20 Abstract

21 Aerosol acidity plays a key role in regulating the chemistry and toxicity of atmospheric aerosol particles.
22 The trend of aerosol pH and its drivers are crucial in understanding the multiphase formation pathways
23 of aerosols. Here, we reported the first trend analysis of aerosol pH from 2011 to 2019 in eastern China.
24 The implementation of the Air Pollution Prevention and Control Action Plan leads to -35.8%, -
25 37.6%, -9.6%, -81.0% and 1.2% changes of $PM_{2.5}$, SO_4^{2-} , NH_x , NVCs and NO_3^- in YRD during this
26 period. Different from the fast changes of aerosol compositions due to the implementation of the Air
27 Pollution Prevention and Control Action Plan, aerosol pH shows a moderate change of -0.24 unit over
28 the 9 years. Besides the multiphase buffer effect, the opposite effects of SO_4^{2-} and non-volatile cations
29 changes play key roles in determining the moderate pH trend, contributing to a change of +0.38 and
30 -0.35 unit, respectively. Seasonal variations in aerosol pH were mainly driven by the temperature, while
31 the diurnal variations were driven by both temperature and relative humidity. In the future, SO_2 , NO_x
32 and NH_3 emissions are expected to be further reduced by 86.9%, 74.9% and 41.7% in 2050
33 according to the best health effect pollution control scenario (SSP1-26-BHE). The corresponding
34 aerosol pH in eastern China is estimated to increase by ~ 0.9 , resulting in 8% more NO_3^- and 35% less
35 NH_4^+ partitioning/formation in the aerosol phase, which suggests a largely reduced benefit of NH_3 and
36 NO_x emission control in mitigating haze pollution in eastern China.

37

38 1 Introduction

39 Aerosol acidity is an important parameter in atmospheric chemistry studies. It affects the particle mass
40 and chemical composition by regulating the reactions of aerosols, and is closely associated with human
41 health, ecosystems and climate (Li et al., 2017; Nenes et al., 2020b; Pye et al., 2020; Su et al., 2020).
42 Aerosol acidity has attracted increasing concern in recent years because of its impacts on the
43 thermodynamics of gas-particle partitioning, pH-dependent condensed-phase reactions and trace metal
44 solubility (Cheng et al., 2016; Fang et al., 2017; Guo et al., 2017b; Guo et al., 2016; He et al., 2018; Song
45 et al., 2018; Weber et al., 2016; Su et al., 2020).

46 Aerosol pH is normally estimated using thermodynamic models, such as E-AIM (Clegg et al., 1998)

47 and ISORROPIA II, due to the limitations of direct aerosol pH measurement techniques (Fountoukis and
48 Nenes, 2007; Hennigan et al., 2015). The global distribution of aerosol pH generally ranges from 1 to
49 6 (Pye et al., 2020; Zheng et al., 2020; Su et al., 2020). Aerosols in the United States are highly acidic,
50 with pH values of approximately 1–2 (Guo et al., 2015; Nah et al., 2018; Pye et al., 2018; Zheng et al.,
51 2020). Aerosols in mainland China and Europe have similar average aerosol acidity levels (pH = 2.5–
52 6) (Guo et al., 2018; Jia et al., 2018; Masiol et al., 2020; Shi et al., 2019; Tan et al., 2018; Wang et al.,
53 2019; Zheng et al., 2020).

54 Aerosol pH exhibits notable spatial and temporal variability, which is affected by changes in factors
55 such as temperature, relative humidity (RH), and aerosol compositions (Pye et al., 2018; Nenes et al.,
56 2020a; Tao et al., 2020; Zheng et al., 2020). Very few studies have investigated the trend and spatial
57 variability of aerosol pH and its drivers. Weber et al. (Weber et al., 2016) showed that aerosols tend to
58 remain highly acidic upon the reduction of SO_4^{2-} during summertime in the southeastern United States.
59 Based on the 10-year observations in six Canadian sites, Tao and Murphy (Tao and Murphy, 2019)
60 suggested that meteorological parameters are more important than the chemical compositions in
61 controlling aerosol pH variations. Zheng et al. (Zheng et al., 2020) found that aerosol liquid water content
62 (ALWC) and temperature are the main factors that contribute to the pH difference between the wintertime
63 North China Plain and summertime southeastern United States, whereas the change of chemical
64 composition only plays a minor role (15%). In China, the trend of aerosol pH and its drivers remain
65 poorly understood, especially in recent years when the emissions and aerosol compositions undergo
66 substantial changes.

67 To tackle severe particulate matter pollution in China, the Chinese government released the Air
68 Pollution Prevention and Control Action Plan (hereinafter referred to as the Action Plan) in September
69 2013, which is the first plan to specify air quality goals in China (Cai et al., 2017; Liu et al., 2018; Zheng
70 et al., 2018). The implementation of the Action Plan has led to significant changes in the concentrations
71 and chemical characteristics of fine particulate ($\text{PM}_{2.5}$). Aerosol pH may change due to the significant
72 changes of the chemical composition in $\text{PM}_{2.5}$, which may feedback to the multiphase formation
73 pathways of aerosols such as sulfate, nitrate and ammonium (Cheng et al., 2016).

