15 **Abstract**

16 Despite the growing interest in understanding haze formation in Chinese megacities, air  
17 pollution has been largely overlooked for the Harbin-Changchun (HC) metropolitan area located in  
18 the severe cold climate region in Northeast China. In this study, we unfolded significant variations  
19 of fine particulate matter (PM<sub>2.5</sub>) in HC's central city (Harbin) during two sequential heating seasons  
20 of 2018–2019 and 2019–2020, and explored major drivers for the observed variations. The two  
21 campaigns showed comparable organic carbon (OC) levels but quite different OC sources. The  
22 biomass burning (BB) to OC contribution decreased substantially for 2019–2020, which was  
23 attributed primarily to the transition of local policies on agricultural fires, i.e., from the “legitimate  
24 burning” policy released in 2018 to the “strict prohibition” policy in 2019. Meanwhile, the  
25 contribution of secondary OC (OC<sub>sec</sub>) increased significantly, associated with the much more  
26 frequent occurrences of high relative humidity (RH) conditions during the 2019–2020 measurement

27 period. Similar to  $OC_{sec}$ , the major secondary inorganic ions, i.e., sulfate, nitrate and ammonium  
28 (SNA), also exhibited RH-dependent increases. Given the considerable aerosol water contents  
29 predicted for the high-RH conditions, heterogeneous reactions were likely at play in secondary  
30 aerosol formation even in the frigid atmosphere in Harbin (e.g., with daily average temperatures  
31 down to below  $-20\text{ }^{\circ}\text{C}$ ). In brief, compared to 2018–2019, the 2019–2020 measurement period was  
32 characterized by a policy-driven decrease of biomass burning OC, a RH-related increase of  $OC_{sec}$   
33 and a RH-related increase of SNA, with the former two factors generally offsetting each other. In  
34 addition, we found that open burning activities were actually not eliminated by the “strict prohibition”  
35 policy released in 2019, based on a synthesis of air quality data and fire count results. Although not  
36 occurred during the 2019–2020 measurement period, agricultural fires broke out within a short  
37 period before crop planting in spring of 2020, and resulted in off-the-chart air pollution for Harbin,  
38 with 1- and 24-hour  $PM_{2.5}$  concentrations peaking at  $\sim 2350$  and  $900\text{ }\mu\text{g}/\text{m}^3$ , respectively. This study  
39 indicates that sustainable use of crop residues remains a difficult challenge for the massive  
40 agricultural sector in Northeast China.

## 41 **1. Introduction**

42 Despite nationwide reductions in anthropogenic emissions (Zhang et al., 2019), severe haze  
43 pollution characterized by high concentrations of fine particulate matter (PM<sub>2.5</sub>) is far from being  
44 effectively controlled in China, e.g., haze episodes were observed in Beijing even during the  
45 COVID-19 lockdown (Lv et al., 2020). This reveals the complex yet poorly understood responses  
46 of air pollution to changes of primary emission. While secondary aerosol production has been  
47 thought to be largely responsible for this lack of understanding, the chemical mechanisms remain  
48 vague (Le et al., 2020; Wang et al., 2020b; Huang et al., 2021). For example, state-of-the-art models  
49 incorporating gas-phase and cloud chemistry frequently underestimated sulfate and secondary  
50 organic aerosol (SOA) concentrations for winter haze events in Beijing (Wang et al., 2014; Zheng  
51 et al., 2015a; Cheng et al., 2016; Liu et al., 2020a). The underestimation was more significant with  
52 increasing relative humidity (RH) or aerosol water content (AWC) levels, pointing to the importance  
53 of aqueous-phase reactions in aerosol water (Wang et al., 2016; Shrivastava et al., 2017; Su et al.,  
54 2020; Liu et al., 2021b). On the other hand, quantitative prediction of secondary aerosols formed  
55 through aqueous-phase reactions remains challenging, partially due to uncertainties in aerosol pH  
56 (Guo et al., 2017b; Song et al., 2018; Zheng et al., 2020) and oxidant concentrations (Ye et al., 2018;  
57 Wang et al., 2020a). In addition, despite the role of heterogeneous chemistry has been widely  
58 accepted for sulfate formation, its effects on SOA remain unclear, with more evidences indicating  
59 an enhancement effect (Hu et al., 2016; Kuang et al., 2020; Liu et al., 2020a; Wang et al., 2021a)  
60 overwhelming those suggesting little influence of RH or AWC on SOA formation (Zheng et al.,  
61 2015b). In all, there is a growing interest in understanding haze pollution in Chinese megacities (Shi  
62 et al., 2019), especially regarding the driving factors responsible for the spatio-temporal variations,

63 since these factors are essential for the development of efficient air pollution control strategies.

64 Studies on haze in China have been historically concentrated in the North China Plain (NCP),  
65 especially around Beijing. Recently, new hotspots began to emerge, e.g., the Harbin-Changchun  
66 (HC) metropolitan area. HC is located in the severe cold climate region in Northeast China, and  
67 includes 11 cities in the two provinces of Heilongjiang and Jilin. Compared to NCP and other  
68 traditional hotspots of air pollution research (e.g., the Yangtze River Delta), HC is characterized by  
69 its extremely cold winter when the daily average temperatures could drop to below  $-20\text{ }^{\circ}\text{C}$ . Thus,  
70 the heating season is usually as long as six months in HC, lasting from late fall through early spring  
71 of next year. During this period, intensive energy use is expected, e.g., coal combustion for central  
72 heating in urban areas and household biomass burning for space-heating in rural areas. The intensive  
73 energy use, to a large extent, determines the relatively high baseline of  $\text{PM}_{2.5}$  pollution in HC's  
74 heating season. According to the open access air quality data routinely published by China National  
75 Environmental Monitoring Center (<http://106.37.208.233:20035/>), the monthly averages of  $\text{PM}_{2.5}$   
76 measured during winter in Harbin stayed above  $55\text{ }\mu\text{g}/\text{m}^3$  from 2013 throughout 2020, whereas the  
77 corresponding value could drop to below  $30\text{ }\mu\text{g}/\text{m}^3$  for Beijing.

78 Another feature of HC is that it is located in a main agricultural region in China. For example,  
79 Heilongjiang Province provided  $\sim 13\%$  and  $15\%$  of the national rice and corn productions in 2019,  
80 respectively, with only  $\sim 5\%$  of China's land area (National Bureau of Statistics of China, 2020).  
81 The massive agricultural sector results in a huge amount of crop residues, which are produced after  
82 harvesting in autumn and must be disposed before planting in spring of the next year. Although  
83 nominally prohibited, open burning persists as an important approach for the disposal of crop  
84 residues in Northeast China, with a time window largely overlapped with the heating season. These

85 agricultural fires frequently resulted in heavily-polluted PM<sub>2.5</sub> episodes, e.g., with 24-hour PM<sub>2.5</sub>  
86 peaking at ~650 µg/m<sup>3</sup> during early November of 2015 in Harbin (Li et al., 2019b). Given that the  
87 agricultural fires were never eliminated, interim provisions were released by Heilongjiang Province  
88 in 2018, which approved a window of approximately 3 months (from 11 December, 2018 to 9 March,  
89 2019) for open burning of crop residues (Department of Ecology and Environment of Heilongjiang  
90 Province, 2018). However, the interim provisions were amended in 2019, i.e., the “legitimate  
91 burning” policy was terminated and was replaced by a toughest-ever policy on open burning, which  
92 required that agricultural fires should be strictly prohibited for the period of 15 September, 2019 to  
93 15 May, 2020. The rapid transition of open burning policy reflects the ongoing attempts of local  
94 government to control the severe haze pollution caused by agricultural fires. However, the most  
95 effective and reliable approach remains inconclusive, given that very little is known about the role  
96 of biomass burning in PM<sub>2.5</sub> pollution in Northeast China. Actually, PM<sub>2.5</sub> in Northeast China is far  
97 from being well characterized yet with limited studies (e.g., Cao et al., 2016; Yang et al., 2017; Li  
98 et al., 2019b; Zhang et al., 2020), especially regarding sources and chemical mechanisms of aerosol  
99 formation.

