18 **Abstract.** Strict seasonal emission controls are a popular measure in China for addressing severe air pollution, in  
19 particular fine particulate matter (PM<sub>2.5</sub>). Here we evaluate the efficacy of these measures, with a particular focus  
20 on the strict emission controls imposed on pollution sources in 28 cities in and around the Beijing-Tianjin-Hebei  
21 region (BTH) in autumn-winter 2017/2018. For this we use the GEOS-Chem chemical transport model and air  
22 pollutant measurements from the national and Beijing local monitoring networks, after evaluating the network  
23 data with independent measurements and correcting large biases in the bottom-up emissions inventory. The  
24 network measurements are temporally consistent ( $r > 0.9$  for PM<sub>2.5</sub> and  $r > 0.7$  for gases) with the independent  
25 measurements, though with systematic differences of 5-17% for nitrogen dioxide (NO<sub>2</sub>) and 16-28% for carbon  
26 monoxide (CO). The average decrease in monitoring network PM<sub>2.5</sub> in BTH in autumn-winter 2017/2018 relative  
27 to the previous year is 27%, declining from 103 to 75  $\mu\text{g m}^{-3}$ . The regional decline in PM<sub>2.5</sub> in the model is 20%,  
28 exceeding the regional target of 15%. According to the model, pollution control measures led to decline in PM<sub>2.5</sub>  
29 precursor emissions of 0.27 Tg NO<sub>x</sub> (as NO), 0.66 Tg sulfur dioxide (SO<sub>2</sub>), 70 Gg organic carbon (OC), and 50  
30 Gg black carbon (BC). We find though that these alone only lead to an 8% decline in PM<sub>2.5</sub> and that interannual  
31 variability in meteorology accounts for more than half (57%) the decline. This demonstrates that year-on-year  
32 comparisons are misleading for assessing the efficacy of air pollution measures and should be taken into  
33 consideration when extending such measures beyond BTH.

## 34 **1 Introduction**

35 Strict seasonal emission controls are an increasingly popular measure to reduce severe air pollution in China, in  
36 particular elevated concentrations of fine particles, or PM<sub>2.5</sub>, in autumn-winter. The Chinese government improved  
37 such measures in 28 cities in and around the Beijing-Tianjin-Hebei region (BTH) (so-called “2+26” cities) in

38 northern China in autumn and winter 2017/2018. Targets were set to reduce regional mean  $PM_{2.5}$  by 15% and  
39 city-specific  $PM_{2.5}$  by 10-25% relative to the previous year (MEE, 2017). BTH experiences severe air pollution  
40 in China despite substantial decline in  $PM_{2.5}$  of ~40% from 2013 to 2017 from enacting emission controls as part  
41 of the 5-year Action Plans (Zhang et al., 2019). Annual mean  $PM_{2.5}$  in BTH in 2017 was  $64 \mu\text{g m}^{-3}$  (Wang et al.,  
42 2019); far greater than the national standard of  $35 \mu\text{g m}^{-3}$  (MEE, 2012) and the World Health Organization (WHO)  
43 guideline of  $10 \mu\text{g m}^{-3}$ . Severe pollution days (defined as days with 24-hour mean  $PM_{2.5} \geq 150 \mu\text{g m}^{-3}$ ), mostly in  
44 autumn and winter, have declined in frequency, but still occurred in 78 days in 2016. Down from 122 days in  
45 2013 (Li et al., 2019a). Severe  $PM_{2.5}$  pollution is due to a combination of large primary emissions of particles and  
46 gas-phase precursors from multiple sources (Zhang et al., 2018), very active heterogeneous chemistry enhancing  
47 formation of secondary inorganic and organic aerosols (Huang et al., 2014), and accumulation of pollution due to  
48 meteorological conditions such as low windspeeds, shallow planetary boundary layer and high relative humidity  
49 (RH) (An et al., 2019; Bei et al., 2020; Le et al., 2020; Wu et al., 2019).

50

51 Dominant local  $PM_{2.5}$  sources in BTH in autumn-winter include sustained contributions from the energy sector  
52 and road traffic (Tong et al., 2020), and seasonal contributions from industrial and residential combustion of coal  
53 and other solid fuels (Ma et al., 2017; Yun et al., 2020), and widespread burning of crop residue (Li et al., 2020c).  
54 Mitigation measures in China have led to a nation-wide decrease in emissions of the primary  $PM_{2.5}$  components  
55 black carbon (BC) and organic carbon (OC) of 28% for BC and 32% for OC from 2013 to 2017 (Zheng et al.,  
56 2018). Emissions of prominent gas-phase  $PM_{2.5}$  precursors such as nitrogen oxides ( $NO_x \equiv NO + NO_2$ ) and sulfur  
57 dioxide ( $SO_2$ ) have declined by 21% for  $NO_x$  and 59% for  $SO_2$  over the same time period. Trends in other  $PM_{2.5}$   
58 precursors are less certain. Emissions of ammonia ( $NH_3$ ), mostly from agriculture, are likely to have increased or  
59 remained constant (Zheng et al., 2018). Similar to  $NH_3$ , emissions of non-methane volatile organic compounds  
60 (NMVOCs), mostly from industrial activity and solvent use, are either stable or increasing (Li et al., 2019c; Liu  
61 et al., 2018b; Zhang et al., 2017a; Zheng et al., 2018). Non-local sources also make a substantial contribution to  
62  $PM_{2.5}$  in BTH throughout the year. Dong et al. (2020) used a regional air quality model to estimate that regional  
63 transport of non-local  $PM_{2.5}$  accounted for 33-68% of total monthly mean  $PM_{2.5}$  in BTH in 2017.

64

65 Many mitigation measures were implemented in autumn-winter 2017/2018 to reduce  $PM_{2.5}$  in the 28 cities in and  
66 around BTH. These are detailed in the “Air Pollution Action Plan in Autumn and Winter of 2017-2018 for the  
67 Beijing-Tianjin-Hebei Region and its Surrounding Areas” report by the Chinese Ministry of Ecology and  
68 Environment (MEE) (MEE, 2017). Briefly, these include a sector-wide cap on total consumption of coal, phase-  
69 out of small inefficient and outdated industrial coal-fired boilers, reduction in production capacity of heavy  
70 industries such as iron and cement, switching from coal to cleaner fuels in homes, and mandated controls on  
71 construction site fugitive dust emissions. Other short-term and reactionary measures included shutdown of  
72 intensive industries and construction sites throughout the emission control period and instantaneous shutdown of  
73 additional industrial plants in response to forecasts of elevated  $PM_{2.5}$ . Tougher emission standards and higher  
74 quality vehicular fuel were imposed on on-road vehicles. Agricultural residue burning was banned and strictly  
75 enforced, and installation of emission control technologies were mandated for all large emitters of industrial  
76 NMVOCs. The MEE used national network observations of  $PM_{2.5}$  to determine that regional reduction targets  
77 were achieved in BTH and that only 3 of the 28 cities did not meet their city-specific targets (MEE, 2018).