74 In this study, we performed a comprehensive analysis of the long-term trends of aerosol pH and its
75 drivers in the Yangtze River Delta of eastern China. In this study, a thermodynamic model, ISORROPIA

76 II (version 2.1)(Fountoukis and Nenes, 2007) was applied to estimate the pH based on 9-year continuous
77 online measurements of PM_{2.5} compositions at an urban site in Shanghai. The main purposes of this study
78 were to: (1) characterizing the long-term trend in aerosol pH; (2) investigate the seasonal and diurnal
79 variations of aerosol pH and the main factors that affect these changes and (3) predict further pH under
80 different emission control scenarios and its impact on the formation of ammonium and nitrate. The results
81 presented here may help to advance our understanding of aerosol chemistry in China and support the
82 development of effective pollution control strategy.

83 2 Material and Methods

84 2.1 Ambient measurements

85 The observational site in this study is located in the Shanghai Academy of Environmental Sciences
86 (SAES, 31°10'N, 121°25'E), a mixed commercial and residential district in the southwest central urban
87 area of Shanghai (Fig. S1). In the absence of a significant nearby industrial source, this sampling site can
88 be regarded as a representative urban area influenced by a wide mixture of emission sources. A detailed
89 description can be found in previous studies(Qiao et al., 2014; Zhou et al., 2016).

90 The sampling was conducted from 2011 to 2019. Hourly mass concentrations of water-soluble gases
91 (HCl, HNO₂, SO₂, HNO₃, NH₃) and major water-soluble inorganic ions in PM_{2.5}, including SO₄²⁻, nitrate
92 (NO₃⁻), chloride (Cl⁻), ammonium (NH₄⁺), sodium (Na⁺), potassium (K⁺), calcium (Ca²⁺) and
93 magnesium (Mg²⁺), were measured using an on-line analyser to monitor aerosols and gases (MARGA
94 ADI 2080, Applikon Analytical B.V). The details of measurements were given in Qiao et al.(Qiao et al.,
95 2014). To better track the retention time changes of different ion species and ensure their concentrations
96 to be measured successfully, an internal calibration was conducted every hour with Lithium Bromide
97 (LiBr) standard solution (Qiao et al., 2014; Zhou et al., 2016). In addition, cleaning the sampling system
98 of MARGA and the multi-points calibrations with the standard solutions were performed every three
99 months to ensure the accuracy of MARGA. Figure S2 compares the sum of SO₄²⁻, NO₃⁻ and Cl⁻ with
100 the sum of NH₄⁺, Na⁺, K⁺, Ca²⁺ and Mg²⁺ in neq/m³ to check the charge balance. The correlation between
101 cation and anion was strong (R²=0.94), with a slope of 1.00, indicating that these ion species represented
102 the major ions in PM_{2.5}, and the anion and cation were charge balanced. In previous studies,
103 intercomparison experiments between MARGA and filter-based method have been carried out, and the

104 data measured by MARGA show acceptable accuracy and precision(Rumsey et al., 2014; Huang et al.,
105 2014). The mass concentrations of PM_{2.5} were simultaneously measured using an on-line PM monitor
106 (FH 62 C14 series, Thermo Fisher Scientific) using beta attenuation techniques at a time resolution of 5
107 min. The temperature and RH were also measured at a time resolution of 1 min.

108 2.2 Aerosol pH prediction

109 The aerosol pH was predicted using the ISORROPIA II thermodynamic model(Fountoukis and Nenes,
110 2007). ISORROPIA II can calculate the equilibrium H_{air}^+ and aerosol liquid water content of inorganic
111 material ($ALWC_i$) by inputting the concentrations of the total SO_4^{2-} (TH_2SO_4 , replaced by observed
112 SO_4^{2-}), total NO_3^- (TNO_3 , gas HNO_3 plus particle NO_3^-), total ammonia (NH_x , gas NH_3 plus particle
113 NH_4^+), total Cl^- (TCl , replaced by observed Cl^- due to the low concentration and measurement
114 uncertainties of HCl)(Rumsey et al., 2014), non-volatile cations (NVCs, observed Na^+ , K^+ , Ca^{2+} , Mg^{2+})
115 and meteorological parameters, including temperature and RH(Guo et al., 2016). H_{air}^+ and $ALWC_i$ are
116 then used to obtain the PM_{2.5} pH by Eq. (1).

$$117 \quad pH = -\log_{10} H_{aq}^+ \cong -\log_{10} \frac{1000H_{air}^+}{ALWC_i + ALWC_o} \cong -\log_{10} \frac{1000H_{air}^+}{ALWC_i}, \quad (1)$$

118 where H_{aq}^+ is the H^+ concentration in solution (mol/L), H_{air}^+ is the H^+ loading for an air sample ($\mu\text{g}/\text{m}^3$)
119 and $ALWC_i$ and $ALWC_o$ are the aerosol liquid water contents of inorganic and organic species,
120 respectively ($\mu\text{g}/\text{m}^3$). $ALWC_o$ was calculated by Eq. (2) (Guo et al., 2015).

$$121 \quad ALWC_o = \frac{m_{org}\rho_w}{\rho_{org}} \frac{k_{org}}{\left(\frac{1}{RH}-1\right)}, \quad (2)$$