100 In this study, we investigated the variations of Harbin aerosol during two sequential heating  
101 seasons of 2018–2019 and 2019–2020, with focuses on the roles of (1) rapid transition of open  
102 burning policy and (2) significant change of meteorological conditions (especially relative  
103 humidity), which would influence primary emissions and secondary aerosol formation, respectively.  
104 Policy implications for improving air quality in the HC region were also discussed.

## 105 **2. Methods**

### 106 **2.1 Field observation and additional data sets used**

107 Two campaigns were conducted at an urban site located in the campus of Harbin Institute of  
108 Technology (HIT; 45°45'24" N, 126°40'49" E) during the heating seasons of 2018–2019 (from 16  
109 October, 2018 to 14 April, 2019;  $N = 180$ ) and 2019–2020 (from 16 October, 2019 to 4 February,  
110 2020;  $N = 112$ ), following the same sampling and analytical procedures. As described for the 2018–  
111 2019 campaign (Cheng et al., 2021a), a low volume sampler (MiniVol; Airmetrics, OR, USA)  
112 operated at a flow rate of 5 L/min was used to collect airborne  $PM_{2.5}$  onto pre-baked quartz-fiber  
113 filters (2500 QAT-UP; Pall Corporation, NY, USA), and the measured species included organic  
114 carbon (OC), elemental carbon (EC), organic tracers for biomass burning (levoglucosan and  
115 mannosan) and water-soluble inorganic ions (sulfate, nitrate, ammonium, etc.). Briefly, OC and EC  
116 were determined by a thermal/optical carbon analyzer (DRI-2001; Atmoslytic Inc., CA, USA),  
117 using the IMPROVE-A temperature protocol with transmittance charring correction. Precision of  
118 the carbon analyzer was investigated by analyzing the samples using another protocol (NIOSH).  
119 Comparisons of total carbon and optical attenuation results between the two protocols suggested  
120 good repeatability for both the carbon and transmittance measurements (Figure S1). Levoglucosan  
121 and mannosan were detected by a Dionex ion chromatography (IC) system (ICS-5000<sup>+</sup>; Thermo  
122 Fisher Scientific Inc., MA, USA), using the high-performance anion-exchange chromatography  
123 coupled to pulsed amperometric detection (HPAEC-PAD) method. In addition, the IC was also used  
124 to measure the inorganic ions. Precision of the IC was evaluated by analyzing selected solutions 5–  
125 10 times, and the relative standard deviations were found to be within 5% for all the water-soluble  
126 species detected, either organic or inorganic. Based on the observed aerosol components,  $PM_{2.5}$  mass  
127 was reconstructed as the sum of organic matter (determined as  $1.6 \times OC$ ), EC and inorganic ions.  
128 The reconstructed  $PM_{2.5}$  will be specified as  $(PM_{2.5})^*$  in the following discussions.

129 Air quality data including PM<sub>2.5</sub>, sulfur dioxide (SO<sub>2</sub>), nitrogen dioxide (NO<sub>2</sub>), carbon  
130 monoxide (CO), etc. were obtained from China's National Urban Air Quality Real Time Publishing  
131 Platform (<http://106.37.208.233:20035/>). They were measured at monitoring sites operated by the  
132 China National Environmental Monitoring Center (CNEMC), and could be accessed with a time  
133 resolution of 1 hour. There are a total of 12 CNEMC sites in Harbin. Results from the nearest one  
134 to the filter sampling site (~2.4 km apart), i.e., Taiping Hongwei Park, were used in this study. In  
135 addition, hourly meteorological data including temperature and relative humidity (RH) were  
136 obtained from Weather Underground (<https://www.wunderground.com>).

137 Using levoglucosan as the reference component, the relative abundances of water-soluble  
138 potassium (K<sup>+</sup>) were found to increase substantially for five samples collected during the Chinese  
139 New Year periods in February of 2019 ( $N = 2$ ; Cheng et al., 2021a) and in January of 2020 ( $N = 3$ ;  
140 Figure S2), pointing to significant influence of firework emissions. Given that such emissions may  
141 result in primary sulfate and nitrate which are difficult to quantify, the firework events were  
142 excluded, and the remaining sulfate and nitrate were considered secondary in the following  
143 discussions. Then taking together observational results from the filter sampling and CNEMC sites,  
144 the sulfur oxidation ratio (SOR) was determined as the molar ratio of sulfate to the sum of sulfate  
145 and SO<sub>2</sub>, and the nitrogen oxidation ratio (NOR) was determined similarly based on nitrate and NO<sub>2</sub>.

## 146 **2.2 Thermodynamic simulation**

147 The ISORROPIA-II model (Fountoukis and Nenes, 2007) was used to predict aerosol water  
148 content (AWC) and aerosol pH. The calculations were conducted in two ways, namely the “reverse”  
149 and “forward” modes. For the “reverse” mode, the measured aerosol-phase data were deployed as  
150 input to derive AWC and pH directly. For the “forward” mode, the model was run in an iteration

151 way (Liu et al., 2021a). Briefly, we used the measured aerosol-phase data as initial input, ran  
152 ISORROPIA-II in the “forward” mode to predict gas-phase concentrations of semi-volatile species  
153 (e.g., ammonia and nitric acid), and used the sum of predicted gas-phase and measured aerosol-  
154 phase concentrations as the input for next round. The calculations were repeated until the simulated  
155 results were stable and in line with the observational data. Although the “reverse” and “forward”  
156 mode simulations showed comparable AWC levels for this campaign (Figure S3), the latter  
157 approach has been suggested to give more accurate and robust estimation of pH (Guo et al., 2017a;  
158 Song et al., 2018). Thus, AWC and pH results predicted by the iteration approach were used in the  
159 following discussions.

## 160 **2.3 Source apportionment**

161 Source apportionment was performed using EPA’s Positive Matrix Factorization (PMF) model  
162 (version 5.0), with times series of OC, EC, levoglucosan, chloride, nitrate, sulfate and ammonium  
163 from both campaigns as inputs. A total of five factors were resolved, and their profiles were shown  
164 in Figure S4. Two factors (BB-1 and BB-2) were strongly associated with primary biomass burning  
165 emissions, since almost all the levoglucosan (~90%) were apportioned to these two factors whereas  
166 neither of them was a major contributor to secondary ions. Another two factors were inferred to  
167 represent secondary aerosols (SA-1 and SA-2), as they had zero EC but the majority of nitrate and  
168 sulfate. The last factor (non-BB<sub>pri</sub>) was attributed to primary emissions from non-BB sources,  
169 because more than 50% of EC but little levoglucosan was found in this factor.