78

79 As demonstrated by studies assessing changes in air quality during the lockdown period in response to the SARS-  
80 CoV-2 pandemic, variability in meteorology is also a large contributor to fluctuations in air quality in BTH (Le et  
81 al., 2020; Shi et al., 2021). This necessitates that assessment of the efficacy of such measures includes detailed  
82 understanding of the contribution of strict emission controls and other factors like meteorology. A recent study  
83 by Zhang et al. (2021) assessed city-scale changes in air quality in each of the 28 cities using the high-resolution  
84 Community Multi-Scale Air Quality model coupled to the Weather Research and Forecasting Model for  
85 meteorology (CMAQ-WRF). CMAQ-WRF was driven with a national bottom-up inventory for the year preceding  
86 the emission controls and a regional bottom-up emission inventory for the year of the emission control period.  
87 They determined that the contribution of emission controls to the decrease in simulated PM<sub>2.5</sub> in each city ranged  
88 from 2% to 82% and that meteorology was often a dominant contributor, ranging from 18% to 98%. Here we take  
89 a regional perspective, after correcting for large biases in the bottom-up emission inventories for BTH with the  
90 China national and Beijing regional monitoring network observations which we also assess against independent  
91 measurements. We apply the corrected inventory to the GEOS-Chem chemical transport model (CTM) to  
92 determine regional-scale emission reductions resulting from strict mitigation measures in autumn-winter  
93 2017/2018 and the contribution of these and meteorology to improved regional air quality, as such measures are  
94 now widely adopted in China.

## 95 **2 Air pollutant concentration changes detected with the national and local monitoring networks**

96 Ambient monitoring of PM<sub>2.5</sub> and trace gases in BTH includes reference monitors from the China National  
97 Environmental Monitoring Network (CNEMN) and the local Beijing Municipal Environmental Monitoring  
98 Network (BJMEMN) (Zhang et al., 2020). We use observations of hourly SO<sub>2</sub>, NO<sub>2</sub>, CO, and PM<sub>2.5</sub> for the  
99 autumn-winter emission reduction period (2017/2018) and the preceding year (2016/2017) at sites operational in  
100 both years: 402 for CNEMN and 35 for BJMEMN. Data from both networks are from the Sina Air Quality Data  
101 Platform (<http://beijingair.sinaapp.com/>; last accessed 17 October 2020, now hosted at <https://quotsoft.net/air/>).  
102 Data from both networks have been extensively used to quantify changes in surface air pollution (Li et al., 2019b;  
103 Silver et al., 2018; Wan et al., 2021; Wang et al., 2014; Zhai et al., 2019), though independent evaluation of the  
104 measurements is limited. A previous study used statistical techniques and intercomparison of air pollutant  
105 measurements to determine that outliers make only a small contribution ( $\leq 1\%$ ) to measurements of air pollutants  
106 relevant to this work (Wu et al., 2018).

107

108 We assess CNEMN and BJMEMN measurements against PM<sub>2.5</sub> from the US Embassy in Beijing and PM<sub>2.5</sub> and  
109 trace gas (SO<sub>2</sub>, NO<sub>2</sub>, and CO) measurements from the winter portion of the intensive Atmospheric Pollution &  
110 Human Health in a Chinese Megacity (APHH) campaign, hereafter referred to as APHH. The APHH campaign  
111 included a comprehensive suite of aerosol and gas-phase measurements from the 325-m tower at the urban  
112 Institute of Atmospheric Physics (IAP) measurement site and a few air quality measurements at a rural site (Pinggu)  
113 located ~60 km from the Beijing city centre (Shi et al., 2019). APHH data are from the National Environmental  
114 Research Council (NERC) Centre for Environmental Data Archive (CEDA) (Fleming et al., 2017). US Embassy  
115 PM<sub>2.5</sub> measurements in Beijing, obtained with US EPA measurement and quality control protocols (Martini et al.,  
116 2015), are from the US Department of State Air Quality Monitoring Program (<http://www.stateair.net/>; last

117 accessed 17 October 2020) for autumn-winter 2016/2017 and from the OpenAQ data portal  
118 (<http://www.openaq.org/>; last accessed 17 October 2020) for autumn-winter 2017/2018. We use APHH data for  
119 November-December 2016 and US Embassy PM<sub>2.5</sub> for October 2016-March 2017 and October 2017-March 2018.  
120 These are compared to the nearest national and local monitoring network sites. For APHH, these are the CNEMN  
121 Aotizhongxin site (39.98°N, 116.40°E) and the BJMEMN Xizhimenbei site (39.95°N, 116.35°E), each located  
122 ~3 km from the APHH urban site (39.97°N 116.37°E). For the US Embassy, these are the CNEMN site  
123 Nongzhanguan (39.94°N, 116.46°E) and the BJMEMN site Dongsihuan (39.94°N, 116.48°E), each ~1 km from  
124 the US Embassy (39.95°N, 116.47°E).

125

126 Figure 1 compares hourly CNEMN and BJMEMN PM<sub>2.5</sub> to APHH and US Embassy PM<sub>2.5</sub>. PM<sub>2.5</sub> from both  
127 CNEMN and BJMEMN are temporally consistent with APHH and US Embassy PM<sub>2.5</sub> ( $r \geq 0.96$ ). The surface  
128 monitoring networks also reproduce the variance in hourly PM<sub>2.5</sub> (Slopes of 1.0-1.1). Network sites are  
129 systematically higher than APHH by 10% for CNEMN and 17% for BJMEMN, though compared to US Embassy  
130 site PM<sub>2.5</sub> the difference is small, ranging from negligible (0.2% less) to 6.4% more than US Embassy PM<sub>2.5</sub>. In  
131 general, the BJMEMN measurements are 6-17% more than APHH, likely due to spatial variability in local  
132 emissions. The decline in PM<sub>2.5</sub> in the control period relative to the previous year at these sites is 43% according  
133 to US Embassy PM<sub>2.5</sub>, decreasing from 97  $\mu\text{g m}^{-3}$  to 55  $\mu\text{g m}^{-3}$ . A similar decline is obtained with the nearby  
134 BJMEMN (43% decline) and CNEMN (42% decline) sites shown in Fig. 1.