122 where m_{org} is the mass concentration of organic aerosol, ρ_w is the density of water ($\rho_w=1.0\text{g}/\text{cm}^3$),
123 ρ_{org} is the density of organics ($\rho_{org}=1.4\text{g}/\text{cm}^3$)(Guo et al., 2015), and k_{org} is the hygroscopicity
124 parameter of organic aerosol ($k_{org} = 0.087$)(Li et al., 2016). The annual $ALWC_o$ calculated were 1.4–
125 $2.5\mu\text{g}/\text{m}^3$, only accounting for 4.3%–7.5% of the total aerosol liquid water content. The pH predictions
126 in previous studies were insensitive to $ALWC_o$ unless the mass fraction of $ALWC_o$ to the total
127 aerosol liquid water content was close to unity(Guo et al., 2015). The use of $ALWC_i$ to predict pH is
128 therefore fairly accurate and common(Battaglia et al., 2017; Ding et al., 2019). In this study,
129 ISORROPIA II was run in the forward mode and ‘metastable’ state. Calculations using total (gas and
130 aerosol) measurements in the forward mode are less affected by measurement errors(Hennigan et al.,

131 2015; Song et al., 2018). A detailed description of the pH calculations can be found in previous
132 studies(Guo et al., 2017a; Guo et al., 2015; Song et al., 2018).

133 Figure S3 compares the predicted and measured concentrations of NH_3 , NH_4^+ , NO_3^- and HNO_3 . The
134 results show that the modelled and measured NH_3 , NH_4^+ and NO_3^- concentrations are in good agreement,
135 with R^2 values above 0.89 and slopes near 1.00, indicating that the thermodynamic analysis accurately
136 represents the aerosol state and that deviations in the calculated pH values are lower than that in modelled
137 NH_3 (Weber et al., 2016). However, the predicted and measured concentrations of HNO_3 show a poor correlation,
138 as reported in previous studies(Ding et al., 2019; Guo et al., 2015). This may be attributed to lower gas-
139 phase concentrations than particle-phase concentrations and the measurement uncertainties of HNO_3
140 from MARGA(Rumsey et al., 2014). The development of an alternative approach is therefore required
141 to accurately represent HNO_3 .

142 2.3 Sensitivity analysis and drivers of aerosol pH

143 To investigate the factors that drive changes in aerosol pH, sensitivity tests of pH to different factors,
144 including temperature, RH, SO_4^{2-} , TNO_3 , NH_x , Cl^- and NVCs, were performed. Figure S4 shows how
145 these factors affected the aerosol pH. In the sensitivity tests, we found that an elevated temperature and
146 SO_4^{2-} could decrease pH. As shown in Figure S4, particles tend to become more acidic at higher
147 temperatures. The temperature dependence of pH is mainly determined by the phase partitioning of
148 $\text{NH}_3/\text{NH}_4^+$ based on the equilibria $\text{NH}_3(\text{g}) \leftrightarrow \text{NH}_3(\text{aq})$ and $\text{NH}_3(\text{aq}) + \text{H}_2\text{O} \leftrightarrow \text{NH}_4^+ + \text{OH}^-$, which are
149 governed by the temperature-dependent constants K_H and K_b , respectively(Hennigan et al., 2015; Zheng
150 et al., 2020). Figures S4 also show that elevations in NH_x , NVCs and RH can increase the aerosol pH
151 and ALWC. For TNO_3 and Cl^- , we find their impacts on the aerosol pH were rather weak through
152 sensitivity test and thus are not discussed in detail here.

153 In this study, we also try to quantify the effects of different factors on the annual, seasonal and
154 diurnal variations of aerosol pH to identify the most important determinants. To quantify the effects of
155 individual factors on the aerosol pH, we first estimated the pH by using the ISORROPIA model with
156 initial values of the different factors, including annual, seasonal and hourly mean value of temperature,
157 RH, SO_4^{2-} , TNO_3 , NH_x , Cl^- and NVCs. We then estimated the changed pH ($\text{pH}_{\text{change}}$) by varying one
158 factor while holding the other factors fixed. The difference in aerosol pH (ΔpH , $\Delta\text{pH} = \text{pH}_{\text{change}} - \text{pH}$)

159 represents the effect of an individual factor change on the aerosol pH.

160 **3 Results and Discussion**

161 **3.1 Long-term trends of aerosol pH**

162 **3.1.1 Trends of aerosol pH.**

163 The 9-year time series of aerosol pH calculated by ISORROPIA II is shown in Figure 1a. A declining
164 trend in $PM_{2.5}$ pH from 3.30 ± 0.58 in 2011 to 3.06 ± 0.55 in 2019 was observed, with the fitted decrease
165 rate of around 0.04 unit pH per year, which may be related to chemical composition changes (Figs. S5-
166 S6) due to the pollution control measures taken in the Yangtze River Delta (YRD) region. The Chinese
167 government started to implement the Action Plan, a series of air pollution control policies, in September
168 2013, which resulted in a clear decline in $PM_{2.5}$ and its chemical components (Cheng et al., 2019; Li et
169 al., 2019). Compared to the concentrations before the implement of the Action Plan (i.e., 2011-2012
170 averages), $PM_{2.5}$, SO_4^{2-} , NH_x and NVCs after the implement of the Action Plan (i.e., 2018-2019 averages)
171 decreased by 35.8%, 37.6%, 9.6% and 81.0%, respectively, while NO_3^- increased by 1.2% (Fig. S5). In
172 terms of the chemical profiles, SO_4^{2-} , NH_4^+ and NO_3^- remain the most abundant inorganic water-soluble
173 ions, accounting for 83.4%–94.1% of the total ions in $PM_{2.5}$. While the proportions of NH_4^+ and NO_3^-
174 increased continuously (increased by 2.2% and 13.1% from 2011 to 2019, respectively), those of NVCs
175 and SO_4^{2-} decreased by 6.0% and 4.6%, respectively. Despite of the substantial change of aerosol
176 abundance and composition, the aerosol pH shows a moderate change. The effects of chemical
177 composition changes in $PM_{2.5}$ on the aerosol pH are further discussed in Section 3.1.2.

