## 20 Abstract

21 Aerosol acidity plays a key role in regulating the chemistry and toxicity of atmospheric aerosol particles. 22 The trend of aerosol pH and its drivers are crucial in understanding the multiphase formation pathways 23 of aerosols. Here, we reported the first trend analysis of aerosol pH from 2011 to 2019 in eastern China, 24 calculated with ISORROPIA model based on observed gas and aerosol compositions. The 25 implementation of the Air Pollution Prevention and Control Action Plan led to -35.8%, -37.6%, -9.6%, -26 81.0% and 1.2% changes of  $PM_{2.5}$ ,  $SO_4^{2-}$ ,  $NH_x$ , non-volatile cations (NVCs) and  $NO_3^{-}$  in the Yangtze 27 River Delta (YRD) region during this period. Different from the fast changes of aerosol compositions 28 due to the implementation of the Air Pollution Prevention and Control Action Plan, aerosol pH showed 29 a minormoderate change of -0.24 unit over the 9 years. Besides the multiphase buffer effect, the opposite 30 effects from the changes of  $SO_4^{2-}$  and non-volatile cations played key roles in determining the moderate 31 pH trend, contributing to a change of +0.38 and -0.35-unit, respectively. Seasonal variations in aerosol 32 pH were mainly driven by the temperature, while the diurnal variations were driven by both temperature 33 and relative humidity. In the future,  $SO_2$ ,  $NO_x$  and  $NH_3$  emissions are expected to be further reduced by 34 86.9%, 74.9% and 41.7% in 2050 according to the best health effect pollution control scenario (SSP1-35 26-BHE). The corresponding aerosol pH in eastern China is estimated to increase by  $\sim 0.19$ , resulting in 36 4% more NO<sub>3</sub><sup>-</sup> and 12% more NH<sub>4</sub><sup>+</sup> partitioning/formation in the gas phase, which suggests that NH<sub>3</sub> and 37 NO<sub>x</sub> emission controls are effective in mitigating haze pollution in eastern China.

38

## 39 1 Introduction

Aerosol acidity is an important parameter in atmospheric chemistry. It affects the particle mass and chemical composition by regulating the reactions of aerosols, and is closely associated with human health, ecosystems and climate\_(Li et al., 2017; Nenes et al., 2020b; Pye et al., 2020; Su et al., 2020). Aerosol acidity has attracted an increasing concern in recent years because of its impacts on the thermodynamics of gas-particle partitioning, pH-dependent condensed-phase reactions and trace metal solubility\_(Cheng et al., 2016; Fang et al., 2017; Guo et al., 2017b; Guo et al., 2016; He et al., 2018; Song et al., 2018; Weber et al., 2016; Su et al., 2020; Tilgner et al., 2021). 47 Thermodynamic models, such as E-AIM (Clegg et al., 1998) and ISORROPIA II are most commonly 48 used for aerosol pH estimations, due to the limitations and difficulties in its direct measurements-of 49 aerosol pH (Fountoukis and Nenes, 2007; Hennigan et al., 2015). The Previously reported aerosol pH 50 reported globally generally ranges ranged from -1 to 6 in the global scale (Pye et al., 2020; Zheng et al., 51 2020; Su et al., 2020). In United States, aerosols are were reported to be highly acidic, with pH values of 52 approximately 1-2 (Guo et al., 2015; Nah et al., 2018; Pye et al., 2018; Zheng et al., 2020). In comparison, 53 aerosols in mainland China and Europe are were generally less acidic with aerosol pH ranging between 54 2.5 and 6 (Guo et al., 2018; Jia et al., 2018; Masiol et al., 2020; Shi et al., 2019; Tan et al., 2018; Wang 55 et al., 2019; Zheng et al., 2020).

56 Aerosol pH exhibits notable spatial and temporal variability, which is affected by changes in factors 57 such as temperature, relative humidity (RH), and aerosol compositions (Pye et al., 2018; Nenes et al., 58 2020a; Tao et al., 2020; Zheng et al., 2020). Very few studies have investigated the trend and spatial 59 variability of aerosol pH and its drivers. Weber et al. (2016) showed that aerosols remained to be highly 60 acidic even upon the reduction of particulate sulfate (SO42-) during summertime in the southeastern 61 United States. Based on the 10-year observations conducted at six Canadian sites, Tao and Murphy (2019) 62 suggested that meteorological parameters were more important than the chemical compositions in 63 controlling aerosol pH. Zheng et al. (2020) found that aerosol liquid water content (ALWC) and 64 temperature were the main factors that contribute to the pH difference observed between the wintertime 65 North China Plain and summertime southeastern United States, whereas the change of chemical 66 composition only played a minor role (15%). In China, the trend of aerosol pH and its drivers remain 67 poorly understood, especially in recent years when the emissions and aerosol compositions changed 68 substantially.