135

136 Figure 2 compares hourly trace gas measurements from CNEMN, BJMEMN and APHH. The CNEMN and  
137 BJMEMN trace gas instruments include chemiluminescence for NO<sub>2</sub>, UV fluorescence for SO<sub>2</sub>, and IR absorption  
138 for CO. Though CO is not a precursor of PM<sub>2.5</sub>, its abundance affects the oxidative potential of the atmosphere  
139 and also offers a means to indirectly assess PM<sub>2.5</sub> precursor emissions of NMVOCs that oxidize to form CO. Most  
140 measurements from the local and national networks, with the exception of 31% of the CNEMN SO<sub>2</sub> data and 16%  
141 of the BJMEMN SO<sub>2</sub> data, are above the instrument detection limit (indicated in Fig. 2). The surface network is  
142 temporally consistent with APHH ( $r > 0.7$  for all species). CNEMN NO<sub>2</sub> is <10% more than NO<sub>2</sub> from APHH,  
143 likely due to susceptibility of the monitoring network instruments to interference from decomposition of NO<sub>x</sub>  
144 reservoir compounds to NO<sub>2</sub> (Dunlea et al., 2007; Reed et al., 2016). Shah et al. (2020) estimate a positive bias of  
145 ~6% due to this interference. Differences in CNEMN SO<sub>2</sub> (19% less than APHH) and CO (16% more than APHH)  
146 are large and reflect differences in variance (CNEMN vs APHH SO<sub>2</sub> slope of 0.8, CNEMN vs APHH CO slope  
147 of 1.4). BJMEMN exceeds APHH by 17-28% for all trace gases.

148

149 To aid interpretation of the differences between the network sites and independent measurements, we also assess  
150 consistency between CNEMN and BJMEMN for the sites shown in Figs. 1 and 2. These are ~5 km apart and the  
151 BJMEMN site is closer to a heavily trafficked ring road than the CNEMN site. The sites are strongly correlated for  
152 PM<sub>2.5</sub> ( $r = 0.97$ ) and all trace gases ( $r = 0.89$ - $0.92$ ), but CNEMN is less than BJMEMN by 11% for NO<sub>2</sub>, 33% for  
153 SO<sub>2</sub>, 9% for CO, and 6% for PM<sub>2.5</sub> due to the lower relative influence of road traffic sources. This is consistent  
154 with the relatively large positive differences between BJMEMN and the independent measurements in Figs. 1 and  
155 2.

156

157 Both networks also measure ozone, but we do not consider this here, as ozone pollution is most severe in spring  
158 and summer in China (Yang et al., 2020). We estimate mean ozone of 15-19  $\mu\text{g m}^{-3}$  at the two monitoring network  
159 sites used in Fig. 2. This can be compared to the summer mean ozone air quality metric, mean maximum daily 8-  
160 h average ozone, of 120-160  $\mu\text{g m}^{-3}$  in northern China (Li et al., 2019b).

161

162 We show in Fig. 3 the spatial distribution of the network observed changes in air pollutant concentrations in and  
163 around BTH in the control period (autumn-winter 2017/2018) relative to the preceding year (autumn-winter  
164 2016/2017). In what follows, we refer to these time periods as AW2017 for autumn-winter 2017/2018 and  
165 AW2016 for autumn-winter 2016/2017. Only CNEMN and BJMEMN sites that are operational in both periods  
166 are used. These include 164 sites within the control domain (region shaded grey in Fig. 3) and 273 sites in the  
167 surrounding area. The decline in air pollutant concentrations in AW2017 relative to AW2016 at sites within the  
168 emission control region is 16% for  $\text{NO}_2$ , 44% for  $\text{SO}_2$ , 31% for CO, and 29% for  $\text{PM}_{2.5}$ , surpassing the 15%  $\text{PM}_{2.5}$   
169 reduction target set for BTH. Surface concentrations of ozone (not shown) increase by 19% in response to decline  
170 in  $\text{NO}_x$ . Even with this increase, ozone is still substantially lower than in spring and summer (Liu et al., 2018a).  
171 Smaller reductions of 0.5% for  $\text{NO}_2$ , 31% for  $\text{SO}_2$ , 13% for CO, and 10% for  $\text{PM}_{2.5}$  occur in the surrounding area.  
172 In the southeast portion of the domain shown in Fig. 3, both  $\text{NO}_2$  and  $\text{PM}_{2.5}$  increase by 5-8%. Fang et al. (2019)  
173 reported an increase in emissions from industries in the non-control area that in Fig. 3 appear to offset air quality  
174 improvements that would be expected from decline in influence of pollution from BTH.

### 175 **3 BTH air pollution and emissions for the year preceding emission controls**

176 We use the GEOS-Chem model (version 12.0.0; <https://doi.org/10.5281/zenodo.1343547>) with the evaluated  
177 surface network measurements to constrain precursor emissions of  $\text{PM}_{2.5}$  in and around BTH. The model is nested  
178 over East Asia ( $11^\circ\text{S}$ - $55^\circ\text{N}$ ,  $60^\circ$ - $150^\circ\text{E}$ ) at a horizontal resolution of  $0.5^\circ \times 0.625^\circ$  (latitude  $\times$  longitude). The model  
179 is driven with assimilated meteorology from the NASA Modern-Era Retrospective analysis for Research and  
180 Applications version 2 (MERRA-2) updated hourly for 2D fields and every 3 hours for 3D fields. Dynamic (3-  
181 hourly) boundary conditions are from a global simulation at  $4^\circ \times 5^\circ$ . Monthly anthropogenic emissions for China  
182 in AW2016 are from the regional bottom-up Multi-resolution Emission Inventory for China (MEIC)  
183 (<http://www.meicmodel.org/>; last accessed 4 March 2020) available for 2000-2017 at  $0.5^\circ \times 0.625^\circ$ . MEIC  
184 includes emissions of  $\text{SO}_2$ ,  $\text{NO}_x$ , CO, NMVOCs,  $\text{NH}_3$ , and primary particles from  $\sim 700$  anthropogenic sources  
185 (Zheng et al., 2018; Li et al., 2017). In its implementation in GEOS-Chem, MEIC emissions are lumped into five  
186 sectors: industry, power plants, transportation, agriculture and residential. Primary particles are emitted as  
187 hydrophobic and hydrophilic BC and OC, and speciated NMVOCs are mapped to those in GEOS-Chem using the  
188 NMVOCs species mapping tables in Li et al. (2014).

189

190 The model includes detailed coupled gas- and aerosol-phase chemistry to represent the formation and loss of  $\text{PM}_{2.5}$ .  
191 Individual aerosol components are modelled as externally mixed. These include sulfate, nitrate, ammonium (Park  
192 et al., 2004; Wang et al., 2013), OC (Heald et al., 2006), BC (Li et al., 2016), dust (Fairlie et al., 2007), and sea  
193 salt (Jaegle et al., 2011). Formation of secondary sulfate-nitrate-ammonium aerosols are computed with  
194 ISORROPIA-II (Fountoukis and Nenes, 2007). Physical loss processes include dry and wet deposition (Amos et  
195 al., 2012; Liu et al., 2001; Wang et al., 1998). We implement a revised treatment of wet scavenging described and

196 first implemented in GEOS-Chem by Luo et al. (2019). This replaces fixed values of in-cloud condensation water  
197 with dynamic values from MERRA-2. This leads to more rapid wet deposition rates and addresses a positive bias  
198 in modelled nitrate and ammonium, in particular in winter, when compared to surface observations in China,  
199 Europe, and the US (Luo et al., 2020). We sample the model in AW2016 and AW2017 following two months  
200 spin-up before each period of interest for chemical initialization.