178 The $PM_{2.5}$ in Shanghai was moderately acidic with daily pH range from 1.15 to 5.62, similar to
179 those from other cities in China (Shi et al., 2019; Tan et al., 2018). Table S1 shows the pH data from the
180 literature, which were calculated using thermodynamic models of different cities in summer and winter.
181 In general, the $PM_{2.5}$ pH ranges in Chinese cities were higher than those in US cities yet similar to those
182 in European cities.

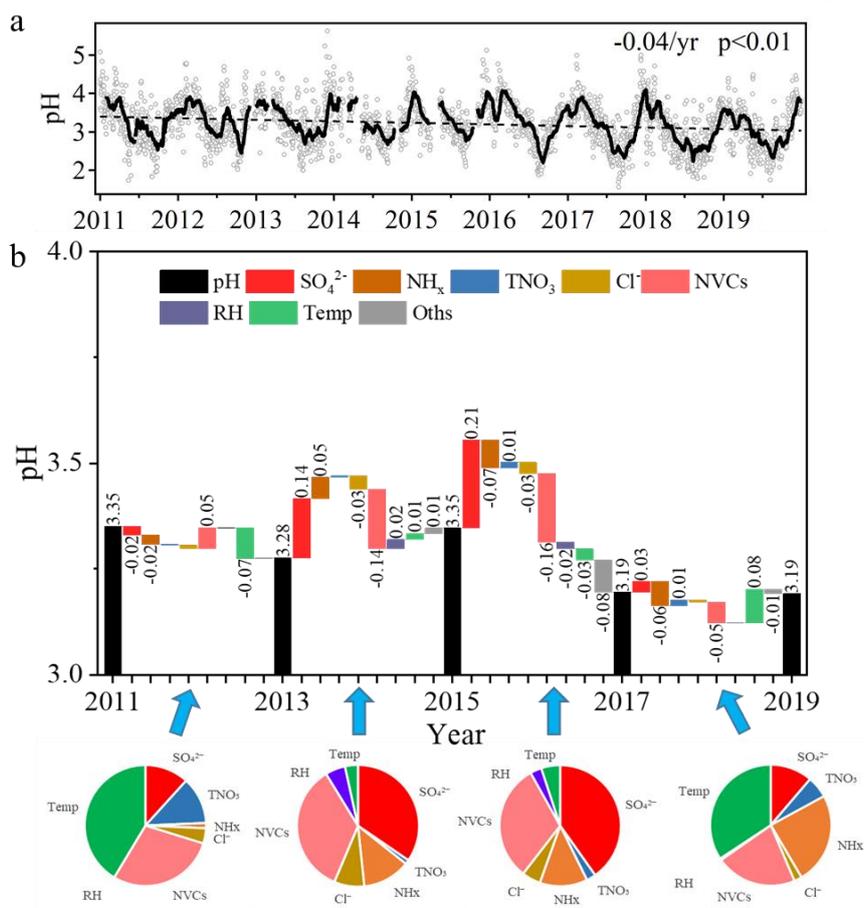

183 **3.1.2 Driving factors.**

184 Figure 1b shows the contributions of individual factors to the ΔpH from 2011 to 2019. Note that in Fig.
185 1b, the aerosol pH was calculated from the annual averages of input parameters. This is different from

186 Sect 3.1.1, where the annual pH is the average of hourly values based on hourly observation data. The
187 aerosol pH decreased from 3.35 in 2011 to 3.28 in 2013. The main factors that affected the pH in this
188 period (prior to the implementation of the Action Plan) were the temperature and NVCs. Upon
189 implementation of the Action Plan (2013-2019), the concentrations of $PM_{2.5}$ and its chemical components
190 decreased substantially (Fig. S5); hence, the role of the chemical composition in the aerosol pH become
191 more prominent than the period of 2011-2013. The pH value continuously decreased from 3.28 in 2013
192 to 3.19 in 2019. Changes in SO_4^{2-} and NVCs were more important determinants of the change of aerosol
193 pH, resulting in ΔpH of +0.38 units and -0.35 units from 2013 to 2019, respectively. Besides the effect
194 of reduction in SO_4^{2-} (Fu et al., 2015; Xie et al., 2020), our results suggest that the change in NVCs may
195 also play an important role in determining the trend of aerosol pH. The effects of SO_4^{2-} and NVCs on pH
196 were much weaker during 2017–2019 than during 2013–2017, consistent with the fact that the decline in
197 pollutant concentrations has slowed in recent years (Fig. S6). Thus, temperature and NH_x become the
198 main drivers of the ΔpH during 2017–2019.

199 From 2013 to 2019, changes in the NH_x and Cl^- were associated with 0.08 and 0.06 decreases in
200 ΔpH , respectively, whereas TNO_3 had little effect on the ΔpH . Overall, the changes in SO_4^{2-} and NVCs
201 were the main drivers of the ΔpH under the implemented Action Plan, and NH_x appeared to play an
202 increasingly important role in determining the aerosol pH through the years.