## 170 **3. Results and discussion**

### 171 **3.1 Variation of biomass burning (BB) OC**

172 Although comparable OC levels were observed during the 2018–2019 and 2019–2020

173 measurement periods (averaging  $20.66 \pm 18.17$  and  $20.64 \pm 16.76 \mu\text{gC}/\text{m}^3$ , respectively), the former  
174 campaign exhibited substantially higher contributions of levoglucosan to OC (Figure 1a). Here we  
175 applied the levoglucosan to OC ratio (LG/OC) as the indicator for BB impact, given that the absolute  
176 concentrations of ambient levoglucosan could be influenced by other factors in addition to biomass  
177 burning (e.g., wind speed and planetary boundary layer height). LG/OC averaged  $1.83 \pm 1.18$  and  
178  $1.17 \pm 0.30\%$  (on a basis of carbon mass) during 2018–2019 and 2019–2020, respectively, indicating  
179 that the influence of biomass burning was stronger during the former campaign. This difference was  
180 mainly caused by the 2018–2019 samples collected during and after the “legitimate burning” periods  
181 (periods of P-2 and P-3, with average LG/OC ratios of  $2.09 \pm 1.42$  and  $2.15 \pm 0.94\%$ , respectively;  
182 Figure 1b), whereas the LG/OC ratios observed before the onset of “legitimate burning” (P-1,  
183 averaging  $1.20 \pm 0.36\%$ ) were in general comparable with those during the 2019–2020 campaign.

184 Recalling the different open burning policies released in 2018 and 2019, the observed  
185 variations of LG/OC appeared to be associated with agricultural fires. According to the relationship  
186 between levoglucosan and OC, Cheng et al. (2021a) classified the 2018–2019 samples into three  
187 groups (Cases A, B and C) with LG/OC ranges of  $< 1.5\%$ ,  $1.5\text{--}3.0\%$  and  $> 3.0\%$ , respectively.  
188 Levoglucosan exhibited strong linear correlations with OC for all the three cases ( $r \geq 0.95$ ), with  
189 slopes, i.e.,  $\Delta\text{LG}/\Delta\text{OC}$  (approximately equivalent to LG/OC given the close-to-zero intercepts), of  
190 1.1, 2.3 and 5.0%, respectively. The variation of LG/OC across the three cases was inferred to be  
191 driven mainly by agricultural fires that had relatively low combustion efficiencies, based on a  
192 synthesis of the following evidences (Cheng et al., 2021a): (1) the levoglucosan to  $\text{K}^+$  ratios and  
193 levoglucosan to mannosan ratios observed throughout the 2018–2019 campaign were in line with  
194 the characteristics of BB smoke emitted by the burning of crop residues; (2) no dependence of

195 LG/OC on temperature was observed, indicating that the variations of LG/OC could not be  
196 explained by biomass burning for household space-heating in rural areas; (3) elevated LG/OC ratios  
197 were typically associated with intensive fire counts, i.e., open burning of crop residues, around  
198 Harbin; (4) chemical signatures associated with combustion phase exhibited changes toward  
199 smoldering-dominated burning from Cases A through C, e.g.,  $\Delta\text{EC}/\Delta\text{CO}$  (derived from linear  
200 regression of EC on CO) decreased whereas the levoglucosan to  $\text{K}^+$  ratios increased. Following  
201 Cheng et al. (2021a), LG/OC ratios higher than 1.5% were considered an indicator for apparent  
202 impacts of agricultural fires around Harbin. As shown in Figures 1c–1d, approximately 50% of the  
203 2018–2019 samples exhibited LG/OC above 1.5%, with various fractions for the three periods, i.e.,  
204 15, 64 and 71% for P-1, P-2 and P-3 samples, respectively. Thus, apparent impacts of agricultural  
205 fires were frequently encountered in the 2018–2019 campaign, particularly after the onset of  
206 “legitimate burning”. It is noteworthy that the agricultural fires did not actually disappear after the  
207 ending of “legitimate burning” and instead extended to mid-April of 2019. For the 2019–2020  
208 campaign, however, only less than 5% of the samples showed LG/OC larger than 1.5% (Figure 1c),  
209 indicating the rare occurrence of agricultural fires during the measurement period.

210 Comparison of source apportionment results between the two campaigns also indicated  
211 substantial changes in the influence of agricultural fires. For the 2018–2019 campaign, both the OC  
212 mass apportioned to BB-1 ( $\text{OC}_{\text{BB-1}}$ ; Figure S5) and the contribution of BB-1 to OC ( $f_{\text{BB-1}}$ ; Figure 2)  
213 increased substantially after the onset of “legitimate burning”, likely indicating that this factor was  
214 representative of agricultural fire emissions. This inference was also supported by the comparison  
215 of OC source apportionment results across the three cases (A–C) with increasing LG/OC ratios, i.e.,  
216 with stronger impacts of agricultural fires.  $\text{OC}_{\text{BB-1}}$  increased drastically by ~25 folds (from 1.2 to

217 30.9  $\mu\text{gC}/\text{m}^3$ ) from Cases A through C, with OC attributed to other factors being largely unchanged,  
218 and correspondingly,  $f_{\text{BB-1}}$  increased sharply from 9 to 69% across the three cases (Figure S6). In  
219 addition, it was noticed that negligible EC was apportioned to the BB-1 factor (Figure S4), which  
220 was the characteristic of smoldering-dominated combustion as supported by numerous BB source  
221 emission studies (McMeeking et al., 2009; May et al., 2014; Pokhrel et al., 2016; McClure et al.,  
222 2020; Wang et al., 2020c). This feature was consistent with the inference that the agricultural fires  
223 had relatively low combustion efficiencies (Cheng et al., 2021a). During the 2018–2019 campaign,  
224 the contribution of agricultural fires to OC was rather small (9%) before the onset of “legitimate  
225 burning”, whereas after this time point, the contribution increased to ~40% (Figure 2). The overall  
226  $f_{\text{BB-1}}$  was 34% for the entire measurement period of 2018–2019, suggesting agricultural fire  
227 emissions as the dominant source of OC. For the 2019–2020 campaign, however,  $f_{\text{BB-1}}$  was  
228 substantially lower (9%; Figure 2), comparable with that determined for the 2018–2019 samples  
229 collected during P-1, i.e., before the onset of “legitimate burning”. Regarding the temporal variation  
230 of agricultural fire impacts, therefore, the same patterns were observed based on the comparisons of  
231 LG/OC and PMF results across various measurement periods.

232 Unlike  $\text{OC}_{\text{BB-1}}$ , OC masses apportioned to the BB-2 factor ( $\text{OC}_{\text{BB-2}}$ ) were comparable for the  
233 2018–2019 samples collected before, during and after the “legitimate burning” periods (Figure S5).  
234  $\text{OC}_{\text{BB-2}}$  was also largely unchanged across the three cases (A–C) with stronger impacts of  
235 agricultural fires (Figure S6). Therefore, it seems that BB-2 was associated with biomass burning  
236 activities that did not have significant daily variation, with the most likely candidate being  
237 household combustion of crop residues (for cooking and heating). In addition,  $\text{OC}_{\text{BB-2}}$  appeared to  
238 be slightly higher for the 2019–2020 campaign compared to 2018–2019 (6.24 vs. 4.51  $\mu\text{gC}/\text{m}^3$ ;

239 Figure S5), presumably because more crop residues were consumed through household use in  
240 response to the “strict prohibition” open burning policy.