201

202 We find from initial comparison of the model to the surface observations that the model in AW2016 is  
203 considerably less than observed NO<sub>2</sub> (by 48%), SO<sub>2</sub> (by 42%), and CO (by 57%) over the entire domain shown  
204 in Fig. 3. We attribute this to an underestimate in precursor emissions of these in the MEIC. Previous studies  
205 reported that MEIC trends in NO<sub>x</sub>, SO<sub>2</sub>, and CO emissions are consistent with trends in satellite observations of  
206 column densities and weather-normalised surface measurements (Vu et al., 2019; Zheng et al., 2018), but studies  
207 assessing and identifying similar underestimates to ours are limited to very local assessment of the inventory.  
208 Squires et al. (2020) determined that MEIC NO<sub>x</sub> and CO emissions are overestimated at the urban APHH site  
209 from comparison to fluxes calculated using the eddy-covariance method, though their comparison was for  
210 different years (measurements in 2016, MEIC in 2013). We calculate scale factors to apply to the MEIC based on  
211 our initial comparison to the network site measurements. These include spatially uniform scale factors of 1.5  
212 applied to NO<sub>x</sub> emissions and 2.4 applied to CO emissions across the whole domain shown in Fig. 3. Spatially  
213 variable scale factors of 2.1-6.8 are applied to seven grid squares for the MEIC SO<sub>2</sub> emissions. These are  
214 concentrated in Shanxi province west of BTH, a region with large coal-fired power plants (Xie et al., 2018). These  
215 grids account for the majority of the domain average 42% underestimate in modelled SO<sub>2</sub> concentrations. Local  
216 enhancements in CO can include primary emissions and secondary contributions from oxidation of NMVOCs.  
217 Emission inventory estimates of NMVOCs are subject to large uncertainties, mainly due to poorly quantified  
218 industrial emissions (Li et al., 2017) and lack of reliable data for scattered areal sources such as residential coal  
219 burning (Li et al., 2019c; Peng et al., 2019; Shi et al., 2020). We find though that modelled CO is relatively  
220 unaffected by NMVOCs emissions. A sensitivity simulation with MEIC NMVOCs emissions increased by 50%  
221 only increases surface CO concentrations by 0.2%. Given this, we attribute the model underestimate in CO surface  
222 concentrations to the emissions. We do not adjust MEIC primary emissions of BC and OC, due to limited  
223 constraints on these from the observations. APHH eddy covariance fluxes of BC obtained in winter suggest a  
224 large overestimate (59 times) in MEIC BC emissions (Joshi et al., 2021), though this may be due to very local  
225 influence of traffic that is diluted at the resolution of the MEIC (Joshi et al., 2021).

226

227 Figure 4 compares GEOS-Chem and monitoring network air pollutant concentrations for BTH and the  
228 surrounding area after applying scale factors to MEIC emissions of SO<sub>2</sub>, NO<sub>x</sub>, and CO. Emissions scaling of NO<sub>x</sub>  
229 improves the modelled variance in NO<sub>2</sub>. The regression slope increases from 0.86 (not shown) to 0.93 (Fig. 4).  
230 There is still an underestimate in modelled background NO<sub>2</sub> (intercept = -12.8 μg m<sup>-3</sup>) that leads to a model NO<sub>2</sub>  
231 normalized mean bias (NMB) of -33%. The monitoring network includes sites close to busy roads that may be  
232 influenced by local traffic emissions that would be diluted at the 50-67 km resolution of the model. The BJMEMN  
233 sites are categorised by location and we find that excluding roadside sites leads to a 5-8% decrease in mean  
234 BJMEMN NO<sub>2</sub> (2-8% decrease for the other pollutants) and would only partially resolve the remaining  
235 underestimate in modelled NO<sub>2</sub> in Fig. 4. Other factors that could contribute to the remaining discrepancy include

236 short atmospheric lifetime of NO<sub>2</sub>, relatively coarse model resolution, and a positive 5-17% bias in the monitoring  
237 network measurements (Fig. 2). Any further increases in MEIC NO<sub>x</sub> emissions would worsen the model NMB in  
238 PM<sub>2.5</sub> of 15%, as nitrate from oxidation of NO<sub>x</sub> is the dominant component of PM<sub>2.5</sub> (29% in AW2016 for the  
239 entire domain in Fig. 3, according to GEOS-Chem).

240

241 Emissions scaling of SO<sub>2</sub> improves spatial consistency for concentrations of SO<sub>2</sub> from  $r = 0.54$  (not shown) to  $r$   
242  $= 0.90$  (Fig. 4). There is still a model bias -29% mostly due to 2 grids in Shanxi province with observed SO<sub>2</sub> of  
243 161-200 μg m<sup>-3</sup> and modelled SO<sub>2</sub> of 109-122 μg m<sup>-3</sup> (Fig. 4). The model underestimate in CO decreases from -  
244 57% to -14% and the remaining model bias may be due to a 16-28% positive bias in the monitoring network (Fig.  
245 2). The improvement in spatial correlation for CO is marginal, increasing from  $r = 0.35$  to  $r = 0.45$ . Scaling MEIC  
246 emissions of SO<sub>2</sub> and NO<sub>x</sub> increases the modelled PM<sub>2.5</sub> NMB from 8% with the original emissions to 15% with  
247 the scaled emissions. This may be due to remaining uncertainties in MEIC emissions of BC, OC, and NH<sub>3</sub>.

248

249 Figure 5 compares observed and modelled PM<sub>2.5</sub> composition at the urban and rural APHH sites. The model  
250 overestimates total PM<sub>2.5</sub> by 10% at the urban site and 34% at the rural site. Components are measured with a  
251 semicontinuous analyzer for OC and BC (Han et al., 2014; Kondo et al., 2006) and ion chromatography following  
252 particle collection with a Partisol for sulfate, nitrate, and ammonium (Taiwo et al., 2014; Xu et al., 2021). OC is  
253 compared instead of organic aerosol (OA), due to uncertainties in conversion of OC to OA (Xing et al., 2013).  
254 According to the observations, OC is the dominant PM<sub>2.5</sub> component, with a carbon mass contribution to total  
255 PM<sub>2.5</sub> of 23% at the urban site and 33% at the rural site. The total contribution of secondary inorganic aerosols is  
256 similar (31%) at both sites and includes 9% sulfate, 13% nitrate, and 9% ammonium at the urban site and similar  
257 contributions (8% sulfate, 13% nitrate, and 10% ammonium) at the rural site. BC is 4% of total PM<sub>2.5</sub> at both sites.  
258 The model underestimates OC (9% urban, 10% rural) and sulfate (both 4%), overestimates nitrate (28%, 30%),  
259 slightly overpredicts BC (4%, 5%), and is similar for ammonium (both 10%).

