14 **Abstract.** The aim of this paper is ~~two-fold: to provide guidance on how to best interpret TROPOMI trace gas~~  
15 ~~retrievals and to highlight how TROPOMI trace gas data can be used and interpreted~~ to understand event-based  
16 impacts on air quality from regional to city-scales around the globe. For this study, we present the observed changes  
17 in the atmospheric column amounts of five trace gases (NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO and CHOCHO) detected by the  
18 Sentinel-5P TROPOMI instrument, driven by reductions of anthropogenic emissions due to COVID-19 lockdown  
19 measures in 2020. We report clear COVID-19-related decreases in TROPOMI NO<sub>2</sub> concentrations column amounts  
20 on all continents. For megacities, reductions in column amounts of tropospheric NO<sub>2</sub> range between 14% and 63%.  
21 For China and India supported by NO<sub>2</sub> observations, where the primary source of anthropogenic SO<sub>2</sub> is coal-fired  
22 power generation, we were able to detect sector-specific emission changes using the SO<sub>2</sub> data. For HCHO and  
23 CHOCHO, we consistently observe anthropogenic changes in two-week averaged column amounts over China and  
24 India during the early phases of the lockdown periods. That these variations over such a short time scale are detectable  
25 from space, is due to the high resolution and improved sensitivity of the TROPOMI instrument. For CO, we observe  
26 a small reduction over China which is in concert with the other trace gas reductions observed during lockdown,  
27 however large, interannual differences prevent firm conclusions from being drawn. The joint analysis of COVID-19  
28 lockdown-driven reductions in satellite observed trace gas column amounts, using the latest operational and scientific  
29 retrieval techniques for five species concomitantly is unprecedented. However, the meteorologically and seasonally  
30 driven variability of the five trace gases does not allow for drawing fully quantitative conclusions on the reduction of  
31 anthropogenic emissions based on TROPOMI observations alone. We anticipate that in future, the combined use of  
32 inverse modelling techniques with the high spatial resolution data from S5P/TROPOMI for all observed trace gases  
33 presented here, will yield a significantly improved sector-specific, space-based analysis of the impact of COVID-19  
34 lockdown measures as compared to other existing satellite observations. Such analyses will further enhance the  
35 scientific impact and societal relevance of the TROPOMI mission.

36

37 **Key words:** Air quality, Trace gases, Sentinel-5P, TROPOMI, COVID-19, emissions

38 **1 Introduction**

39 In an effort to limit the transmission of the SARS-CoV-2 virus responsible for the Coronavirus disease 2019 (hereafter  
40 referred as COVID-19), drastic lockdown measures were implemented around the globe in the first half of 2020. These  
41 policies led to dramatic reductions in human activity, especially in the transport and industrial sectors, resulting in  
42 large decreases in the concentration of air pollutants (Bauwens et al., 2020; Shi and Brasseur, 2020; Forster et al.,  
43 2020; Diamond and Wood, 2020; Kroll et al., 2020; Le Quéré et al., 2020; Guevara et al., 2021; Gkatzelis et al., 2021).  
44 These changes were observed over China as early as February 2020 (Bauwens et al., 2020; Liu et al., 2020; Zhang, Z.  
45 et al., 2020; Zhao, N. et al., 2020) and were detected later in many other countries as similar lockdown measures were  
46 adopted (Bauwens et al., 2020; Broomandi et al., 2020; Collivignarelli et al., 2020; Lee et al., 2020; Gkatzelis et al.,  
47 2021; [Koukouli et al., 2021](#)).