241 The two biomass burning factors constituted 57% of OC for the 2018–2019 campaign (Figure  
242 2). Before the onset of “legitimate burning”, the total contribution of biomass burning ( $f_{BB}$ ) was 46%  
243 and was dominated by the BB-2 factor (i.e., household burning of crop residues), whereas after this  
244 time point,  $f_{BB}$  increased to 59% and was dominated by BB-1 (agricultural fires). For the Case C  
245 samples, i.e., under the strongest impacts of agricultural fires,  $f_{BB}$  was as high as 79% (Figure S6).  
246 A prominent reduction in  $OC_{BB-1}$ , however, occurred for the 2019–2020 measurement period, and  
247  $f_{BB}$  dropped to 39% with BB-2 as the dominant contributor (Figures 2 and S5). It is noteworthy that  
248 compared to the typical  $f_{BB}$  determined during winter in Beijing (~10–20%, derived from field  
249 observations using aerosol mass spectrometer; Hu et al., 2016; Sun et al., 2018; Li et al., 2019a; Xu  
250 et al., 2019), the BB contributions were much higher in Harbin even when the contribution of  
251 agricultural fires was limited (e.g., during the 2019–2020 campaign, and P-1 in 2018–2019),  
252 pointing to strong emissions from residential burning of crop residues throughout the heating season  
253 in Northeast China.

### 254 3.2 Variation of secondary OC

255 OC masses apportioned to the SA-1 and SA-2 factors ( $OC_{sec}$ ) were considered secondary.  $OC_{sec}$   
256 were 3.9 and 7.6  $\mu\text{gC}/\text{m}^3$  for the 2018–2019 and 2019–2020 campaigns, respectively, constituting  
257 19 and 37% of OC (Figures 2 and S5). It was noticed that for biomass burning OC and  $OC_{sec}$ , their  
258 inter-campaign differences showed comparable absolute values but opposite signs. This explains  
259 why the two heating seasons had significantly different OC sources but almost the same OC levels.

260 As shown in Figure 3,  $OC_{sec}$  exhibited a positive dependence on RH, with an explosive increase

261 of  $OC_{sec}$  after RH exceeded 80%. Only ~6% of the 2018–2019 samples (10 out of 180) experienced  
262 such humid conditions, whereas this fraction was as high as ~37% for 2019–2020 (corresponding  
263 to 42 out of the 112 samples). Thus the potential influence of RH on SOA formation was primarily  
264 investigated based on results from the 2019–2020 campaign. Figure 4 compares OC source  
265 apportionment results across different RH ranges (< 60%, 60–80% and > 80%), which are termed  
266 low-, medium- and high-RH conditions, respectively, for this measurement period. Not only  $OC_{sec}$   
267 but also its contribution to OC ( $f_{sec}$ ) increased significantly from the low- through high-RH  
268 conditions, by factors of 9.8 and 2.6, respectively. Although the 2019–2020 campaign experienced  
269 much lower ambient temperatures (as low as  $-20\text{ }^{\circ}\text{C}$ ) compared to Beijing’s winter ( $\sim 0\text{ }^{\circ}\text{C}$ ), the  $f_{sec}$   
270 of Harbin reached 42% for the RH range of > 80%, generally comparable with the typical range of  
271 oxygenated organic aerosol (OOA) contribution ( $\sim 35\text{--}60\%$ ) determined under humid winter  
272 conditions in Beijing (Sun et al., 2013, 2014, 2018; Hu et al., 2016; Xu et al., 2019). Given the  
273 considerable AWC levels predicted for the high-RH conditions (typically above  $50\text{ }\mu\text{g}/\text{m}^3$ ; Figure  
274 3), it was inferred that heterogeneous reactions might be at play in the RH-dependent increase of  
275  $f_{sec}$ .

276 The OC to EC ratio (OC/EC) is also a commonly used indicator for SOA, giving rise to the  
277 EC-tracer method for the estimation of  $OC_{sec}$  mass. However, it has long been recognized that SOA  
278 formation is usually not the only factor that can increase OC/EC, and another factor that could be  
279 playing a crucial role is the biomass smoke with relatively high emission ratios of OC to EC. Among  
280 the three primary factors resolved in this study, OC/EC for the primary emissions of BB-1  
281 (extremely high as negligible EC was apportioned to this factor; Figure S4) and BB-2 (3.5) were  
282 both larger than that of non- $BB_{pri}$  (2.8). Thus the influences of not only SOA but also biomass

283 burning emissions need to be considered when interpreting the observed OC/EC. For the 2018–2019  
284 campaign, the temporal variation of OC/EC was mainly driven by biomass burning emissions  
285 (especially the BB-1 factor), as can be seen from the positive dependence of OC/EC on levoglucosan  
286 and the comparison of OC/EC across the three cases with increasing LG/OC (Figure S7). In this  
287 case, the EC-tracer method should be used with caution, since the basic assumption, i.e., variation  
288 of OC/EC can be attributed primarily to SOA formation, was invalid. Unlike 2018–2019, SOA was  
289 the dominant driver for the variation of OC/EC during the 2019–2020 measurement period, as  
290 indicated by the positive dependence of OC/EC on sulfate and the comparison of OC/EC across the  
291 low- through high-RH conditions (Figure S8). During the 2019–2020 campaign, similar patterns of  
292 temporal variation were observed for OC<sub>sec</sub> retrieved using the EC-tracer method and PMF approach,  
293 and both results supported the RH-dependent increase of OC<sub>sec</sub> (Figure S9). However, compared to  
294 the PMF-based  $f_{\text{sec}}$ , the EC-tracer method resulted in a higher contribution of OC<sub>sec</sub> to OC for the  
295 high-RH conditions (60% vs. 42%). This is not surprising, as variation of biomass burning emissions  
296 could also contribute to the elevated OC/EC of the high-RH conditions (Figure S8), but this  
297 contribution could not be distinguished from that of SOA by the EC-tracer method. Nonetheless,  
298 enhanced SOA formation was evident for the high-RH conditions, which mainly occurred within  
299 the coldest months (December and January) during the 2019–2020 measurement period.