260

261 Previous studies have reported similar biases in simulated OC, sulfate and nitrate in China from GEOS-Chem  
262 (Miao et al., 2020) and other CTMs (Chen et al., 2019; Gao et al., 2018). Miao et al. (2020) reported a year-round  
263 underestimate in OA that they attribute to biases in precursor emissions and lack of seasonality in fixed secondary  
264 OA (SOA) yields used to estimate SOA formation from precursor emissions of NMVOCs. They also identified a  
265 year-round underestimate in sulfate that peaks at 54% in winter (Miao et al., 2020), similar to the 50%  
266 underestimate we obtain at the urban IAP site. The model underestimate in sulfate may in part be due to the  
267 remaining underestimate in MEIC SO<sub>2</sub> emissions (Fig. 4) after scaling MEIC SO<sub>2</sub> emissions. The model may also  
268 be missing key sulfate formation processes during haze events (Bloss et al., 2021; Wang et al., 2016; Wang et al.,  
269 2020), though the measurements may also be impacted by interference from hydroxymethane sulfonate (HMS)  
270 (Moch et al., 2018; Song et al., 2019). The overestimate in modelled nitrates is a common issue and has been  
271 attributed by Miao et al. (2020) to an overestimate in aerosol nitrate precursors at night exacerbated by errors in  
272 boundary layer dynamics. Despite biases in PM<sub>2.5</sub> composition, the model reproduces day-to-day variability in  
273 24-hour mean PM<sub>2.5</sub> ( $r = 0.66-0.71$ ) and its components ( $r = 0.50-0.78$ ) at both sites.

274

275 Figure 6 shows total anthropogenic emissions of gaseous PM<sub>2.5</sub> precursors and primary PM<sub>2.5</sub> (OC and BC) for  
276 AW2016 obtained after applying scaling factors to the MEIC based on discrepancies in modelled and observed  
277 air pollutant concentrations. Total anthropogenic emissions in BTH (area shaded grey in Fig. 3) in AW2016, the  
278 year prior to the control period, are 2.4 Tg NO<sub>x</sub> as NO, 1.6 Tg SO<sub>2</sub>, 150 Gg BC, 240 Gg OC, and 41 Tg CO.  
279 NMVOCs (2.0 Tg C) and NH<sub>3</sub> (0.64 Tg) are not shown in Fig. 6, as these are unchanged from AW2016 to  
280 AW2017. Though emissions of NO<sub>x</sub>, CO and SO<sub>2</sub> increase in AW2016 relative to the default MEIC emissions  
281 due to our emissions scaling, there is no change in the relative contribution of different sectors. The major sector  
282 contributions include industry for NO<sub>x</sub> (44%), SO<sub>2</sub> (56%), and CO (39%), transport for NO<sub>x</sub> (34%), and residential  
283 fuel use for domestic heating and cooking for SO<sub>2</sub> (28%), CO (42%), BC (47%) and OC (79%).

#### 284 **4 Influence of emissions and meteorology on air quality in AW2017**

285 To estimate the emission changes in the model due to controls implemented in BTH in AW2017, we regrid the  
286 relative changes in the surface air quality observations (Fig. 3) to a 1° × 1.25° resolution grid to achieve reasonably  
287 extensive coverage across the whole domain shown in Fig. 3. For grids without surface observations (17% of the  
288 grids in the emission control region, 51% outside it), we interpolate across nearest neighbouring grids.  
289 Anthropogenic emissions beyond the geographic limits in Fig. 3 are unchanged. Due to lack of observations of  
290 OC and BC concentrations, we initially use the relative change in total measured PM<sub>2.5</sub>. This ranges from a  
291 decrease in AW2017 relative to AW2016 of 5% to 53% in BTH. We find with this initial approach that the model  
292 underestimates the percent reduction in PM<sub>2.5</sub> in AW2017 relative to AW2016. This suggests that the decline in  
293 primary PM<sub>2.5</sub> may be greater than the decline in total PM<sub>2.5</sub>, corroborated by the greater decline in primary PM<sub>2.5</sub>  
294 emissions in the bottom-up inventories used by Zhang et al. (2021) than the decline in measured total PM<sub>2.5</sub> for  
295 around half of the 28 cities. This may be because the regulations mostly targeted sources that have large primary  
296 PM<sub>2.5</sub> emissions, such as coal combustion, industry, vehicles, fugitive dust and biomass burning (Zhang et al.,  
297 2017b; Zheng et al., 2017). We iterate to obtain BC and OC emissions scaling factors that are 1.4 times more than  
298 the percent change in total PM<sub>2.5</sub>.

299

300 Figure 7 shows the spatial distribution of modelled and observed PM<sub>2.5</sub> concentrations and relative changes in  
301 PM<sub>2.5</sub> in and around BTH. The average decrease in observed PM<sub>2.5</sub> is 28% in BTH, declining from 103 μg m<sup>-3</sup> in  
302 AW2016 to 75 μg m<sup>-3</sup> in AW 2017. A similar decline is obtained with the model for grids coincident with the  
303 sites (25% decrease from 112 μg m<sup>-3</sup> in AW2016 to 85 μg m<sup>-3</sup> in AW2017). The decline in modelled PM<sub>2.5</sub> for all  
304 BTH grids is 20% and compared to 16% for the whole domain. In Beijing, observed PM<sub>2.5</sub> decreases from 96 μg  
305 m<sup>-3</sup> in AW2016 to 57 μg m<sup>-3</sup> in AW2017, a 40% reduction. The decline in the model for all 13 grids covering  
306 Beijing (39.25-41.25°N, 115.3125-117.8125°E) is more modest (33% decline from 75 μg m<sup>-3</sup> in AW2016 to 50  
307 μg m<sup>-3</sup> in AW2017) than the grids coincident with the monitoring network sites. Regardless, both values exceed  
308 the 25% target set for Beijing (MEE, 2017).

309

310 Figure 8 further compares observed and modelled relative changes in PM<sub>2.5</sub>. This confirms the skill of the model  
311 at reproducing the relative change in PM<sub>2.5</sub>, despite an overall positive bias in total PM<sub>2.5</sub> (Figs. 4 and 7) and  
312 individual PM<sub>2.5</sub> components (Fig. 5). The modelled relative changes in PM<sub>2.5</sub> are somewhat more spatially  
313 consistent with the observations in BTH ( $r = 0.82$ ) than the surrounding area ( $r = 0.76$ ). The variance is closer to

314 unity for BTH (slope = 0.84) than the surrounding area (slope = 0.74). The relative change in  $PM_{2.5}$  outside the  
315 emission control domain is -10% according to the observations, and -11% in the coincident model grids. During  
316 the emission control period, the area surrounding BTH in the domain shown in Fig. 7 is likely influenced by  
317 anthropogenic emissions from neighbouring regions that are the same in AW2017 and AW2016. This may account  
318 for the differences in the direction of change for 14 model grids (decline) compared to the observations (increase)  
319 in Fig. 8.