To tackle severe particulate matter pollution in China, the Chinese government released the Air Pollution Prevention and Control Action Plan (hereinafter referred to as the Action Plan) in September 2013, which is the first plan specifying air quality goals in China\_(Cai et al., 2017; Liu et al., 2018; Zheng et al., 2018). The implementation of the Action Plan has led to significant changes in the concentrations and chemical compositions of fine particulate matter (PM<sub>2.5</sub>). Aerosol pH may change due to the significant changes of the chemical composition in PM<sub>2.5</sub>, which may feedback to the multiphase formation pathways of aerosols such as sulfate, nitrate and ammonium (Cheng et al., 2016; Vasilakos et 76 al., 2018; Nenes et al., 2020a).

In this study, we performed a comprehensive analysis on the long-term trends of aerosol pH and its drivers in the Shanghai, China. A thermodynamic model, ISORROPIA II (version 2.1) (Fountoukis and Nenes, 2007) was applied to estimate the pH based on 9-year continuous online measurements of  $PM_{2.5}$ composition at an urban site in Shanghai. The main purposes of this study are to: (1) characterize the long-term trend of aerosol pH; (2) investigate the seasonal and diurnal variations of aerosol pH and the main factors that affect these changes and (3) predict future pH under different emission control scenarios. The results presented here may help to advance our understanding in aerosol chemistry, providing <u>a</u>

- 84 scientific basis on the development of effective pollution control strategy in the future.
- 85 2 Material and Methods

### 86 2.1 Ambient measurements

The observational site in this study is located at the Shanghai Academy of Environmental Sciences (SAES, 31°10′N, 121°25′E), which sits in the densely populated city centre of Shanghai (Figure S1). In the absence of significant nearby industrial sources, this sampling site represents a typical urban area of Shanghai affected by severe emissions from vehicular traffic, commercial, and residential activities (Qiao et al., 2014; Zhou et al., 2016).

92 Gases and PM<sub>2.5</sub> components were continuously sampled by an on-line analyser to monitor aerosols 93 and gases (MARGA ADI 2080, Applikon Analytical B.V) from 2011 to 2019. Hourly mass 94 concentrations of major inorganic components were obtained, including gaseous components, i.e., HCl, 95 HNO<sub>2</sub>, SO<sub>2</sub>, HNO<sub>3</sub>, NH<sub>3</sub> and particulate components, i.e., SO<sub>4</sub><sup>2-</sup>, nitrate (NO<sub>3</sub><sup>-</sup>), chloride (Cl<sup>-</sup>), 96 ammonium (NH4<sup>+</sup>), sodium (Na<sup>+</sup>), potassium (K<sup>+</sup>), calcium (Ca<sup>2+</sup>) and magnesium (Mg<sup>2+</sup>)-. Details of 97 measurements were have been given in Qiao et al. (2014), thus is are only briefly described here. To 98 better track the changes in retention time of different ion species and ensure their concentrations were 99 measured correctly, an internal standard check was conducted every hour with Lithium lithium Bromide 100 bromide (LiBr) standard solution (Qiao et al., 2014; Zhou et al., 2016). The sampling system of MARGA 101 was cleaned and the-multi-points calibrations with the standard solutions were performed every three 102 months to ensure the accuracy of the measurements. To ensure the data quality, the ion balance between the measured charge equivalent concentrations of cation (NH4<sup>+</sup>, Na<sup>+</sup>, K<sup>+</sup>, Ca<sup>2+</sup> and Mg<sup>2+</sup>) and anion 103

104  $(SO_4^{2-}, NO_3^{-} \text{ and } Cl^{-})$  species was examined as shown in Figure S2. Good correlation ( $R^2R^2=0.94$ ) was 105 found between the cations and anions, suggesting very good data quality during the measurement period. 106 We note that data during 2011-2016 were more scattered than those during 2017-2019, likely due to the significant decreases in Ca2+, K+ and Mg2+ from 2011 to 2019 (Figure S3-S5). In previous studies, 107 108 intercomparison experiments between MARGA and filter-based method have been carried out, and the 109 data measured by MARGA showed acceptable accuracy and precision\_(Rumsey et al., 2014; Huang et 110 al., 2014; Stieger et al., 2018). A Thermal/Optical Carbon Aerosol Analyzer (model RT-4, Sunset 111 laboratory Inc.) equipped with a PM<sub>2.5</sub> cyclone was used for the organic carbon measurement at a time 112 resolution of 1 hour. The mass concentrations of PM<sub>2.5</sub> were simultaneously measured using an on-line 113 beta attenuation PM monitor (FH 62 C14 series, Thermo Fisher Scientific) at a time resolution of 5 min. 114 The tTemperature and RH, which are important factors affecting aerosol pH, were also measured at a 115 time resolution of 1 min. Annually averaged temperature and RH from 2011 to 2019 are shown in Figure 116 S6. The t-test results revealed that temperature rose significantly at a rate of 1.2 %/yr ( $p \le 0.01$ ), while 117 RH changed little.