### 300 **3.3 Variation of secondary inorganic aerosol**

301 Both sulfate and SOR exhibited increasing trends as RH became higher (Figure 5), e.g., SOR  
302 averaged  $0.09 \pm 0.04$  and  $0.20 \pm 0.07$  for the RH ranges of below and above 80%, respectively. The  
303 apparent increase of SOR after RH exceeded 80% pointed to enhanced sulfate formation,  
304 presumably through heterogeneous reactions given the high AWC levels (as can be seen from Figure

305 3). In addition, NO<sub>2</sub> appeared to be at play in the heterogeneous conversion of SO<sub>2</sub> to sulfate,  
306 because the RH-dependent increase of SOR was more significant for the samples with relatively  
307 high NO<sub>2</sub> concentrations (e.g., above 30 µg/m<sup>3</sup>; Figure 6). Based on the observational results  
308 available, however, it was inconclusive whether NO<sub>2</sub> was the dominant oxidant for the  
309 heterogeneous formation of sulfate. Simulation results by ISORROPIA-II suggested moderately  
310 acidic aerosols (pH of 4.2 ± 1.1) for the high-RH conditions, and the importance of other oxidants  
311 (e.g., H<sub>2</sub>O<sub>2</sub>) could be comparable with or even overwhelm NO<sub>2</sub> for the oxidation of SO<sub>2</sub> in aerosol  
312 water at such pH levels (Guo et al., 2017b; Liu et al., 2017; Ye et al., 2018; Wang et al., 2021b).  
313 Nonetheless, the relationship between SOR and RH observed in Harbin was in general consistent  
314 with the wintertime results from Beijing. However, the threshold RH for sharp increase of SOR was  
315 higher in Harbin (80%) than that in Beijing (~40–70%), and the SOR in Harbin with RH above 80%  
316 (averaging 0.2) were at the lower end of the corresponding values observed during winter in Beijing  
317 (typically with averages of ~0.2–0.6) (Sun et al., 2013; Zheng et al., 2015b; Zhang et al., 2018; Li  
318 et al., 2019a; Liu et al., 2020b). A likely cause for these differences was the relatively low  
319 temperatures during the measurement period, which would reduce the rate coefficients of relevant  
320 aqueous-phase reactions (Cheng et al., 2016).

321 The 2018–2019 and 2019–2020 campaigns exhibited comparable sulfate concentrations for the  
322 RH range of below 80%, with median values of 3.72 and 3.39 µg/m<sup>3</sup>, respectively (Figure S10).  
323 RH-dependent increase of sulfate was evident for both campaigns but was less significant for the  
324 former one, e.g., the median sulfate were 5.32 and 15.84 µg/m<sup>3</sup> for the high-RH conditions of 2018–  
325 2019 and 2019–2020, respectively. As mentioned earlier, only 10 out of the 180 samples from the  
326 2018–2019 campaign fell into the high-RH conditions. Among these 10 samples, the RH-dependent

327 increase of sulfate was observed for only three ones with NO<sub>2</sub> concentrations of above 60 µg/m<sup>3</sup>,  
328 but was not evident for the remaining samples which had much lower NO<sub>2</sub> (mostly below 30 µg/m<sup>3</sup>;  
329 Figure 7). For the 2019–2020 campaign, however, the majority of the samples with RH above 80%  
330 showed NO<sub>2</sub> concentrations of above 60 µg/m<sup>3</sup>, accompanied with elevated sulfate. Therefore, the  
331 different NO<sub>2</sub> levels under high-RH conditions between the two campaigns (with median  
332 concentrations of 21.27 and 72.41 µg/m<sup>3</sup> during 2018–2019 and 2019–2020, respectively; Figure  
333 S11) was a likely cause of the more significant RH-dependent increase of sulfate observed during  
334 the 2019–2020 campaign.

335 The 2019–2020 campaign also exhibited more significant RH-dependent increase of nitrate,  
336 similar to sulfate (Figure S12). In addition, an obvious difference between the two campaigns was  
337 that the nitrate to sulfate (NO<sub>3</sub><sup>-</sup>/SO<sub>4</sub><sup>2-</sup>) ratios tended to be higher during 2019–2020 (Figure S13),  
338 with an average of 1.28 ± 0.51 (compared to 1.10 ± 0.66 for 2018–2019). This trend was somewhat  
339 surprising, as the 2019–2020 measurement period experienced substantially lower temperatures  
340 than 2018–2019 (Figure S13) and consequently was expected to be impacted by stronger heating-  
341 induced coal combustion emissions, which were a large source of SO<sub>2</sub>. However, SO<sub>2</sub> were actually  
342 lower for the 2019–2020 campaign, presumably due to the implementation of clean air actions  
343 targeting pollutants from coal combustion. On the other hand, NO<sub>2</sub> were higher during 2019–2020.  
344 Factors responsible for this increase were unclear, while a possible explanation was that the  
345 meteorological conditions of 2019–2020 were generally less favorable for dispersion of air  
346 pollutions, as indicated by the frequent occurrences of high RH. In this case, the decrease of SO<sub>2</sub>  
347 emissions in 2019–2020 was inferred to be more significant after accounting for the unfavorable  
348 meteorological conditions. In general, the 2019–2020 campaign exhibited higher NO<sub>2</sub> to SO<sub>2</sub> ratios

349 (Figure S13), which were in line with the observed variation of nitrate to sulfate ratios.

350 In addition to the relative abundances of NO<sub>2</sub> and SO<sub>2</sub>, the influence of their gas-to-particle  
351 conversion ratios should also be considered when comparing NO<sub>3</sub><sup>-</sup>/SO<sub>4</sub><sup>2-</sup> across different conditions.  
352 The two campaigns differed with respect to humidity levels and biomass burning emissions, both  
353 of which could influence SNA formation. Although NOR and SOR were indeed influenced by RH,  
354 NO<sub>3</sub><sup>-</sup>/SO<sub>4</sub><sup>2-</sup> did not show clear dependence on RH (Figure S14). In addition, there were  
355 observational evidences indicating that biomass burning emissions could enhance photochemical  
356 oxidation of NO<sub>2</sub> whereas this effect was much weaker for SO<sub>2</sub> (Akagi et al., 2012; Collier et al.,  
357 2016), i.e., stronger BB impacts favor the increase of NO<sub>3</sub><sup>-</sup>/SO<sub>4</sub><sup>2-</sup>. Therefore, the larger NO<sub>3</sub><sup>-</sup>/SO<sub>4</sub><sup>2-</sup>  
358 during the 2019–2020 campaign could not be explained by the reduced BB influences or the  
359 elevated RH levels, and instead should be attributed primarily to the higher NO<sub>2</sub> to SO<sub>2</sub> ratios. The  
360 increasing trend of NO<sub>2</sub>/SO<sub>2</sub> observed in this study was consistent with inventory results which  
361 typically indicated a more rapid decrease of SO<sub>2</sub> emissions compared to NO<sub>2</sub> during recent years in  
362 China (Zheng et al., 2018).

### 363 **3.4 Variation of aerosol composition**

364 The discussions above indicated significant differences between the two campaigns regarding  
365 the characteristics of both primary emissions and secondary aerosol formation. This in turn resulted  
366 in substantially different aerosol compositions between the two measurement periods, with the  
367 dominant drivers for the variation of aerosol composition being different as well (Figure 8).

368 For the 2018–2019 campaign, the contribution of OA to (PM<sub>2.5</sub>)<sup>\*</sup> was much higher than that of  
369 SNA (60 vs. 28%). The variation of (PM<sub>2.5</sub>)<sup>\*</sup> composition was driven mainly by biomass burning  
370 emissions (especially those from agricultural fires), which tended to increase the OA contribution

371 and correspondingly decrease the relative abundance of SNA. During the most intensive BB  
372 episodes (with LG/OC above 3.0%), the OA contribution reached 66% whereas the SNA  
373 contribution dropped to 23%. For the 2019–2020 campaign, however, the contribution of SNA to  
374 (PM<sub>2.5</sub>)\* was largely comparable with OA (41 vs. 49%), and heterogeneous chemistry became the  
375 dominant driver for the variation of (PM<sub>2.5</sub>)\* composition. The relative abundances of both SNA and  
376 SOA increased considerably from the low-RH through high-RH conditions, with their total  
377 contributions reaching 62% for the RH range of above 80%.