203

204 **Figure 1. (a) Long-term trends in aerosol pH during 2011–2019 in Shanghai. Gray dots and black lines**
 205 **represent the daily pH values and 30-day moving average pH values, respectively. (b) Fractional**
 206 **contribution of individual drivers to the change in aerosol pH during 2011–2019. RH, relative humidity;**
 207 **Temp, temperature; NVCs, non-volatile cations; NH_x , total ammonia; TNO_3 , total nitrate.**

208 3.2 Seasonal variation

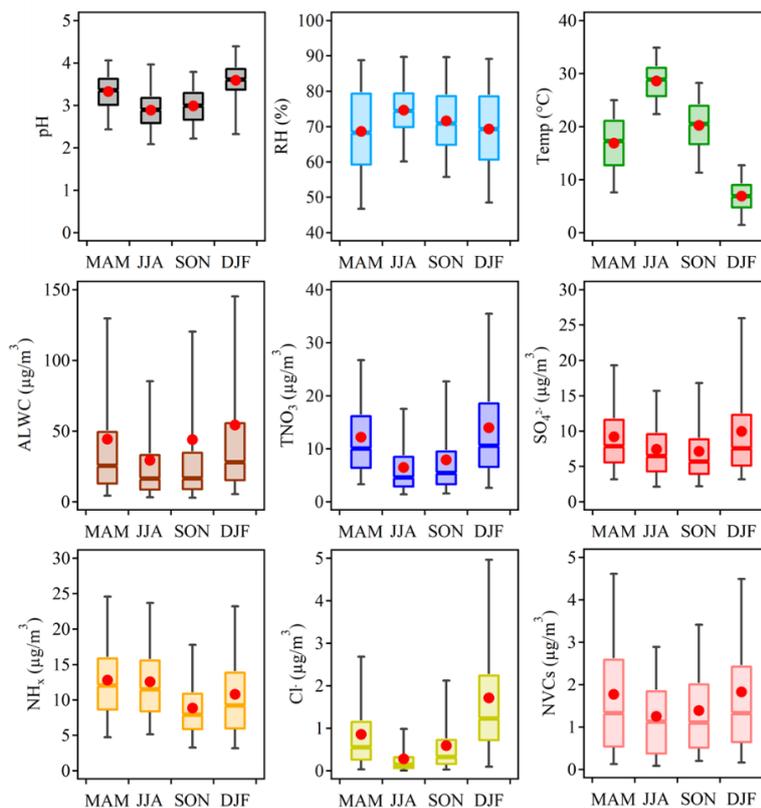

209 Figure 2 shows the seasonal variations of aerosol pH in Shanghai. The average pH values were $3.33 \pm$
 210 0.49 , 2.89 ± 0.49 , 2.99 ± 0.52 and 3.59 ± 0.57 in spring (March–May, MAM), summer (June–August,
 211 JJA), fall (September–November, SON) and winter (December–February, DJF), respectively. The
 212 highest aerosol pH was found in winter while the lowest pH was found in summer. This is with similar
 213 seasonal trend but generally lower levels than that observed in Beijing and other NCP cities (Tan et al.,

214 2018; Ding et al., 2019; Shi et al., 2019; Wang et al., 2020), due to the generally lower aerosol
215 concentrations in YRD.

216 According to the multiphase buffer theory, the peak buffer pH, pK_a^* regulates the aerosol pH in a
217 multiphase-buffered system, and temperature can largely drive the seasonal variation of aerosol pH
218 through its impact on pK_a^* (Zheng et al., 2020). Figure 3 confirms this conclusion, and shows a dominant
219 role of temperature in driving the seasonal variation of aerosol pH. The temperature was associated with
220 a max Δ pH of 0.63 from fall to winter. Besides temperature, the main factors affecting aerosol pH are
221 NH_x and SO_4^{2-} (Fig. 3), contributing 16% and 12% of the changes, respectively. Our results suggest a
222 central role of temperature in the determination of seasonal variations in aerosol pH, consistent with the
223 results of Tao and Murphy (Tao and Murphy, 2019) at six Canadian sites and the prediction by the
224 multiphase buffer theory (Zheng et al., 2020). In comparison, some previous studies emphasized the
225 importance of chemical compositions in seasonal variations (Tan et al., 2018; Ding et al., 2019), which
226 is mainly due to the different sensitivity analysis methods applied.