118

# 119 2.2 Aerosol pH prediction

120 The aerosol pH was predicted using the ISORROPIA II thermodynamic model\_(Fountoukis and Nenes, 121 2007). ISORROPIA II can calculate the equilibrium  $H_{air}^+$  and aerosol liquid water content of inorganic 122 material  $(ALWC_i)$  by inputting the concentrations of the total  $SO_4^{2-}$  (TH<sub>2</sub>SO<sub>4</sub>, replaced by observed 123  $SO_4^{2-}$ ), total  $NO_3^{-}$  (TNO<sub>3</sub>, gas HNO<sub>3</sub> plus particle  $NO_3^{-}$ ), total ammonia (NH<sub>x</sub>, gas NH<sub>3</sub> plus particle 124  $NH_4^+$ ), total Cl<sup>-</sup> (TCl, replaced by observed Cl<sup>-</sup> due to the low concentration and measurement 125 uncertainties of HCl) (Fu et al., 2015; Ding et al., 2019), non-volatile cations (NVCs, observed Na<sup>+</sup>, K<sup>+</sup>, 126  $Ca^{2+}$ ,  $Mg^{2+}$ ) and meteorological parameters (temperature and RH) (Guo et al., 2016).  $H_{air}^+$  and  $ALWC_i$ 127 are then used to obtain the  $PM_{2.5}$  pH by Eq. (1).

128 
$$pH = -log_{10}H_{aq}^+ \cong -log_{10}\frac{1000H_{air}^+}{ALWC_i + ALWC_o} \cong -log_{10}\frac{1000H_{air}^+}{ALWC_i}$$
, (1)

where  $H_{aq}^+$  is the H<sup>+</sup> concentration in solution (mol/L),  $H_{air}^+$  is the H<sup>+</sup> loading for an air sample (µg/m<sup>3</sup>) and *ALWC<sub>i</sub>* and *ALWC<sub>o</sub>* are the aerosol liquid water contents of inorganic and organic species,

131 respectively ( $\mu g/m^3$ ). *ALWC*<sub>o</sub> is calculated by Eq. (2) (Guo et al., 2015).

132 
$$ALWC_o = \frac{m_{org}\rho_w}{\rho_{org}} \frac{k_{org}}{(\frac{1}{RH} - 1)} , \qquad (2)$$

133 where  $m_{org}$  is the mass concentration of organic aerosol,  $\rho_w$  is the density of water ( $\rho_w=1.0$ g/cm<sup>3</sup>), 134  $\rho_{org}$  is the density of organics ( $\rho_{org}=1.4$ g/cm<sup>3</sup>)\_(Guo et al., 2015), and  $k_{org}$  is the hygroscopicity 135 parameter of organic aerosol ( $k_{org} = 0.087$ )\_(Li et al., 2016). The concentration of organic aerosol was 136 estimated by multiplying the measured concentration of organic carbon by a factor of 1.6 (Turpin and 137 Lim, 2001). The average concentrations of  $ALWC_0$  and  $ALWC_i$  in Shanghai from 2011 to 2019 were 138 4.1 (±10.2) and 32.6 (±52.5)  $\mu$ g/m<sup>3</sup>, respectively. ALWC<sub>o</sub> only accounted for 11.1% of the total aerosol 139 liquid water content. The pH predictions in previous studies were insensitive to  $ALWC_o$  unless the 140 mass fraction of ALWC<sub>o</sub> to the total aerosol liquid water content was close to unity (Guo et al., 2015). 141 The use of  $ALWC_i$  to predict pH is therefore fairly accurate and common\_(Battaglia et al., 2017; Ding 142 et al., 2019; Battaglia Jr et al., 2019). In this study, ISORROPIA II was run in the forward mode and 143 'metastable' state. Calculations using total (gas and aerosol) measurements in the forward mode are 144 less affected by measurement errors (Hennigan et al., 2015; Song et al., 2018). A detailed description of 145 the pH calculations can be found in previous studies (Guo et al., 2017a; Guo et al., 2015; Song et al., 146 2018).

147 Figure <u>S6-S7</u> compares the predicted vs. measured concentrations of NH<sub>3</sub>, NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup> and HNO<sub>3</sub>. The 148 results show that the predicted and measured concentrations of NH<sub>3</sub>, NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> are in good 149 agreement ( $R^2 > 0.89$ ) and slopes close to 1.00, indicating that the thermodynamic analysis accurately 150 represents the aerosol state and that deviations in the calculated pH values are lower than that in modelled 151 NH<sub>3</sub> (Weber et al., 2016). However, the predicted and measured concentrations of HNO<sub>3</sub> are not well 152 corrected correlated, which is also observed in previous studies (Ding et al., 2019; Guo et al., 2015). The 153 reason for the gap can be attributed to (1) lower concentrations of gas-phase HNO<sub>3</sub> than that of particle-154 phase NO<sub>3</sub>, (2) HNO<sub>3</sub>-measurement by MARGA are has high uncertainty for HNO<sub>3</sub> measurement 155 (Rumsey et al., 2014). The development of an alternative approach is therefore warranted to accurately 156 represent HNO<sub>3</sub> in the future.