378       During the 2019–2020 measurement period, significantly higher levels of major secondary ions  
379 were observed than 2018–2019, i.e., the total concentrations of sulfate, nitrate and ammonium (SNA)  
380 averaged 27.30 and 15.53 µg/m<sup>3</sup>, respectively. This difference was largely explained by the RH-  
381 dependence. For the 2019–2020 campaign, the sampling events with RH above 80% were mainly  
382 encountered in January of 2020 (*N* = 20) as well as in December of 2019 (*N* = 17), when the daily  
383 average temperatures were typically below –10°C. The frequent occurrences of high RH were  
384 uncommon for Harbin’s winter, as can be seen from the comparison of RH in January across the  
385 past twenty years (Figure 9). Thus, the 2019–2020 campaign provided a unique opportunity to  
386 explore heterogeneous chemistry in Chinese cities located in the severe cold climate region, and  
387 might be considered as an upper limit regarding the RH-dependent enhancement of secondary  
388 aerosols. On the other hand, the effective increase of SNA and SOA under high-RH conditions  
389 implied the abundances of gaseous precursors, both organic and inorganic. To avoid the occurrence  
390 of extreme pollution events, a more fundamental solution would point to the effective control of  
391 gaseous pollutants.

### 392 **3.5 Agricultural fires missed by the 2019–2020 campaign**

393 The 2019–2020 campaign was designed to cover the entire heating season but was interrupted  
394 by the outbreak of COVID-19. Although there was no observational result on aerosol composition  
395 after 5 February, 2020, a severe PM<sub>2.5</sub> episode caused by agricultural fires was identified during 17–  
396 18 April, 2020, as indicated by the intensive fire counts recorded for Harbin and the surrounding  
397 areas (Figure 10). According to the open-access air quality data, the 24-hour PM<sub>2.5</sub> in Harbin reached  
398 ~500 and 900 µg/m<sup>3</sup> on these two days, respectively, with the hourly concentrations peaking at  
399 ~2350 µg/m<sup>3</sup>. During this period, similarly high PM<sub>2.5</sub> levels were observed for a nearby city, Suihua,  
400 which is located in the same region (the Song-Nen Plain) as Harbin. Based on a synthesis of air  
401 quality data and air mass trajectory, we found that the massive amounts of air pollutants in the  
402 Harbin-Suihua region, which were emitted by the agricultural fires within a concentrated period of  
403 two days, could be transported ~500 km northward to Heihe, a city located on the border between  
404 China and Russia. As shown in Figures 10 and S15, PM<sub>2.5</sub> in Heihe started to increase when the  
405 back trajectory suggested air masses passing over the Harbin-Suihua region, resulting in an episode  
406 with a peak PM<sub>2.5</sub> concentration of ~310 µg/m<sup>3</sup>. The discussions above indicated that although  
407 agricultural fires were not evident during the 2019–2020 measurement period, they were postponed  
408 to late April of 2020. Thus, agricultural fires were not actually eliminated by the toughest-ever  
409 policy on open burning, but broke out within a short period before the planting of crops in spring  
410 instead. It is noteworthy that the intensive open burning activities resulted in not only off-the-chart  
411 air pollutions for the nearby cities but also heavily-polluted episodes for downwind regions far away  
412 from the source areas. We suggest that transboundary transport of agricultural fire emissions from  
413 the Northeast Plain, especially the two provinces of Heilongjiang and Jilin, deserves more attention.

#### 414 **4. Conclusions**

415 Significant differences were observed between aerosol properties measured during two  
416 sequential heating seasons in the central city of the HC metropolitan area, i.e., Harbin. Briefly, the  
417 differences were caused by inter-campaign variations of both primary emissions and secondary  
418 aerosol formation. The 2018–2019 measurement period was characterized by (i) frequent  
419 occurrences of agricultural fires, which were boosted by the “legitimate burning” policy, and (ii)  
420 overall low RH levels which were unfavorable for heterogeneous formation of secondary aerosols.  
421 Correspondingly, the observed  $(\text{PM}_{2.5})^*$  was dominated by organic aerosol, with a substantially  
422 higher contribution than SNA (60 vs. 28%). Biomass burning emissions were the largest OC source  
423 for this measurement period. The BB to OC contribution ( $f_{\text{BB}}$ ) was 46% before the onset of  
424 “legitimate burning” primarily due to household burning of crop residues, and increased to 59%  
425 after the onset of “legitimate burning” with the major contribution from agricultural fire emissions.  
426 In addition to OC, the temporal variations of  $(\text{PM}_{2.5})^*$  mass concentration and chemical composition  
427 were mainly driven by biomass burning as well, especially by agricultural fires. The average  
428  $(\text{PM}_{2.5})^*$  reached  $\sim 100 \mu\text{g}/\text{m}^3$  for the most intensive BB episodes, with an enhanced OA contribution  
429 of 66% and a reduced SNA contribution of 23%.

430 Compared to 2018–2019, the 2019–2020 campaign was influenced by (i) a transition of open  
431 burning policy, i.e., agricultural fires were strictly prohibited, and (ii) frequent occurrences of high-  
432 RH conditions. In this case, no evidence was observed to indicate apparent influence of agricultural  
433 fires, and correspondingly, the  $f_{\text{BB}}$  (39%) was dominated by household burning of crop residues. In  
434 addition, both SNA and secondary OC ( $\text{OC}_{\text{sec}}$ ) exhibited significant RH-dependent increases. For  
435 the RH range of above 80%, SOR and the  $\text{OC}_{\text{sec}}$  to OC contribution reached 0.2 and 42%,  
436 respectively, despite the low ambient temperatures encountered (averaging about  $-16^\circ\text{C}$  in terms of

437 daily average). Unlike 2018–2019, organic aerosol and SNA showed comparable contributions to  
438  $(\text{PM}_{2.5})^*$  for the 2019–2020 campaign (49 vs. 41%), and the variations of  $(\text{PM}_{2.5})^*$  during this  
439 measurement period were mainly driven by secondary components.

## 440 **5. Implications**

441 This study has crucial implications for further improving the air quality in HC region. First,  $f_{\text{BB}}$   
442 remained relatively high for the heating season of Harbin (e.g., compared to the wintertime results  
443 from Beijing), even without apparent influence of agricultural fires. This highlights the importance  
444 of reducing domestic use of crop residues, on top of previous clean air actions implemented for the  
445 residential sector primarily focusing on coal combustion. Second, driven by the transition of open  
446 burning policy, agricultural fires exhibited different patterns but were never eliminated. For example,  
447 although there was no “legitimate burning” period during 2019–2020 and agricultural fires did not  
448 occur as frequently as during 2018–2019, burning did break out in spring of 2020 before crop  
449 planting. Thus, neither the “legitimate burning” policy released in 2018 nor the toughest-ever “strict  
450 prohibition” policy released in 2019 could be considered successful for the effective control of  
451 agricultural fires. More studies are necessary to design a new roadmap towards sustainable use of  
452 crop residues in Northeast China, which may contribute to the dual targets of air quality  
453 improvement and climate change mitigation. Third, it is noteworthy that  $(\text{PM}_{2.5})^*$  averaged  $\sim 115$   
454  $\mu\text{g}/\text{m}^3$  for the high-RH conditions of 2019–2020, even higher than results from the most intensive  
455 BB episodes during 2018–2019. This reveals the need for effective control of gaseous precursors,  
456 both organic and inorganic, of secondary aerosols. Given the increasing trends of  $\text{NO}_2/\text{SO}_2$  and  
457  $\text{NO}_3^-/\text{SO}_4^{2-}$  observed between 2018 and 2020, control of the  $\text{NO}_2$ -related sources should be  
458 strengthened.