48 The TROPOspheric Monitoring Instrument (TROPOMI; Veefkind et al., 2012; Ludewig et al., 2020) on board the  
49 European Copernicus Sentinel-5 Precursor (S5P) satellite, launched on 13 October 2017, is specifically designed for  
50 tropospheric monitoring on the global scale and has a daily revisit time. Compared to its predecessor OMI,  
51 TROPOMI's highest spatial resolution ( $3.5 \times 5.5 \text{ km}^2$ ) is about 16 times better and its signal-to-noise ratio per ground  
52 pixel is substantially higher. This results in a ~~spectacular~~large improvement in measurement sensitivity for relevant  
53 air quality products, including  $\text{NO}_2$ ,  $\text{SO}_2$ ,  $\text{HCHO}$ , and  $\text{CHOCHO}$ , thus enabling the study of rapid emission changes  
54 for even smaller sources as compared to previous instruments. For CO measurements, the daily global coverage of  
55 TROPOMI at a resolution of  $7 \times 5.5 \text{ km}^2$  represents a huge improvement to its predecessor SCIAMACHY  
56 (Bovensmann et al., 1999; Borsdorff et al., 2016; Borsdorff et al., 2017) with a spatial resolution of  $120 \times 30 \text{ km}^2$ .

57 The observations from TROPOMI thus provide a unique opportunity to observe the magnitude and timing of the  
58 changes in tropospheric trace gas constituents, resulting from unprecedented COVID-19 lockdown measures. The  
59 initial TROPOMI observations of dramatic reductions in  $\text{NO}_2$  ~~concentrations~~column amount over regions with strictly  
60 enforced lockdowns, over China in particular, triggered a high level of interest worldwide, and initiated a large number  
61 of studies, mainly aimed at regional scales and largely focused on  $\text{NO}_2$ . However, the unparalleled capacity of  
62 TROPOMI to provide relevant information on COVID-19 driven emission reductions based on multiple species  
63 measurements has not been exploited yet. The objective of this work is to investigate the COVID-19 driven changes  
64 in the ~~concentration~~column amounts of five trace gases ( $\text{NO}_2$ ,  $\text{SO}_2$ , CO,  $\text{HCHO}$ , and  $\text{CHOCHO}$ ) from the global level  
65 down to individual cities using state-of-the-art TROPOMI operational and scientific data products. More specifically,  
66 we aim to

67 1. [Expand-Summarize](#) the analysis of tropospheric  $\text{NO}_2$  [at city-scale for to](#) all continents.

68 A large body of studies investigated the impact of the COVID-19 lockdowns on  $\text{NO}_2$  concentrations (e.g. Bauwens et  
69 al., 2020; Baldasano, 2020; Huang et al., 2020), at regional and continental scale. Here, we analyze the time series of  
70  $\text{NO}_2$  measurements from a single satellite instrument for globally distributed locations on regional to city scales. In  
71 doing so, we further demonstrate the unique capabilities of how the TROPOMI instrument can be used to consistently  
72 track changes in air quality and anthropogenic emissions across the globe.

73  
74     2. Explore the high spatial resolution and simultaneous TROPOMI observations of NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO, and  
75       CHOCHO.

76     While all of these gases have significant anthropogenic sources, they differ in their relative contribution to the energy,  
77     industry, and transport sector emissions, and each sector exhibits a different response to COVID-19 lockdown  
78     measures. Therefore, the combination of several TROPOMI trace gas products contains additional information on  
79     sector-specific emissions and COVID-19 lockdown-induced changes in atmospheric composition. We show that  
80     meaningful trends and source detection can be obtained by using the ~~unprecedentedly~~ high spatial resolution of  
81     TROPOMI data and by averaging that data over relatively short time periods. Although this is in large part the result  
82     of the improved sensitivity of the instrument, we also introduce new developments in trace gas retrieval techniques  
83     and ad-hoc corrections to enhance the sensitivity of the TROPOMI datasets to even smaller emissions and smaller  
84     changes in emissions. In order to achieve these goals, we discuss the strengths and limitations of each of the retrievals  
85     for tracking global to city-scale changes.

86     In the next section, the TROPOMI data will first be described in general terms, followed by a description per species  
87     to address the retrieval methods, as well as a description of how we handle each data product in this study. The goal  
88     of this methods and data section is not only to explain how this study was conducted but also to provide guidance to  
89     data users on how to best interpret and analyze TROPOMI trace gas data not only for lockdown-driven emission  
90     changes but also for other event-driven changes. This will be followed by a context-setting section ~~describing~~  
91     reviewing the global and regional impacts of COVID-19 lockdown measures ~~and city-scale effects on for~~ all  
92     continents, using TROPOMI NO<sub>2</sub> data. The next two sections will describe the effect of the lockdown measures on a  
93     regional scale by examining NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO, and CHOCHO for China and India. The last section will feature  
94     an outlook of future applications for this type of analysis followed by conclusions.