227

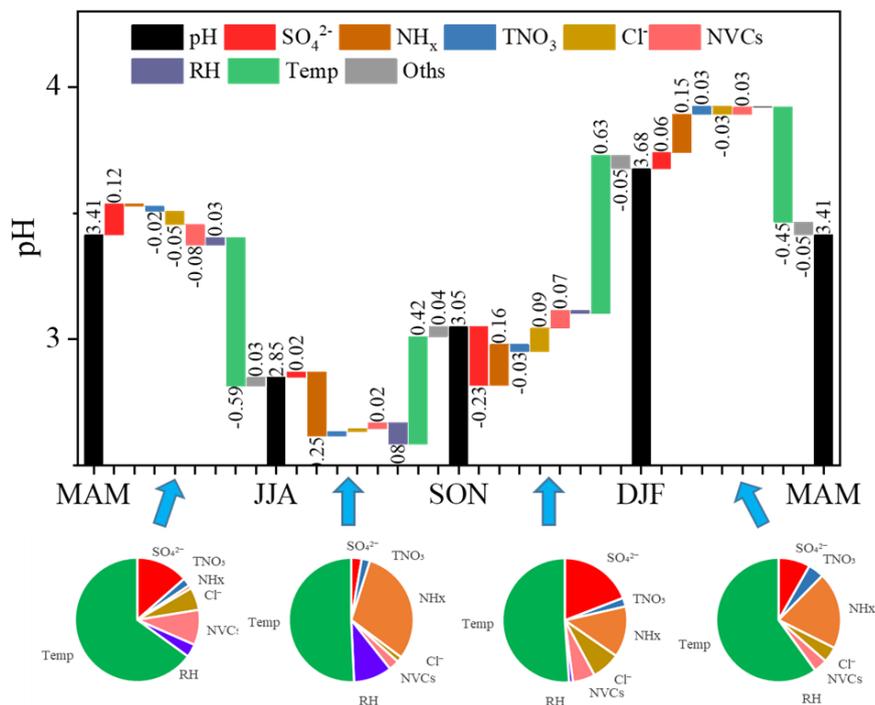

228

229 **Figure 2. Seasonal patterns of the mass concentrations of major components in PM_{2.5}, relative humidity (RH),**

234 **RH, relative humidity; Temp, temperature; NVCs, non-volatile cations; NH_x, total ammonia; TNO₃, total**
 235 **nitrate.**

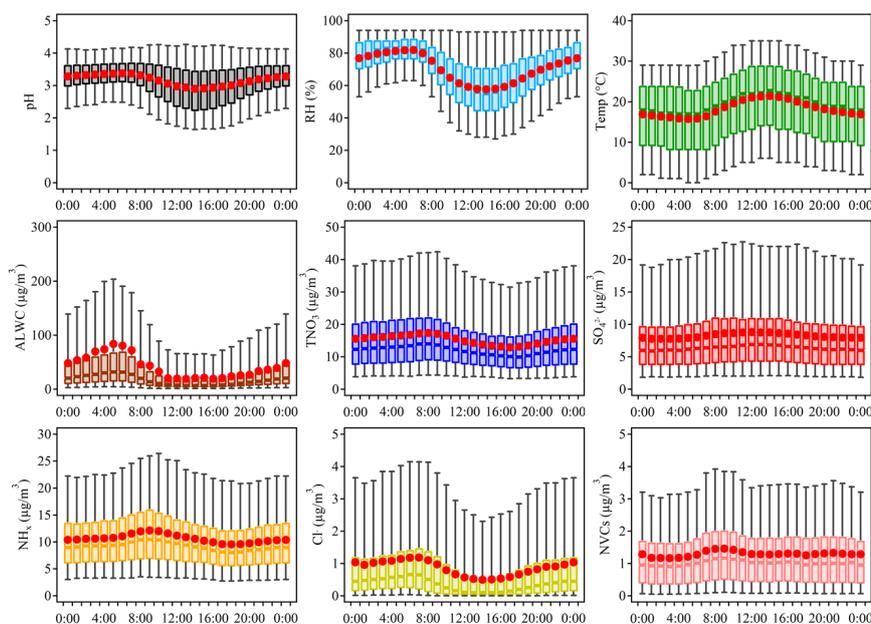

236 3.3 Diurnal variation

237 Figure 4 shows the diurnal variations in the aerosol pH and its potential drivers. Similar to the results in
 238 Beijing(Tao et al., 2020), aerosol pH in Shanghai exhibits notable diurnal variations, being higher during
 239 nighttime.

240 Figure 5 shows the effects of individual factors on the diurnal variations in aerosol pH. Temperature
 241 and RH are among the main drivers of this diurnal variation of aerosol pH, with a max ΔpH of -0.22 and
 242 +0.10 units. As shown in Fig. 4, the maximum RH and ALWC occurred at approximately 5:00. After
 243 sunrise, increase of temperature resulted in an immediate drop of RH and ALWC with ALWC reached
 244 its lowest level in the afternoon. Accordingly, the minimum aerosol pH (~2.8) was also found in the
 245 afternoon with high temperature and low RH. After sunset, the decreasing temperature and increasing