459 It should be noted that the discussions on heterogeneous formation of SOA and SNA did not  
460 necessarily exclude the reactions in fog/cloud water. Actually, based on the observational results  
461 available, we could not robustly distinguish the relative importance of various aqueous-phases  
462 pathways for secondary aerosol formation. To address this problem, air quality modeling with a  
463 focus on HC should be conducted in future studies, which could also quantitatively evaluate the  
464 contributions of various factors (e.g., meteorology, emissions and regional transport) to long-term  
465 trends of PM<sub>2.5</sub> concentration and chemical composition. An essential precondition is that the model  
466 could properly re-produce the observational results, which appears a substantial challenge for  
467 Harbin as indicated by the limited inter-comparison studies, especially for the periods with intensive  
468 agricultural fires or high RH levels (Cheng et al., 2021b).

469 **Data availability.**

470 Data are available from the corresponding author upon request (jiumengliu@hit.edu.cn).

471 **Author contribution**

472 YC and JL designed the study and prepared the paper with inputs from all the coauthors. QY, XC,  
473 YZ, ZD and LL carried out the experiments. GG provided the air quality data. WM and HQ  
474 participated in the field campaign and data analysis. QZ and KB supervised the study.

475 **Competing interests.**

476 The authors declare that they have no conflict of interest.

681

682 **Figure 1.** Comparisons of levoglucosan to OC ratios, i.e., LG/OC (on a basis of carbon mass), and  
 683 the fractions of samples with LG/OC above 1.5% (denoted as  $F$ ), **(a, c)** between the 2018–2019 and  
 684 2019–2020 campaigns, and **(b, d)** across the 2018–2019 samples collected before (P-1), during (P-  
 685 2) and after (P-3) the “legitimate burning” periods. Lower and upper box bounds indicate the 25<sup>th</sup>  
 686 and 75<sup>th</sup> percentiles, the whiskers below and above the box indicate the 5<sup>th</sup> and 95<sup>th</sup> percentiles, the  
 687 solid circles below and above the box indicate the minimum and maximum, and the open circle  
 688 within the box marks the median (the same hereinafter).

689

690 **Figure 2.** Comparison of OC source apportionment results between the 2018–2019 and 2019–2020  
 691 campaigns (left panel), and across the 2018–2019 samples collected before (P-1), during (P-2) and  
 692 after (P-3) the “legitimate burning” periods (right panel).

693

694 **Figure 3.** Dependence of secondary OC (OC<sub>sec</sub>) on RH among the two campaigns, color-coded by  
 695 AWC levels. Results from the 2018–2019 campaign and 2019–2020 campaign were marked using  
 696 stars and circles, respectively. The majority of the data points with RH above 80% were observed  
 697 during 2019–2020. RH exceeded 80% for only ten samples collected during 2018–2019, and only  
 698 three out of these ten samples showed RH-dependent increase of OC<sub>sec</sub>.

699

700 **Figure 4.** Comparisons of OC source apportionment results (upper panel, left axis), the contribution  
 701 contributions of PMF-based  $\text{OC}_{\text{sec}}$  to OC ( $f_{\text{sec}}$ ; upper panel, right axis), and ambient temperatures  
 702 across different RH ranges (lower panel) for the 2019–2020 campaign.

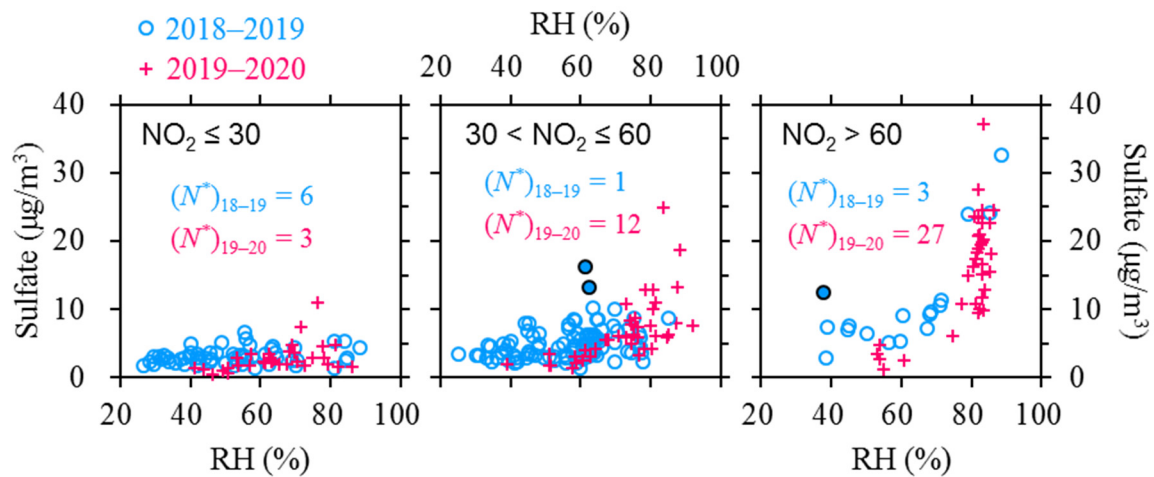

703

704 **Figure 5.** Dependences of **(a)** sulfate and **(b)** SOR on RH. Results from the 2018–2019 and 2019–  
 705 2020 campaigns are combined. Relatively high sulfate are typically observed for the conditions with  
 706 RH above 80%, which is also the case for SOR. There appear to be several outliers showing  
 707 considerably higher sulfate or SOR than other samples at similar RH. All the outliers occurred  
 708 during the 2018–2019 measurement period, and most of them were accompanied with extremely  
 709 high levoglucosan concentrations (above  $5 \mu\text{g}/\text{m}^3$ ), as highlighted by the red arrows. The outlier  
 710 highlighted by the blue arrow was observed with at an ambient temperature of above  $10 \text{ }^\circ\text{C}$ , which  
 711 was uncommon for the heating season. The outliers indicate that factors other than RH were also at  
 712 play in sulfate formation, but the influences were evident for only several samples.

