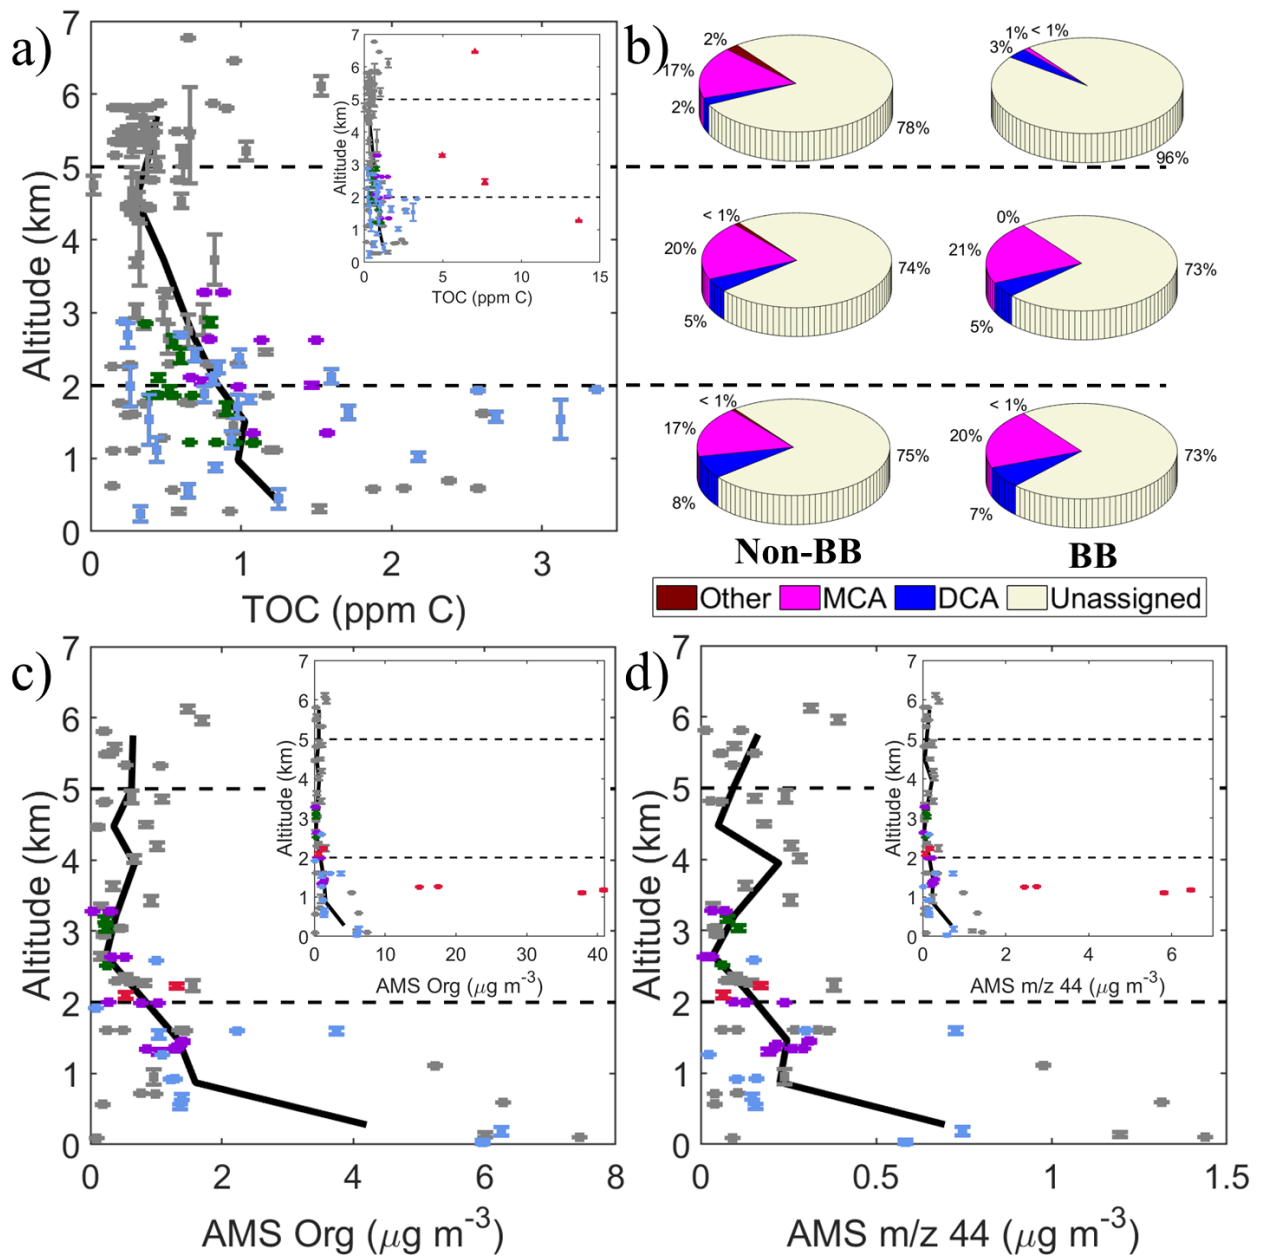

1136 **Figure 1:** TOC (or DOC if TOC values were unavailable) concentrations reported for past
 1137 studies in relation to this work organized by continent. Bars represent the average values and the
 1138 error bars represent the minimum and maximum values. The absence of a solid bar means no
 1139 average was available. No error bars means there was no range given, and * indicates the median
 1140 value was reported rather than an average. Gray, yellow, and blue bars represent studies looking
 1141 at fog, clouds, and rain, respectively. Bars that are outlined in black are studies that used TOC
 1142 and bars outlined in red are studies that used DOC. The n values represent the number of samples
 1143 used in the study and NL means the number of samples were not listed. Bolded n values denote
 1144 airborne samples. This figure is similar to that of Figure 2 in Herckes et al. (2013) with
 1145 additional information presented and organized by continent. (a - Boris et al. (2018), b - Collett Jr. et
 1146 al. (1998), c - Herckes et al. (2002), d - Herckes et al. (2007), e - Straub et al. (2007), f - Erel et al. (1993),

1153

1154 **Figure 2:** Map of sample region where the stars represent the midpoint of the cloud water
 1155 samples where total organic carbon (TOC) was measured. Stars are colored by TOC on a
 1156 logarithmic scale.