95     **2 Methods and Data**

96     In this work, our analysis is primarily based on TROPOMI data for regional lockdown periods in 2020 as compared  
97     to the same periods in 2019 and will be presented in the broader context of the TROPOMI operational data record,  
98     which started on 30 April 2018. We make use of observations from the TROPOMI instrument on board S5P which is  
99     a push-broom imaging spectrometer (Veefkind et al., 2012) measuring in the ultraviolet (UV), visible (VIS), near-  
100     infrared (NIR), and shortwave infrared (SWIR) spectral bands selected to measure the absorption by a large number  
101     of trace atmospheric constituents as well as by clouds and aerosol over absorption regions for clouds and a large  
102     number of trace atmospheric constituents. Using the spectral radiance measurements from TROPOMI, atmospheric  
103     concentrations column amounts of different gases are retrieved as well as cloud and aerosol properties. For this work,  
104     we use the following TROPOMI data products: NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO and CHOCHO as summarized in Table 1. We  
105     did not include the following TROPOMI data products: tropospheric ozone columns, due to the tropics-only spatial  
106     coverage; methane, due to an even longer atmospheric lifetime than CO where its sources were not as impacted by  
107     lockdown measures; and aerosol index, designed to highlight long-range transported and/or elevated plumes of smoke,  
108     dust, and/or ash and which is not a quantitative measure of aerosol amount nor sensitive to near-surface emissions.

109 The S5P satellite flies in a Sun-synchronous orbit, with a local overpass time of 13:30. TROPOMI has a 2600 km  
110 wide swath, providing near-daily global coverage. The spatial sampling of TROPOMI varies over the spectral bands.  
111 The nadir sampling at the start of the operational period on 30 April 2018 was approximately  $3.5 \times 7 \text{ km}^2$  (across- x  
112 along-track) for the ultraviolet and visible bands, and  $7 \times 7 \text{ km}^2$  in the shortwave infrared band. On 6 August 2019,  
113 after implementation of a modified co-adding scheme, the sampling for these bands was improved to  $3.5 \times 5.5 \text{ km}^2$   
114 and  $7 \times 5.5 \text{ km}^2$ , respectively.

115 TROPOMI observations are being widely used within and beyond the scientific community and so it is crucial to  
116 provide information on how these observations can best be used, interpreted, and analyzed. The COVID-19 lockdown  
117 periods provide a unique use-case for the TROPOMI lead algorithm developers to highlight important differences in  
118 the individual atmospheric lifetime and detectability of each trace gas and show how these characteristics are key to  
119 the interpretation of the concomitant observations. It is not sufficient, for example, to illustrate lockdown-driven  
120 changes in emissions simply by selecting a single day or week of TROPOMI column data for a given region as  
121 measured during a lockdown period to the same day or week from year(s) prior (Braaten et al., 2020). We go further  
122 to address the importance of delineating meteorological and seasonal variability from lockdown-driven changes in  
123 emissions.

124 Therefore, we start this methods and data section with a general overview of considerations for the data user to take  
125 into account for analyses aimed at the quantification of changes in the emission of these trace gases. Next, in dedicated  
126 subsections, we provide a summary of the most relevant documentation and retrieval methods employed for each trace  
127 gas (see Table A1). Even though each retrieval is based on the analysis of the amount of trace gas specific absorption  
128 in measured radiance spectra, methods differ significantly per species.

## 129 **2.1 Understanding and Interpreting TROPOMI trace gas retrievals**

130 For this paper we will focus on TROPOMI trace gas retrievals for NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO, and CHOCHO (See Table  
131 1). To understand and interpret the TROPOMI measurements of these trace gas species and how they vary with respect  
132 to COVID-19 lockdown measures, it is necessary to consider their sources, variability through the atmospheric  
133 column, and their atmospheric lifetimes. Although the mechanisms for the emission of each gas are different, there  
134 are several common anthropogenic emission sources, most notably from transportation and industry, as listed in Table  
135 1 which were significantly impacted by lockdown measures.