#### 157 **2.3 Drivers of aerosol pH variations**

To investigate the factors that drive changes in aerosol pH, sensitivity tests of different factors on pH variations, including temperature, RH,  $SO_4^{2-}$ , TNO<sub>3</sub>, NH<sub>x</sub>, Cl<sup>-</sup> and NVCs, were performed with the one-

160 at-a-time method. That is, assuming the aerosol pH estimated under scenario I (pH<sub>1</sub>) differs with from 161 that under scenario II (pH<sub>II</sub>), the pH difference,  $(\Delta pH = pH_{II} - pH_{I})$ , are thus caused by the variations in 162 the factors listed above. To quantify the contributions of individual factors, we varied the factor *i* from 163 the value in scenario I to another value in scenario II and meanwhile kept the other factors fixed. The 164 corresponding changes in pH,  $\Delta pH_i$ , are assumed to represent the contribution of the change of this 165 individual factor to the overall aerosol pH variations. The unresolved contributors to pH differences, i.e., 166  $\Delta pH - \sum_i \Delta pH_i$ , are attributed to "others", which may represent the contribution of covariations between 167 the factors. -Note that because of the nonlinear dependence of pH to different factors, the sum of 168 contributions of individual factors can be slightly different from the overall contributions of all factors. 169 This method was used for the results presented in Figure 1b, Figure 3 and Figure 5, where the 170 corresponding scenarios represented the average conditions in different years (Figure 1b), seasons 171 (Figure 3) or diurnal periods (Figure 5).

# 172 **3** Results and Discussion

# 173 **3.1 Long-term trends of aerosol pH**

### 174 **3.1.1 Trends of aerosol pH.**

175 The 9-year time series of aerosol pH calculated by ISORROPIA II is shown in Figure 1a. A declining 176 trend in PM<sub>2.5</sub> pH from  $3.30 \pm 0.58$  in 2011 to  $3.06 \pm 0.55$  in 2019 was observed, with the fitted decrease 177 rate of around 0.04-unit pH per year, which may be related to chemical composition changes (Figure 178 S78-S859) due to the pollution control measures taken in the Yangtze River Delta (YRD) region. The 179 Chinese government started to implement carry on the Action Plan, a series of air pollution control 180 policies, in September 2013, which resulted in a decline in PM2.5 and its chemical components (Cheng et 181 al., 2019; Li et al., 2019). Compared to the concentrations before the implementation of the Action Plan 182 (i.e., average of 2011-2012 averages),  $PM_{2.5}$ ,  $SO_4^{2-}$ ,  $NH_x$  and NVCs during 2018-2019 decreased by 183 35.8%, 37.6%, 9.6% and 81.0%, respectively, while NO<sub>3</sub><sup>-</sup> increased by 1.2% (Fig. S7S8). Through the 184 years, SO<sub>4</sub><sup>2-</sup>, NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> were kept beingremained the most abundant inorganic water-soluble ions, 185 accounting for 83.4%–94.1% of the total ions in PM<sub>2.5</sub>. While the proportions of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> showed 186 continuous increases (increased by 2.2% and 13.1% from 2011 to 2019, respectively), those of NVCs

and  $SO_4^{2-}$  decreased by 6.0% and 4.6%, respectively. Despite the substantial change of aerosol abundance and composition, the aerosol pH only showed shows a moderate minor change. The effects of changes in PM<sub>2.5</sub> chemical composition on the aerosol pH will be detailed in Section 3.1.2.

190 The PM<sub>2.5</sub> in Shanghai was moderately acidic with a daily pH averaging 3.18 and ranging range from 191 1.15 to 5.62, similar to those from other cities in China\_(Shi et al., 2019; Tan et al., 2018). Compared 192 with other countries globally (Table S1), aerosol pH values in Chinese cities of 1.82 to 5.70 were higher 193 than those in US cities of 0.55 to 2.20 (Guo et al., 2015; Pye et al., 2018; Nah et al., 2018), yet similar to 194 those in European cities of 2.30 to 3.90 (Guo et al., 2018; Masiol et al., 2020). Among all of the Chinese 195 cities, the aerosol pH was highest in Inner Mongolia, which might be caused by a higher contribution of 196 crustal dust-in Inner Mongolia (Wang et al., 2019). The pH values in Shanghai and Guangzhou were 197 lower than those in North China, which may be due to higher concentrations of NH<sub>3</sub> and dust emissions 198 over the latter region (Shi et al., 2007; Liu et al., 2019).