320

321 The emissions that we estimate for the control period (AW2017) are also shown in Fig. 6. According to our  
322 approach, total emissions reductions in AW2017 compared to AW2016 in BTH are 0.27 Tg  $NO_x$  as NO, 0.66 Tg  
323  $SO_2$ , 9.7 Tg CO, 70 Gg OC, and 50 Gg BC. Emissions of  $NH_3$  and NMVOCs are unchanged due to limited  
324 constraints on these. There is an Ammonia Monitoring Network in China (AMoN-China), but there are only 8  
325 sites in BTH, and the data are not publicly available (Pan et al., 2018). Relating  $NH_3$  concentrations to emissions  
326 is also complicated by its ability to partition to sulfate aerosols (Fu et al., 2017) that decline by 36%, according to  
327 the model, in AW2017 relative to AW2016 due to decline in  $SO_2$  emissions. There were also no mandatory  
328 measures targeting  $NH_3$  sources during AW2017. Agricultural activities such as fertilizer and livestock excreta  
329 (Huang et al., 2012), dominant  $NH_3$  sources in China, are also at a minimum in autumn and winter (Kong et al.,  
330 2019). Zhang et al. (2021) reported that  $NH_3$  emissions were relatively unchanged in almost half of the 28 cities  
331 and varied in others from a 35% decrease to a 33% increase. Controls in BTH in AW2017 should have targeted  
332 NMVOCs sources, but these have limited effect on  $PM_{2.5}$  according to GEOS-Chem. The sensitivity simulation  
333 we conducted with a 50% increase in NMVOCs emissions only causes a 1% increase in surface concentrations of  
334  $PM_{2.5}$ . Mechanisms leading to the formation of wintertime SOA are not well understood. Field campaigns in  
335 winter in Beijing suggest significant SOA formation from oxidation of NMVOCs (Li et al., 2020a; Li et al., 2020b),  
336 whereas Wang et al. (2021) propose that rapid aqueous-phase oxidation of primary OA dominates SOA formation  
337 and would resolve the observed decline in SOA in Beijing in winter at the same time that NMVOCs emissions  
338 have remained relatively constant.

339

340 We also quantify the contribution of meteorology to the decline in  $PM_{2.5}$  in AW2017. To do this, we compare  
341 modelled  $PM_{2.5}$  from the AW2017 simulation (Fig. 7) to a simulation with AW2017 emissions and AW2016  
342 meteorology. The decline in  $PM_{2.5}$  in BTH due to differences in AW2016 and AW2017 meteorology only is 12  
343  $\mu g m^{-3}$  or 57% of the decline in  $PM_{2.5}$  from changes in both emissions and meteorology. The contribution of  
344 meteorology is similar, 54%, in the surrounding area. Our estimate is slightly less than the city-scale study by  
345 Zhang et al. (2019). They attribute 70% of the decline in  $PM_{2.5}$  in BTH to variation in meteorology using CMAQ  
346 driven with WRF meteorology and the national MEIC and regional Beijing emissions inventories. Zhang et al.  
347 (2021) identified large variability in the contribution of emissions and meteorology to decline in  $PM_{2.5}$  across the  
348 28 cities, of 2-82% for emissions and 18-98% for meteorology. We find that the meteorological factors  
349 contributing to decline in  $PM_{2.5}$  in BTH in AW2017 include dilution and dispersion of pollution due to stronger  
350 south-easterly winds and a 7% higher planetary boundary layer in AW2017 than AW2016. Efficiency of formation  
351 of secondary inorganic aerosols would also be less in AW2017 than AW2016 in response to 5% lower RH.  
352 Interannual variability in RH has similarly been identified as the cause for sustained air pollution over BTH despite  
353 a dramatic decline in precursor emissions from lockdown measures imposed to mitigate the spread of the SARS-

354 CoV-2 virus (Le et al., 2020). The meteorological factors that we identified with GEOS-Chem are consistent with  
355 those identified by Zhang et al. (2021) using WRF.

## 356 **5 Conclusions**

357 Strict emission controls were implemented across 28 cities in and around the Beijing-Tianjin-Hebei region (BTH)  
358 in autumn-winter 2017/2018 to address severe air pollution, specifically fine particles (PM<sub>2.5</sub>). We used national  
359 and local surface monitoring network observations of PM<sub>2.5</sub> and trace gases with the GEOS-Chem model to assess  
360 the efficacy of emission controls, following evaluation of the network with independent measurements.

361

362 PM<sub>2.5</sub> and trace gases (NO<sub>2</sub>, SO<sub>2</sub> and CO) from the surface networks are temporally consistent with independent  
363 measurements ( $r > 0.9$  for PM<sub>2.5</sub> and  $r > 0.7$  for gases) and exhibit discrepancies that are in large part due to  
364 variability of these in the urban environment. According to these networks, PM<sub>2.5</sub> in BTH decreased by 28% from  
365 103  $\mu\text{g m}^{-3}$  to 75  $\mu\text{g m}^{-3}$  in the control period relative to the previous year, exceeding the regional target of 15%.

366 The model with emissions scaled to address large biases in NO<sub>x</sub>, SO<sub>2</sub>, and CO emissions, reproduces the spatial  
367 distribution in PM<sub>2.5</sub> ( $r = 0.68$ ). Despite a 15% positive bias in total PM<sub>2.5</sub> and large biases in PM<sub>2.5</sub> composition,  
368 the model captures the relative decline in PM<sub>2.5</sub> in BTH of 25%. According to the model constrained with the  
369 network measurements, decline in emissions in BTH due to strict controls are 0.27 Tg NO<sub>x</sub> as NO, 0.66 Tg SO<sub>2</sub>,  
370 9.7 Tg CO, 70 Gg OC, and 50 Gg BC. These account for less than half the observed decline in PM<sub>2.5</sub> and alone  
371 lead to an 8% reduction in PM<sub>2.5</sub>, falling shorting of PM<sub>2.5</sub> reduction target. The remainder is due to meteorology,  
372 specifically a deeper planetary boundary layer, stronger winds, and lower relative humidity during the control  
373 period.

374

375 This supports the need for much stricter emissions controls in BTH and other parts of China where these controls  
376 are now adopted.

## 377 **Data Availability**

378 The GEOS-Chem model outputs used in this study are available at:

379 [https://github.com/GongdaLu/BTH\\_emission\\_control](https://github.com/GongdaLu/BTH_emission_control).