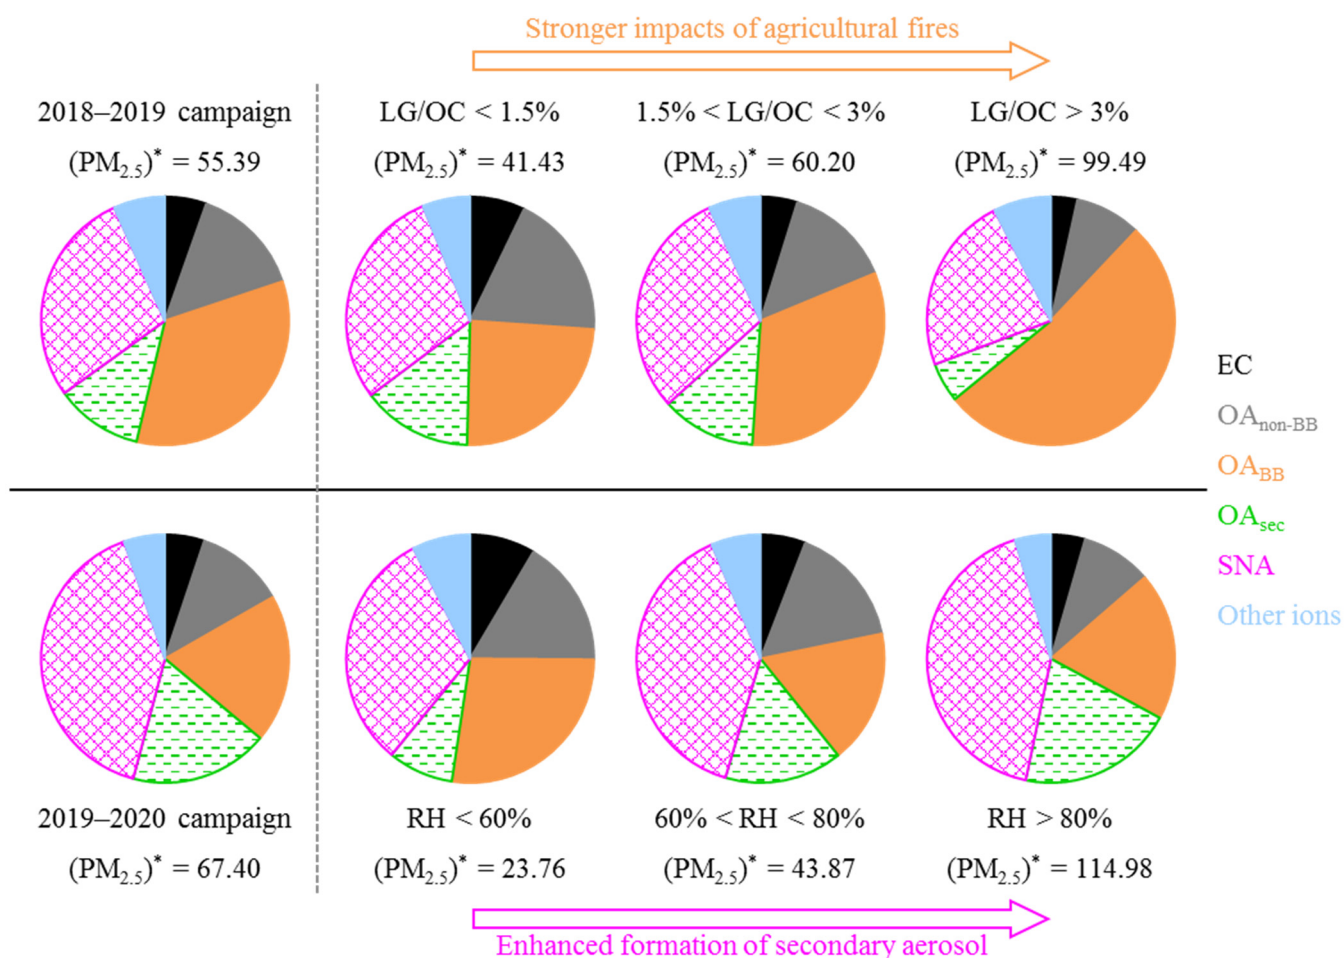

713

714 **Figure 6.** Comparisons of SOR between different RH levels, with results from different NO<sub>2</sub> ranges  
 715 (below 30, 30–60 and above 60 μg/m<sup>3</sup>) shown separately. Results from both the 2018–2019 and  
 716 2019–2020 campaigns are included. The terms “D” and “H” indicate relatively dry (RH below 80%)  
 717 and more humid conditions (RH above 80%), respectively.

718

719 **Figure 7.** Dependences of sulfate on RH in different NO<sub>2</sub> ranges (below 30, 30–60 and above 60  
720 µg/m<sup>3</sup>). Results from the 2018–2019 and 2019–2020 campaigns are shown using different markers.  
721 The outliers in Figure 5a are highlighted by the solid circles. *N*<sup>\*</sup> indicates the number of samples  
722 with RH above 80%. High-RH conditions were typically accompanied with NO<sub>2</sub> concentrations of  
723 below 30 µg/m<sup>3</sup> during 2018–2019, and NO<sub>2</sub> above 60 µg/m<sup>3</sup> during 2019–2020, respectively.

724

725 **Figure 8.** Comparison of aerosol compositions measured for the 2018–2019 and 2019–2020 campaigns. The 2018–  
 726 2019 measurement period experienced relatively dry meteorological conditions (with RH levels rarely exceeding  
 727 80%) and was characterized by a wide window of ~3 months for “legitimate burning”. Correspondingly, variations  
 728 of (PM<sub>2.5</sub>)<sup>\*</sup> concentration (in μg/m<sup>3</sup>) and aerosol composition observed during 2018–2019 were mainly driven by  
 729 agricultural fires. However, the “legitimate burning” policy was terminated in 2019, and the 2019–2020 campaign  
 730 did not show clear evidence for apparent influence of agricultural fires. On the other hand, high-RH conditions  
 731 occurred much more frequently during the 2019–2020 measurement period compared to 2018–2019.  
 732 Correspondingly, variations of (PM<sub>2.5</sub>)<sup>\*</sup> concentration and aerosol composition observed during 2019–2020 were  
 733 mainly driven by RH-dependent increase of secondary aerosols.

734

735 **Figure 9.** Comparison of RH measured during January in Harbin across the past twenty years (from  
 736 2001 through 2020). Time resolution is 1-h for the RH data. No observational result is available for  
 737 January of 2004.

738

739 **Figure 10.** Active fires (red circles) detected by the joint NASA/NOAA Suomi-National Polar  
 740 orbiting Partnership (S-NPP) satellite for Heilongjiang Province during 17–18 April, 2020. Three  
 741 cities located in the Song-Nen Plain are shown using blue dots (the unlabeled city is Daqing), and  
 742 three cities located in the San-Jiang Plain (i.e., Shuangyashan, Qitaihe and Jixi with decreasing  
 743 latitudes) are shown using green dots. The two plains, separated by mountains, are the main  
 744 agricultural regions in Heilongjiang. Intensive agricultural fires are evident for both plains during  
 745 the two-day episode, indicating the open burning activities are province-wide, although prohibited.  
 746 The agricultural fires resulted in severe  $PM_{2.5}$  pollution for nearby cities, e.g., the 24-hour  
 747 concentrations peaked at  $\sim 900$  and  $675 \mu\text{g}/\text{m}^3$  in Harbin and Jixi, respectively. A  $PM_{2.5}$  episode  
 748 was observed even for Heihe ( $\sim 500$  km away from Harbin) on 19 April, 2020, which was attributed  
 749 to the pollutants transported from the Harbin-Suihua region. The solid line indicates the 72-hour back  
 750 trajectory ending at 7:00 in Heihe, accompanied with the highest 1-hour  $PM_{2.5}$  observed on 19 April,  
 751 2020 ( $\sim 310 \mu\text{g}/\text{m}^3$ ). The trajectory indicates transport pathway of air masses impacting Heihe,  
 752 with the segment in black showing locations of the air masses during 17–18 April, 2020.