# 199 **3.1.2 Driving factors.**

200 Figure 1b shows the contributions of individual factors to the  $\Delta pH$  from 2011 to 2019. Here the bar plots 201 indicate the factors contributing to the  $\Delta pH$  between two adjacent scenarios as shown in Figure 1b, e.g., 202 2011 to 2013. See Figure  $\frac{99a-S10a}{S10}$  for the factor contribution to the variation from average conditions. 203 Note that in Fig. 1b, the aerosol pH was calculated from the annual averages of input parameters. This is 204 different from Sect 3.1.1, where the annual pH is the average of hourly values based on hourly 205 observation data. As shown in Figure 1b, the aerosol pH decreased from 3.35 in 2011 to 3.28 in 2013. 206 The main factors that affected the pH during 2011-2013 (prior to the implementation of the Action Plan) 207 were the temperature and NVCs. The pH value also continuously decreased from 3.28 in 2013 to 3.19 in 208 2019. Yet, chemical composition shows more prominent effects on the aerosol pH during 2013-2019 209 compared to that of 2011-2013. As aforementioned, upon implementation of the Action Plan (2013-2019), 210 the concentrations of  $PM_{2.5}$  and its chemical components decreased substantially (Figure  $\frac{5788}{2}$ ). Changes 211 of SO<sub>4</sub><sup>2-</sup> and NVCs were important determinants in the change of aerosol pH, resulting in  $\Delta pH$  of +0.38 212 units and -0.35 units respectively from 2013 to 2019, respectively. Changes in the NH<sub>x</sub> and Cl<sup>-</sup> were 213 associated with 0.08 and 0.06 decreases in  $\Delta pH$ , respectively, whereas TNO<sub>3</sub> had little impact on the  $\Delta pH$ . 214 Hence, besides the effect of reduction in  $SO_4^{2-}$  (Fu et al., 2015; Xie et al., 2020), our results suggest that 215 the change in NVCs may also play an important role in determining the trend of aerosol pH. During

- 216 2017-2019, we found temperature and NH<sub>x</sub> became the main drivers of the  $\Delta pH$ . The effects of SO<sub>4</sub><sup>2-</sup>
- and NVCs on pH were much weaker than those during 2013–2017, consistent with the fact that the
  decline in pollutant concentrations slowed down in recent years (Fig. <u>\$8\$9</u>).

219 Overall, the changes in  $SO_4^{2-}$  and NVCs were the main drivers of the  $\Delta pH$  upon the implementation 220 of the Action Plan, and NH<sub>x</sub> appeared to play an increasingly important role in determining the aerosol 221 pH through the years.

Figure 1. (a) Long-term trends in aerosol pH during 2011–2019 in Shanghai. Gray dots and black lines represent the daily pH values and 30-day moving average pH values, respectively. <u>Shaded areas mark the</u>

226 standard deviation of 30-day moving average pH values. (b) Contributions of individual factors to the ΔpH

from 2011\_to 2019. Here the <u>black</u> bars <u>plots</u> indicate <u>the mean pH of different years</u>, <u>-and the red and</u>

228 green bars represent the factors positive and negative effects of individual factors on ΔpH between two

- 229 <u>adjacent scenarios, e.g., 2011 to 2013, respectively.contributing to the ApH between two adjacent scenarios,</u>
- 230 e.g., 2011 to 2013. The stacked color bars below the dashed line represent the factors that had negative-
- 231 impacts on ApH, and the stacked color bars above the dashed line represent the factors that had positive-
- 232 impacts on ApH. The meanings of the abbreviations: RH, relative humidity; Temp, temperature; NVCs,
- 233 non-volatile cations; NH<sub>x</sub>, total ammonia; TNO<sub>3</sub>, total nitrate; Oths, others.

## 234 3.2 Seasonal variation

- Figure 2 shows the seasonal variations of aerosol pH in Shanghai. The average pH values were 3.33±
- 236 0.49,  $2.89 \pm 0.49$ ,  $2.99 \pm 0.52$  and  $3.59 \pm 0.57$  in spring (March–May, MAM), summer (June–August,
- 237 JJA), fall (September-November, SON) and winter (December-February, DJF), respectively. The

highest aerosol pH was found in winter while the lowest pH was found in summer. While similar-the
seasonal variations of pH in Shanghai were similar to those observed in Beijing and other NCP cities
(Tan et al., 2018; Ding et al., 2019; Shi et al., 2019; Wang et al., 2020), the absolute values were lower,
due to the generally lower concentrations of aerosol chemical compositions in YRD.

242 Figure 3 shows the contributions of individual factors to the  $\Delta pH$  across the four seasons. Here the bar 243 plots indicate the factors contributing to the  $\Delta pH$  between two adjacent seasons, e.g., spring (MAM) to 244 summer (JJA). See Fig-ure S9b-S10b for the factor contribution to the variation from average conditions. 245 The aerosol pH was calculated from the mean averages of input parameters in four seasons, and the  $\Delta pH$ 246 was estimated by varying one factor while holding the other factors fixed in different seasons. According 247 to the multiphase buffer theory, the peak buffer pH, pKa\* regulates the aerosol pH in a multiphase-248 buffered system, and temperature can largely drive the seasonal variation of aerosol pH through its impact 249 on  $pK_a^*$  (Zheng et al., 2020). This is evidenced by the results in Figure 3, as temperature shows a dominant 250 role in driving the seasonal variation of aerosol pH. The temperature was associated with a maximum 251 ΔpH of 0.63 from fall to winter. Besides temperature, the other two main factors affecting aerosol pH 252 were NH<sub>x</sub> and SO<sub>4<sup>2-</sup></sub> (Figure 3), contributing 16% and 12% of the changes, respectively. Our results 253 suggest a central role of temperature in the determination of seasonal variations in aerosol pH, consistent 254 with the results of Tao and Murphy (Tao and Murphy, 2019) at six Canadian sites and the prediction by 255 the multiphase buffer theory (Zheng et al., 2020). In comparison, some previous studies emphasized the 256 importance of chemical compositions in seasonal variations (Tan et al., 2018; Ding et al., 2019), which 257 is mainly due to the different sensitivity analysis methods applied.