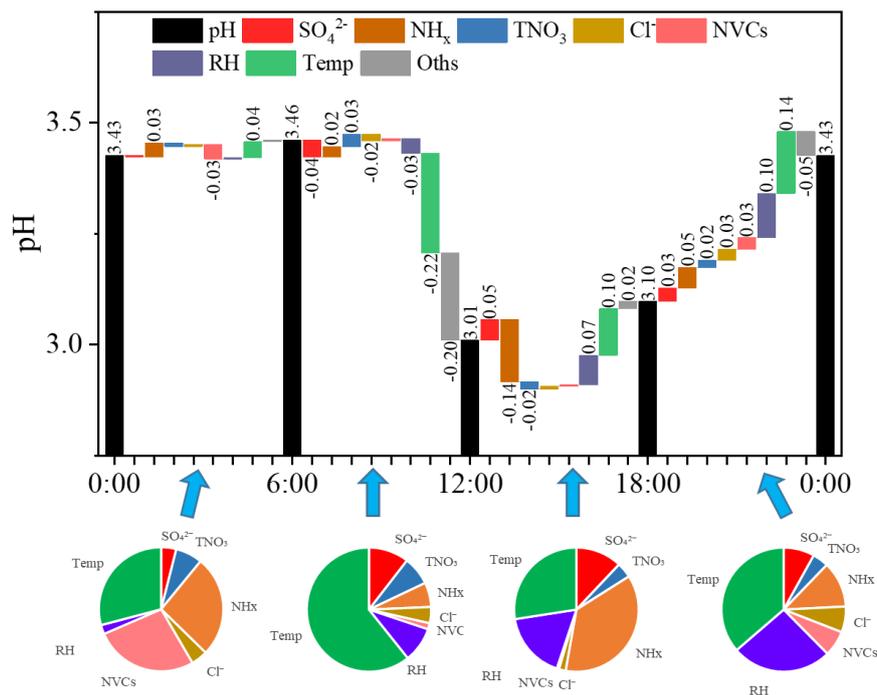

246 RH led to a highest aerosol pH overnight. Minor pH changes were found between 0:00 and 6:00, when
247 temperature and RH also show minor changes. The effects of other factors on the diurnal variations in
248 pH were notably smaller than their effects on seasonal variations, which may be attributed to the
249 relatively small variations of chemical profiles in the course of a day. Among these chemical factors,
250 NH_3 plays the most important roles, followed by SO_4^{2-} . Overall, temperature and RH are more important
251 than the chemical compositions in controlling the diurnal variations in aerosol pH.

252

261 3.4 Future projections

262 A series of prevention and control measures are suggested for continuous improvement of air quality,
 263 which will affect the atmospheric compositions and may subsequently affect the aerosol pH in China. To
 264 explore China's future anthropogenic emission pathways in 2015–2050, Tong et al.(Tong et al., 2020)
 265 developed a dynamic projection model, based on which different emission scenarios were created by
 266 connecting five socio-economic pathway (SSP) scenarios, five representative concentration pathways
 267 (RCP) scenarios (RCP8.5, 7.0, 6.0, 4.5 and 2.6) and three pollution control scenarios (business as usual,
 268 BAU; enhanced control policy, ECP; and best health effect, BHE). These scenarios provide a better
 269 understanding of the future trends in pollutant emissions(Tong et al., 2020).

270 In this study, we chose three different emission reduction scenarios as the future anthropogenic

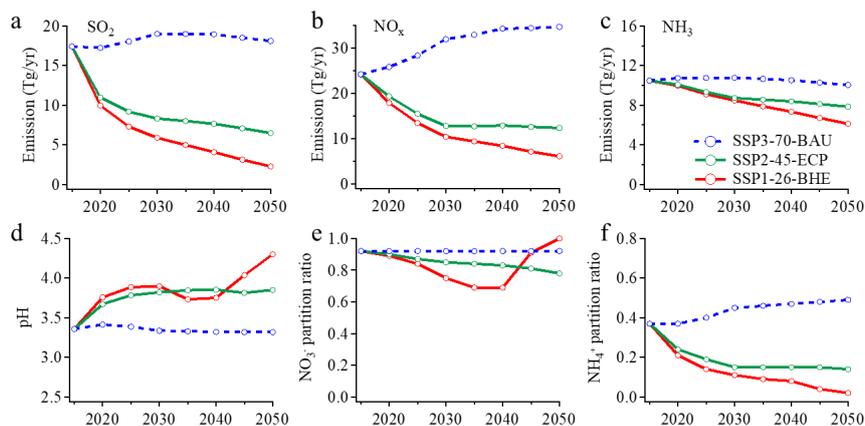

271 emission pathways, including SSP3-70-BAU, SSP2-45-ECP and SSP1-26-BHE, and tried to project the
272 future aerosol pH levels in Shanghai. SSP1-26-BHE, which involves a combination of strong low-carbon
273 and air pollution control policy, has the greatest emission reduction, followed by SSP2-45-ECP. SSP3-
274 70-BAU is a reference scenario without any active actions. Figure 6 shows the emissions of SO_2 , NO_x
275 and NH_3 and predicted pH levels in China from 2015 to 2050 under the three scenarios. We also predicted
276 the aerosol pH based on the assumption that reductions in SO_4^{2-} , TNO_3 and NH_x are equivalent to
277 reductions in their respective precursors (i.e., SO_2 , NO_x and NH_3).