## 380 **Author Contributions**

381 GLu performed the GEOS-Chem simulations, analysed the model and measurement data, and prepared the  
382 manuscript. EAM assisted in the writing and provided supervisory guidance, with co-supervision and editorial  
383 contributions from ZS. JDL provided APHH gas concentration data. ZS, TVV and JX performed PM composition  
384 analyses and provided guidance on using APHH data. QZ provided the original MEIC emission inventory that LS  
385 processed for input to GEOS-Chem. GLuo and FY provided source codes for the updated wet scavenging scheme  
386 in GEOS-Chem.

## 387 **Competing Interests**

388 The authors declare that they have no conflicts of interest.

389 **Acknowledgements**

390 This work was funded by a China Scholarship Council scholarship awarded to GLu and a NERC/EPSRC grant  
391 (grant number EP/R513465/1) awarded to EAM. ZS acknowledges funding from the NERC APHH-Beijing  
392 programme (grant number NE/N007190/1).

679

680

681 **Figure 1.** Evaluation of local and national network PM<sub>2.5</sub> measurements. Points are hourly PM<sub>2.5</sub> measurements. The top row  
682 compares CNEMN to the APHH urban site (left), and CNEMN to the US Embassy in autumn-winter 2016/2017 (AW2016)  
683 (centre) and 2017/2018 (AW2017) (right). The bottom row compares BJEMN to the APHH urban site (left), and BJEMN  
684 to the US Embassy in AW2016 (centre) and AW2017 (right). Reduced major axis (RMA) regression statistics, Pearson's  
685 correlation coefficients ( $r$ ), and the percent difference (Diff = monitoring network minus independent measurement) are given.  
686 Lines are the RMA regression (red) and 1:1 line (blue dashed).

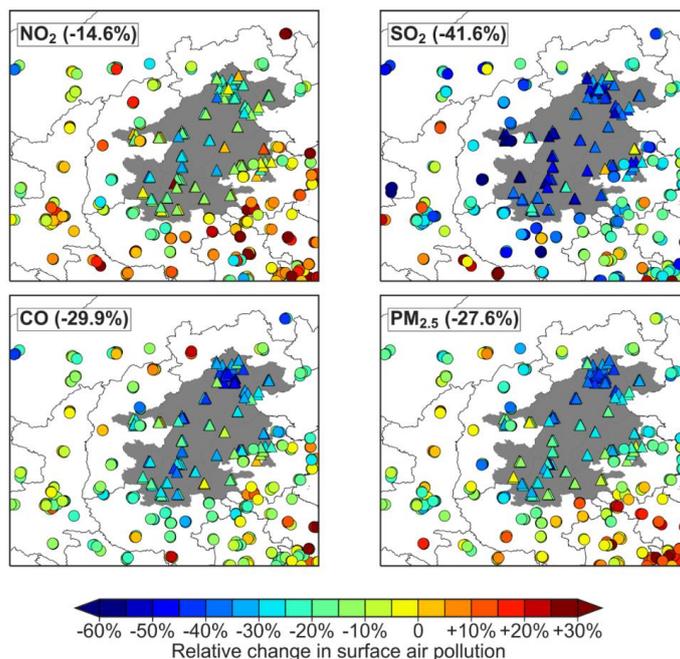

687

688

689 **Figure 2.** Evaluation of local and national network trace gas concentration measurements. Points are hourly measurements.  
690 Panels compare CNEMN (top) and BJEMN (bottom) NO<sub>2</sub> (left), SO<sub>2</sub> (centre) and CO (right) to the APHH urban site in  
691 November-December 2016. RMA regression statistics, Pearson's correlation coefficients ( $r$ ), and the percent difference (Diff  
692 = monitoring network minus independent measurement) are given. Lines are the RMA regression (red) and 1:1 line (blue  
693 dashed). The green dashed line is the reported monitoring network instrument detection limit (MEE, 2012).

694

695

696

697

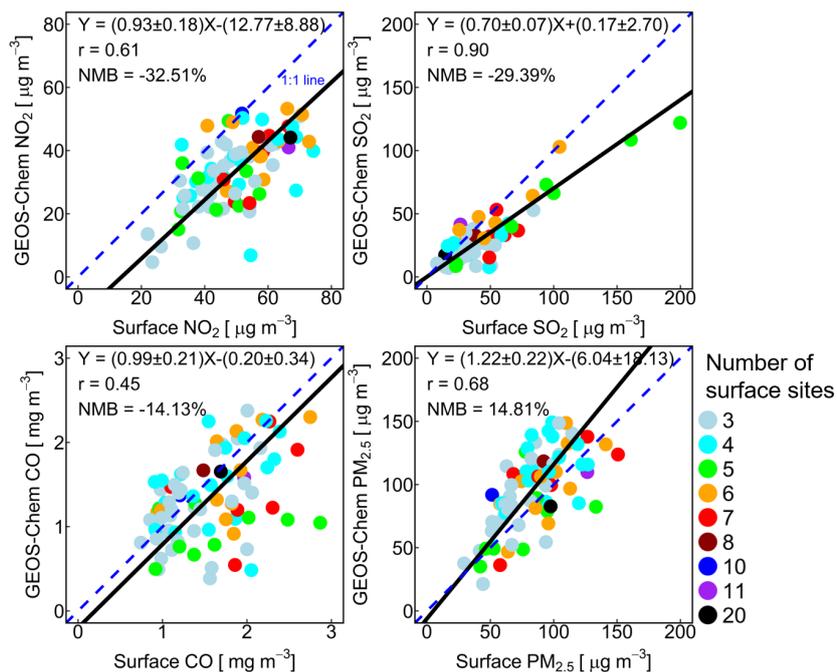

698

699

**Figure 3.** Change in surface air pollution in BTH and the surrounding area in AW2017 relative to AW2016. Individual points are monitoring network site changes for the target region (triangles within area shaded grey) and the surrounding area (circles in the non-shaded area). Values inset give the percent change for sites in the grey domain only. Note the colourbar is uneven.