1157

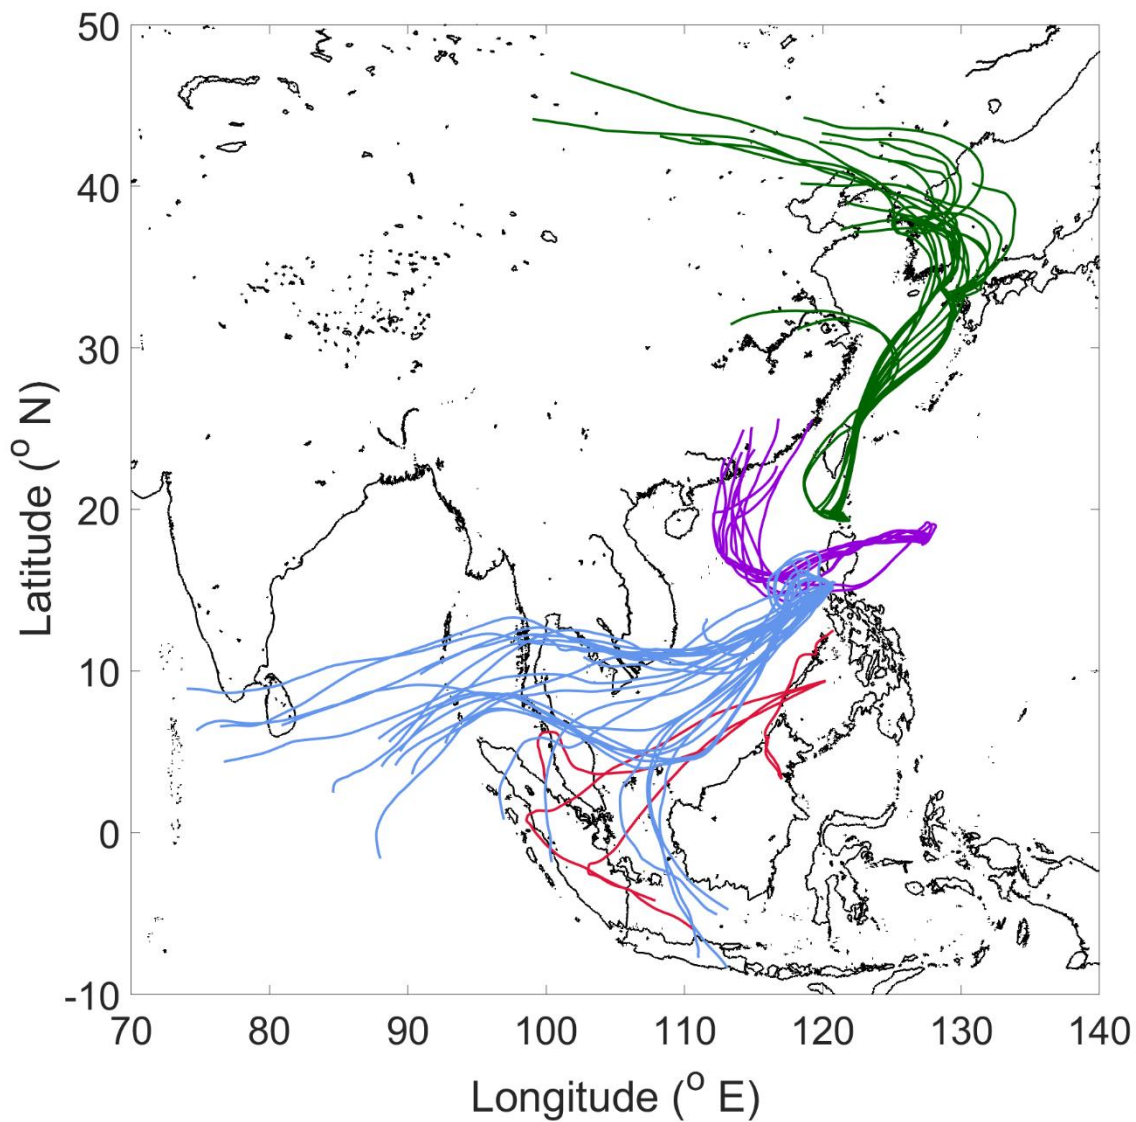

1158

1159 **Figure 3.** (a) Vertical profile of TOC concentrations (n = 159 samples) with the smaller inset
 1160 including four samples with enhanced TOC owing to biomass burning (BB) influence. (b) Mass
 1161 fractions of different subsets of species contributing to TOC at high (> 5 km), mid (2 – 5 km),
 1162 and low (< 2 km) altitude with the beige area representing undetected species. Vertical profile of
 1163 AMS (c) organic and (d) m/z 44 corresponding to spatially and temporally adjacent cloud-free
 1164 periods of the collected cloud water samples. Colors in panels a/b/d represent the case study
 1165 points in Sect. 4: North (green), East (purple), Biomass Burning (red), Clark (blue), non-case
 1166 points (gray). The solid black lines in panels a/b/d represent locally-weighted average values.
 1167 The error bars represent one standard deviation of the altitude variance.

1168

1169 **Figure 4.** Vertical profile of (a) ratio of C mass from measured organics (MO) to TOC for cloud
 1170 water samples, (b) AMS f_{44} in cloud-free air, and (c) AMS-CVI f_{44} in cloudy air. AMS data in (b)
 1171 corresponds to cloud-free periods that were spatially and temporally adjacent to the collected
 1172 cloud water samples, while those in (c) are within the period of cloud water collection times in
 1173 cloud. Colors in panels a/b/d represent the same case study points as Figure 3: North (green),
 1174 East (purple), Biomass Burning (red), Clark (blue), non-case points (gray). The black lines in
 1175 panels a/b/d represent locally-weighted average values.

1176

1177 **Figure 5:** Spatial summary of 120-hour back trajectories for each sample included in respective
1178 case study sample sets: North (green; n = 20), East (purple; n = 11), Biomass Burning (red; n =
1179 4), and Clark (blue; n = 25).