278 As shown in Fig. 6, the future trend of aerosol pH changes little under the weak control policy
279 (SSP3-70-BAU). Correspondingly, there is also little change in the predicted NO_3^- partition ratio ($\text{NO}_3^- /$
280 ($\text{NO}_3^- + \text{HNO}_3$)). However, NH_4^+ partition ratio ($\text{NH}_4^+ / (\text{NH}_4^+ + \text{NH}_3)$) increases substantially, suggesting
281 an enhanced formation of ammonium aerosols. Under the moderate control policy (SSP2-45-ECP), the
282 emissions of SO_2 , NO_x , and NH_3 in 2050 will be reduced by 62.7%, 49.0% and 25.0%, respectively. This
283 would result in an increase in pH of ~ 0.5 , while the decreases in NO_3^- and NH_4^+ partition ratios of 0.14
284 and 0.23 respectively. That is, more nitrate and ammonium will exist in the gas phase as HNO_3 and NH_3 .
285 With the strict control policy (SSP1-26-BHE), the emissions of SO_2 , NO_x and NH_3 in 2050 will be
286 reduced by 86.9%, 74.9% and 41.7%, respectively, and the pH will further increase to 4.30 in 2050. It is
287 noted that the predicted pH values in the SSP1-26-BHE model decrease suddenly during 2030–2040 and
288 then continue to rise, which is due to the decrease in ALWC and increase in pH brought by the decrease
289 of SO_4^{2-} , TNO_3 and NH_x during 2015–2030. These variations result in a transition to the HNO_3 -sensitive
290 regime during 2030–2040, where partitioning gradually shifts from aerosol-phase nitrate to the gaseous
291 phase (Nenes et al., 2020a). Therefore, the decrease in TNO_3 during 2030–2040 lead to a notable decrease
292 of pH. This can also be seen from Fig. 6e, where NO_3^- partition ratio begins to decrease gradually and
293 reaches the HNO_3 -sensitive regime and then rises again under the strict control policy, resulting in NO_3^-
294 partition ratio increased from 0.92 in 2015 to 1.00 in 2050. According to the strict control policy, we also
295 found that NH_4^+ partition ratio has dropped significantly from 0.37 in 2015 to 0.02 in 2050. Because of
296 China's commitment in reducing CO_2 , we expect a further roadmap of emission control similar to the
297 SSP1-26-BHE scenario. In this case, the corresponding aerosol pH in eastern China will increase by ~ 0.9 ,
298 resulting in 8% more NO_3^- and 35% less NH_4^+ partitioning/formation in the aerosol phase. This would
299 suggest a largely reduced benefit of NH_3 and NO_x emission control in mitigating haze pollution in eastern

300 China.

305

306 4 Conclusion

307 The aerosol pH values at an urban site in Shanghai during 2011–2019 were calculated using ISORROPIA
308 II. The aerosol pH decreased from 3.30 ± 0.58 in 2011 to 3.06 ± 0.58 in 2019, which is related to changes
309 in the chemical composition under the implementation of Action Plan in the YRD region. The
310 implementation of the Action Plan leads to -35.8%, -37.6%, -9.6%, -81.0% and +1.2% changes in
311 concentrations of PM_{2.5}, SO₄²⁻, NH_x, NVCs and NO₃⁻ in YRD during this period. Then we quantified the
312 contributions of individual factors to the difference in aerosol pH from 2011 to 2019. Before the
313 implementation of the Action Plan (2011-2013), the main factors that affected the pH were the
314 temperature and NVCs. During the implementation of the Action Plan (2013-2019), SO₄²⁻ and NVCs
315 were the most important determinants of the aerosol pH and were attributed to ΔpH of +0.38 and -0.35
316 units, respectively. Meanwhile, changes in NH_x and Cl⁻ were responsible for decreases in aerosol pH of
317 0.08 and 0.06 pH units, respectively, whereas the effect of TNO₃ was negligible. NH_x appeared to play
318 an increasingly important role in determining aerosol pH through the years.

319 Distinct seasonal variations in the aerosol pH were observed, with maximum and minimum aerosol
320 pH of 3.59 ± 0.57 in winter (DJF) and 2.89 ± 0.49 in summer (JJA), respectively. Temperature through
321 its impact on pK_a^* can largely drive the seasonal variation of aerosol pH in a multiphase-buffered system.
322 Besides temperature, the main factors affecting the seasonal variation of aerosol pH are NH_x and SO_4^{2-} ,
323 which contributed to +16% and +12% pH change, respectively. The diurnal cycle of particle pH is driven
324 by the combined effects of temperature and relative humidity with a maximum ΔpH of -0.22 and +0.10
325 units, respectively. The effects of chemical factors on the diurnal variations in pH were notably smaller
326 than the effects on seasonal variations, which may be attributed to the limited variations of chemical
327 profiles in the course of a day.

328 Finally, to explore the effects of China's future anthropogenic emission control pathways on aerosol
329 pH and compositions, we chose three different emission reduction scenarios proposed by Tong et
330 al. (Tong et al., 2020) for future haze mitigation, naming SSP3-70-BAU, SSP2-45-ECP and SSP1-26-
331 BHE as case studies. We estimated that the future trend of aerosol pH and NO_3^- partition ratio change
332 little under the weak control policy (SSP3-70-BAU). However, NH_4^+ partition ratio increases
333 substantially, suggesting an enhanced formation of ammonium aerosols. The results also demonstrate
334 that future aerosol pH will increase under both strict control policy (SSP1-26-BHE) and moderate control
335 policy (SSP2-45-ECP), but more drastically under former scenario. The significant increase in aerosol
336 pH with strict control policy will lead to more nitrate partitioning in aerosol phase, hence inhibiting future
337 $PM_{2.5}$ pollution control. This finding implicates that variations in aerosol pH will feedback to
338 multiphase formation pathways of aerosols in the atmosphere. In other words, proportional
339 reductions in precursors and follow-up variations in aerosol pH are evidently necessary to be taken into
340 account for future efforts in mitigating haze pollution.

341 **Author Contributions**

342 HS, HW, and CH conceived and led the study. MZ conducted the field measurements and carried out the
343 data analysis. MZ and GZ performed model simulations. MZ, HS, HW, CH, GZ, LQ, SZ, DH, YC, JA
344 discussed the results. LQ, SZ, DH, SL, ST, QW, RY, YM, CC conducted the measurements at the station.
345 MZ, HS and GZ wrote the manuscript with input from all co-authors.

346 **Supplement**

347 The supplement is available in a separate file.