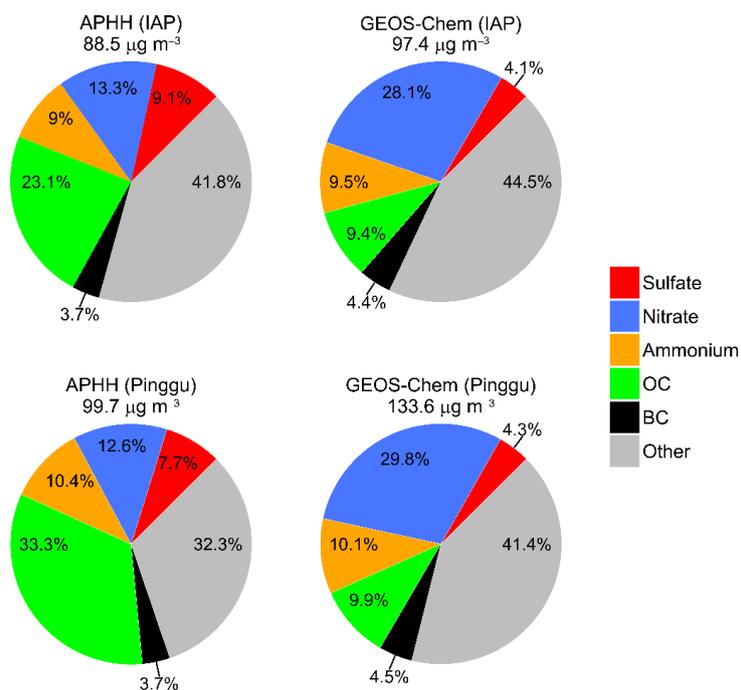

700

701

702 **Figure 4.** Evaluation of GEOS-Chem simulation of air pollutant concentrations in AW2016. Observations are averaged onto  
703 the GEOS-Chem grid. Points are simulated and observed NO<sub>2</sub> (top left), SO<sub>2</sub> (top right), CO (bottom left) and PM<sub>2.5</sub> (bottom  
704 right) in the entire domain in Figure 3 for grid squares with at least three coincident surface sites. Points are coloured by the  
705 number of surface sites. The model uses scaled MEIC emissions (see text for details). RMA regression statistics, Pearson's  
706 correlation coefficients (r), and model normalized mean biases (NMB) are given. Lines are the RMA regression (black) and  
707 1:1 line (blue dashed).

708

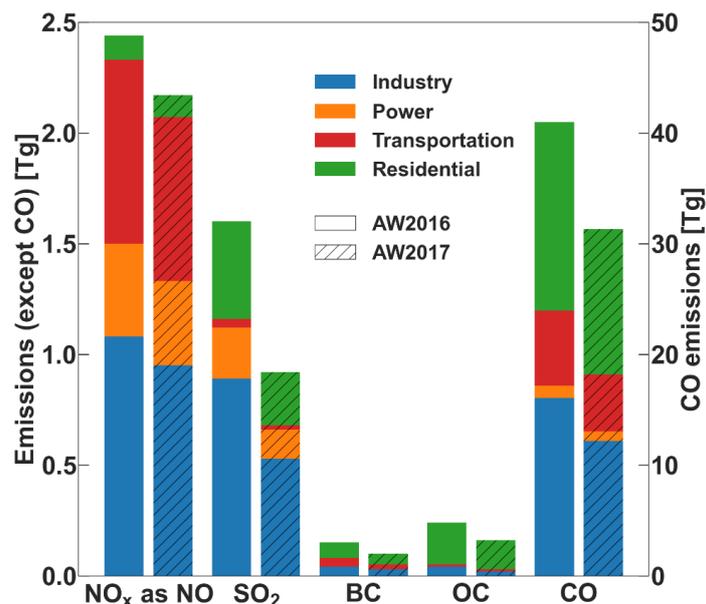

709

710 **Figure 5.** Relative contribution of individual  $\text{PM}_{2.5}$  components during the APHH campaign. Panels are measured (left) and  
711 modelled (right) percent contribution for the urban IAP (top) and rural Pinggu (bottom) sites. Components are sulfate, nitrate,  
712 ammonium, OC, BC and Other. Other is the sum of trace metals, mineral dust and other ions, the non-carbon portion of OC,  
713 and aerosol water at 33-35% relative humidity (RH) for the measurements and 35% RH for the model. Values above the pies  
714 are mean total  $\text{PM}_{2.5}$ .

715

716

717

718 **Figure 6.** Total anthropogenic emissions in BTH in AW2016 and AW2017. Emissions are for grids covering the grey shaded  
 719 area in Figure 3. Emissions are from the MEIC with scaling factors to address discrepancies between the model and  
 720 observations for AW2016 and to reproduce the change in air pollutant concentrations in the AW2017 emission control period  
 721 (see text for details). Vertical axes are emissions for NO, BC, OC, and SO<sub>2</sub> on the left axis and for CO on the right axis.

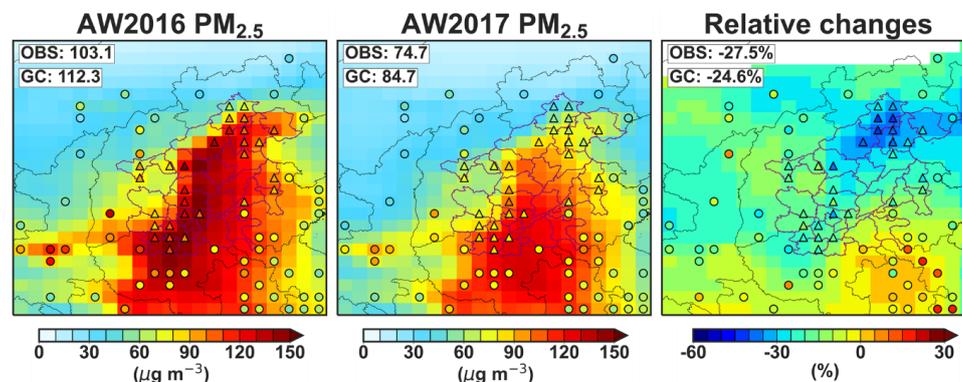

722

723

724

725

726

727

728

729

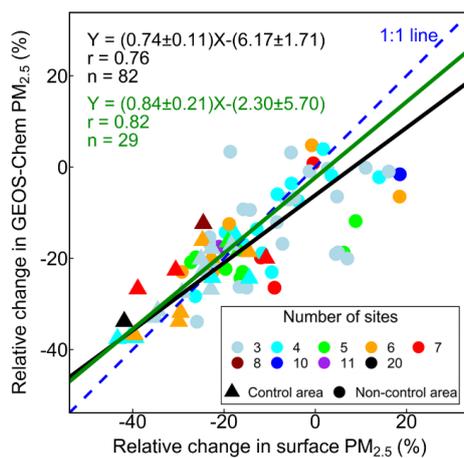

730

731

732

733

**Figure 7.** Spatial distribution of absolute and relative changes in observed and modelled PM<sub>2.5</sub> before and during the strict  
 emission control period. The observed (shapes) and modelled (background) PM<sub>2.5</sub> are shown for AW2016 (left) and AW2017  
 (centre). The right panel is the relative change in observed and modelled PM<sub>2.5</sub>. Observations are distinguished as within  
 (triangles) and outside (circles) the emission control region (grey area in Figure 3). Inset values are the observed (OBS) and  
 modelled (GC) means for sites and coincident grids in the emission control domain. Note the uneven colour scale in the right  
 panel.

734

735 **Figure 8.** Comparison of observed and modelled relative changes in  $PM_{2.5}$ . Triangles indicate data in BTH (grey area in Figure  
736 3) and circles indicate data outside BTH. These are coloured by the number of sites in each GEOS-Chem grid. The RMA  
737 regression statistics and lines, Pearson's correlation coefficients ( $r$ ), and NMB are given for all points (black text) and for those  
738 in BTH (green text).

739