258

Figure 2. Seasonal variations of the mass concentrations of major components in PM<sub>2.5</sub>, relative humidity
(RH), temperature (Temp), predicted aerosol liquid water content (ALWC) and aerosol pH during 2011–2019
in Shanghai.

265 Figure 3. Contributions of individual factors to the  $\Delta pH$  across the four seasons. Here the <u>black</u> bars plots 266 indicate the factor hotwoon two seasons, e.g., spring (MAM) summer 267 stacked color bars below the dthe mean pH of different seasons, and the red and green bars The 268 represent the positive and negative effects of individual factors on  $\Delta pH$  between two adjacent scenarios, e.g., 269 spring (MAM) to summer (JJA), respectively. the factors contributing to the ApH between two adjacent 270 <u>seasons, e.g., spring (MAM) to summer (JJA). The stacked color bars below the d-ashed line represent the</u> 271 factors that had negative impacts on ApH and the stacked color bars above the dashed line represent the 272 increase in ApH. # 274 **3.3 Diurnal variation**

Aerosol pH in Shanghai exhibits notable diurnal variations with high aerosol acidity observed during daytime. Diurnal variations of aerosol pH as well as those of its potential drivers were are depicted in Figure 4. We further explore the effects <u>of</u> individual factors on the  $\Delta$ pH between day and night through sensitivity tests.

279 <u>The Bb</u>ar plot in Figure 5 indicates the factors contributing to the  $\Delta pH$  between two adjacent hour 280 periods, e.g., 0:00 to 6:00. See Figure <u>S9e S10c</u> for the combined effects of contributions from different 281 factors on the average  $\Delta pH$ . The aerosol pH was calculated from the averages of input parameters in 0:00, 282 6:00, 12:00 and 18:00, and  $\Delta pH$  was estimated by varying one factor while holding the other factors 283 fixed in different hours. Temperature and RH were among the main drivers of the diurnal variation of 284 aerosol pH, with a maximum  $\Delta pH$  of -0.22 and +0.10-units, respectively. As shown in Figure 4, the 285 maximum RH and ALWC occurred at approximately 5:00. After sunrise, the increase in temperature 286 resulted in an immediate drop of RH with ALWC reached reaching its lowest level in the afternoon. 287 Accordingly, the minimum aerosol pH ( $\sim$ 2.8) was also found in the afternoon with high temperature and 288 low RH. After sunset, the decreasing temperature and increasing RH led to a highest aerosol pH overnight. 289 Minor changes in pH were found between 0:00 and 6:00, when temperature and RH also showed minor 290 changes. The impacts of other factors, such as SO4<sup>2-</sup>, on the diurnal variations of pH were notably smaller 291 than on seasonal variations, which may be attributed to the relatively small variations of chemical profiles 292 during the course of a day. Among the chemical compositions, NH<sub>x</sub> played the most important role, 293 followed by SO<sub>4<sup>2-</sup></sub>. Overall, temperature and RH were more important than chemical compositions in 294 regulating the diurnal variations of aerosol pH.

297 Figure 4. Diurnal variations of the mass concentrations of major ions in PM2.5, relative humidity (RH), 298 temperature (Temp), predicted aerosol liquid water content (ALWC) and aerosol pH during 2011-2019 in

Figure 5. Contributions of individual factors to the ΔpH between day and night. Here the <u>black</u> bars plots
indicate the mean pH of different hours, and the red and green bars represent the positive and negative effects
of individual factors on ΔpH between two adjacent scenarios, e.g., 0:00 to 6:00, respectively, the factors
contributing to the ΔpH between two adjacent hour periods, e.g., 0:00 to 6:00. The stacked color bars below
the dashed line represent the factors that had negative impacts on ΔpH and the stacked color bars above the
dashed line represent the increase in ΔpH. The meanings of the abbreviations: RH, relative humidity; Temp,
temperature; NVCs, non-volatile cations; NHs, total ammonia; TNO3, total nitrate; Oths, others.

# 310 **3.4 Future projections**

311 A series of prevention and control measures have been suggested for continuous improvement in air 312 quality, which will affect the particulate compositions and subsequently alter the aerosol pH in China. To 313 explore China's future anthropogenic emission pathways in 2015–2050, Tong et al. (2020) 314 developed a dynamic projection model, based on which different emission scenarios were created by 315 connecting five socio-economic pathway (SSP) scenarios, five representative concentration pathways 316 (RCP) scenarios (RCP8.5, 7.0, 6.0, 4.5 and 2.6) and three pollution control scenarios (business as usual, 317 BAU; enhanced control policy, ECP; and best health effect, BHE). These scenarios provide a better 318 understanding of the future trends in pollutant emissions (Tong et al., 2020).

In this study, we chose three different emission reduction scenarios (SSP3-70-BAU, SSP2-45-ECP, and SSP1-26-BHE) as the future anthropogenic emission pathways, and based on which we try to project the future aerosol pH levels in Shanghai. SSP1-26-BHE, which involves a combination of strong low322 carbon and air pollution control policy, has the greatest emission reduction, followed by SSP2-45-ECP. 323 SSP3-70-BAU is a reference scenario that-without additional efforts to constrain emissions. We first 324 tested the sensitivity of aerosol abundances to precursor emissions with the historical data (Figure 325 s10s11), the emissions of Shanghai were obtained by the Multi-resolution Emission Inventory for China 326 (MEIC, http://meicmodel.org/, last access: 15 January 2020). We found that the non-volatile sulfate 327 concentrations generally correlated linearly with that of the SO<sub>2</sub> emissions. For the volatile TNO<sub>3</sub> and 328 NH<sub>x</sub>, the correlations are less linear, likely due to the different deposition velocities of gases and particles 329 (Pye et al., 2020; Weber et al., 2016; Nenes et al., 2021). The historical emission reductions have resulted 330 in a moderate pH decrease (Figure 1), a moderate increase (0.2% per year) in the NO<sub>3</sub> partitioning, and 331 a decrease (-0.6% per year) in the  $NH_4^+$  partitioning (Figure S11S12).

For a first-order estimation, we applied the average  $\Delta a erosol/\Delta precursor emissions in (\mu g/m^3)_/$ (Gg/yr) as derived from the historical (Figure S10aS11a-c) to the future scenario predictions. Figure 6 shows the emissions of SO<sub>2</sub>, NO<sub>x</sub>, NH<sub>3</sub> and predicted pH levels and the effects of major chemical components (NH<sub>x</sub>, SO<sub>4</sub><sup>2-</sup>, and TNO<sub>3</sub>) to the  $\Delta pH$  in Shanghai from 2015 to 2050 under the three scenarios. Based on this assumption, the concentrations of SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> are expected to drop to ~6.3, 5.7 and 2.6 µg/m<sup>3</sup>, respectively in 2050 with the SSP1-26-BHE scenario, generally in agreement with the predicted PM<sub>2.5</sub> levels of ~15 µg/m<sup>3</sup> under such scenario (Shi et al., 2021).

339 Under the reference scenario of SSP3-70-BAU with weak control policy (blue dashed lines in Figure 340 6a-f), SO<sub>2</sub> and NO<sub>x</sub> are predicted to increase, while the NH<sub>x</sub> is relatively stable. NH<sub>x</sub>, SO<sub>4</sub><sup>2-</sup>, and TNO<sub>3</sub> 341 have minor effects on  $\Delta pH$  (Figure 6g). Correspondingly, there are little changes in aerosol pH and the 342 predicted NO<sub>3</sub><sup>-</sup> partitioning ratio (NO<sub>3</sub><sup>-</sup> / (NO<sub>3</sub><sup>-</sup> + HNO<sub>3</sub>)). However, <u>the NH<sub>4</sub><sup>+</sup> partitioning ratio (NH<sub>4</sub><sup>+</sup> / 343 (NH<sub>4</sub><sup>+</sup> + NH<sub>3</sub>)) will increase substantially, suggesting an enhanced formation of ammonium aerosols.</u>

Under the moderate control policy (SSP2-45-ECP), the emissions of SO<sub>2</sub>, NO<sub>x</sub>, and NH<sub>3</sub> in 2050 will be reduced by 62.7%, 49.0% and 25.0%, respectively with corresponding decreases in SO<sub>4</sub><sup>2-</sup>, TNO<sub>3</sub> and NH<sub>x</sub>. The predicted pH will increase by ~0.13, and the NH<sub>4</sub><sup>+</sup> partitioning ratio will decrease by 0.09, indicating that <u>relatively</u> more ammonium will exist in the gas phase as NH<sub>3</sub>. The NO<sub>3</sub><sup>-</sup> partitioning ratios are relatively stable, suggesting its general insensitivity in the predicted pH ranges\_(Nenes et al., 2020a). Changes in the SO<sub>4</sub><sup>2-</sup>, TNO<sub>3</sub> and NH<sub>x</sub> will result in  $\Delta$ pH of +0.18, -0.05 and -0.02-<u>units</u> from 2015 to 350 2050, respectively (Figure 6h).

With the strict control policy (SSP1-26-BHE), the emissions of SO<sub>2</sub>, NO<sub>x</sub> and NH<sub>3</sub> in 2050 will decrease by 86.9%, 74.9% and 41.7%, respectively, and the concentrations of SO<sub>4</sub><sup>2-</sup>, TNO<sub>3</sub> and NH<sub>x</sub> decrease substantially. The pH value will increase continuously by ~0.19 (from 3.36 in 2015 to 3.55 in 2050). Changes in SO<sub>4</sub><sup>2-</sup> are more important determinants of  $\Delta$ pH, resulting in  $\Delta$ pH of +0.28 units from 2015 to 2050. Changes in the TNO<sub>3</sub> and NH<sub>x</sub> are associated with 0.04 and 0.09 decreases in  $\Delta$ pH, respectively. Moreover, the NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> partitioning ratios will decrease by 0.04 and 0.12, respectively, indicating a benefit of NH<sub>3</sub> and NO<sub>x</sub> emission controls in mitigating haze pollution in eastern China.

We also note that above analysis based on the historical average  $\Delta_a \operatorname{erosol} / \Delta_(\operatorname{precursor emissions})$ are—is\_subject to uncertainties associated with changes in the atmospheric oxidation capacity, meteorological conditions, etc.. It is only a first-order estimation, and a full examination with 3-D chemical transport models are is recommended in the future.

362

Figure 6. Emissions of SO<sub>2</sub> (a), NO<sub>x</sub> (b), NH<sub>3</sub> (c), predicted pH (d), NO<sub>3</sub><sup>-</sup> partitioning (NO<sub>3</sub><sup>-</sup> / (NO<sub>3</sub><sup>-</sup> + HNO<sub>3</sub>)) (e) and NH<sub>4</sub><sup>+</sup> partitioning (NH<sub>4</sub><sup>+</sup> / (NH<sub>4</sub><sup>+</sup> + NH<sub>3</sub>)) (f) in China from 2015 to 2050 under the three scenarios published in Tong et al. (Tong et al., 2020). Predicted contributions of individual factors to the  $\Delta$ pH under the

three scenarios, including SSP3-70-BAU (g), SSP2-45-ECP (h) and SSP1-26-BHE (i). The stacked color bars
below the dashed line represent the factors that had negative impacts on ΔpH and the stacked color bars
above the dashed line represent the increase in ΔpH. The meanings of the abbreviations: NH<sub>x</sub>, total ammonia;
TNO<sub>3</sub>, total nitrate; Oths, others.

### 370 4 Conclusion

371 The aerosol pH values at an urban site in Shanghai during 2011–2019, for the first time, were modelled 372 and reported using ISORROPIA II based on observed gas and aerosol composition. Although significant 373 variations of aerosol compositions were observed from 2011 to 2019 in the YRD region, the aerosol pH 374 estimated by model only slightly declined by 0.24 unit. We quantified the contributions from individual 375 factors to the variation of aerosol pH from 2011 to 2019. We found that besides the multiphase buffer 376 effect,  $SO_4^{2-}$  and NVCs changes are key in regulating the aerosol pH from 2011 to 2019 in Shanghai. 377 SO4<sup>2-</sup> and NVCs showed an overall opposite effect on aerosol pH, with a contribution of +0.38 and -0.35 378 unit, respectively.

379 Distinct seasonal variations in the aerosol pH were observed, with maximum and minimum aerosol 380 pH of  $3.59 \pm 0.57$  in winter and  $2.89 \pm 0.49$  in summer, respectively. Seasonal variations in aerosol pH 381 were mainly driven by the temperature, with the maximum  $\Delta pH$  of 0.63 between fall and winter. The 382 diurnal cycle of aerosol pH was driven by the combined effects of temperature and RH which could result 383 in  $\Delta pH$  of -0.22 and +0.10 units, respectively. These results emphasized the importance of meteorological 384 conditions in controlling the seasonal and diurnal variations of aerosol pH.

385 Finally, to explore the effects of China's future anthropogenic emission control pathways on aerosol 386 pH and compositions, we chose three different emission reduction scenarios proposed by Tong et al. Tong 387 et al. (2020) for future haze mitigation, naming SSP3-70-BAU, SSP2-45-ECP and SSP1-26-BHE as case 388 studies. We found that under the weak control policy (SSP3-70-BAU), the future aerosol pH and NO<sub>3</sub><sup>-</sup> 389 partitioning ratio will only have subtle changes. While our results also demonstrate that future aerosol 390 pH will increase under both strict control policy (SSP1-26-BHE) and moderate control policy (SSP2-45-391 ECP) the former will result in a more dramatic increase. The significant increase in aerosol pH is mainly 392 associated with the decrease in  $SO_4^{2-}$ . In addition, the increase in aerosol pH with strict control policy 393 and moderate control policy will lead to relatively more nitrate and ammonium partitioning in the gas

- 394 phase, which is beneficial for future  $PM_{2.5}$  pollution control. These results highlight the potential effects
- 395 of precursors reductions on aerosol pH employing future pollution control policy.

# 396 Author Contributions

- 397 HS, HW, and CH conceived and led the study. MZ conducted the field measurements and carried out the
- data analysis. MZ and GZ performed model simulations. MZ, HS, HW, CH, GZ, LQ, SZ, DH, YC, JA
- discussed the results. LQ, SZ, DH, SL, ST, QW, RY, YM, CC conducted the measurements at the station.
- 400 MZ, HS and GZ wrote the manuscript with input from all co-authors.