136  
137 **Table 1: Summary of the retrieval spectral range, atmospheric lifetime, and primary-main emission sources, for each trace**  
138 **gas addressed in this study.**

139 <b>Trace Gas Data Product Type (retrieval reference)</b>	140 <b>Spectral Range</b>	141 <b>Typical lifetime</b>	142 <b><u>Primary-Main</u> emission sources</b>
143 NO <sub>2</sub> <u>Operational</u> (van Geffen et al., 2019)	144 405-465 nm	145 2 to 12 hours	146 - Transportation - Industry - Power generation - Biomass burning

SO <sub>2</sub> <u>Prototype</u> (Theys et al., 2021)	310.5-326 nm	6 hours to several days	- Power generation - Industry - Transportation - Volcanoes <sup>1</sup>
CO <u>Operational</u> (Landgraf et al., 2016)	2324–2338 nm	Weeks to a month	- <u>Transportation</u> - <u>Residential cooking and heating</u> - <u>Industry</u> <u>Power generation</u> <u>Industry</u> <u>Transportation</u> <u>Residential cooking and heating</u> - Biomass burning - Oxidation of biogenic hydrocarbons - Methane Oxidation - <u>Power generation</u>
HCHO <u>Operational</u> (De Smedt et al., 2018)	328.5-359 nm	Several hours (lifetime of NMVOC precursors up to several days)	Primary and secondary product (NMVOC precursors) from: - Biogenic emissions - Biomass burning - <u>Industry</u> <u>Transportation</u> <u>Transportation</u> <u>Industry</u>
CHOCHO <u>Prototype</u> (Lerot et al., 2010, 2020)	435-460 nm	<u>Several hours</u> <u>(lifetime of NMVOC precursors up to several days)</u> <u>2 to 3 hours</u>	Primary and secondary product (NMVOC precursors) from: - Biogenic emissions - Biomass burning - Transportation - Industry

139 <sup>1</sup>Volcanic emissions are not significant for this work.

140

141 A brief evaluation of how the sources of these trace gases were or were not affected by lockdown-driven changes  
142 lends insight into expected changes. In general, primary production trace gases, like NO<sub>2</sub> and SO<sub>2</sub> with relatively short  
143 atmospheric lifetimes exhibit emission changes most clearly and rapidly. Although NO<sub>2</sub> and SO<sub>2</sub> are both important  
144 primary production anthropogenic pollutants, their sectoral sources are different. For instance, the impact of lockdown  
145 on the transportation sector is expected to have a bigger impact on NO<sub>2</sub> than SO<sub>2</sub>, since this sector is responsible for  
146 about 30% of the global NO<sub>x</sub> emissions and only 1% of the global SO<sub>2</sub> emissions, according to the CAMS-ANT  
147 inventory (Granier et al., 2019). On the other hand, SO<sub>2</sub> emissions are more likely to be impacted by possible changes  
148 in power generation, since this sector accounts for 52% of the global SO<sub>2</sub> emissions and only 30% of the global NO<sub>x</sub>  
149 emission (Granier et al., 2019).

150 For CO, secondary production by methane oxidation and the oxidation of (biogenic) hydrocarbons accounts for at  
151 least 60% of the total atmospheric CO, followed by contributions from biomass burning and fossil fuel use (Müller et  
152 al., 2018; Holloway et al., 2000). Anthropogenic CO emissions originate from the industry, transportation, and

153 residential sectors and account for about 30% of the global emissions (Granier et al., 2019). However, it is noted that  
154 the relative contribution of these sources varies per global region (Granier et al., 2019 (Janssens-Maenhout et al.,  
155 2015). Although local impacts of lockdown are likely for locations with strong anthropogenic CO emissions, overall  
156 a much smaller lockdown-driven impact is expected for CO based on its longer atmospheric lifetime and smaller  
157 contributions from lockdown affected sources (Clark et al., 2021).

158 Both HCHO and CHOCHO are short-lived indicators of non-methane volatile organic compound (NMVOC)  
159 emissions resulting from biogenic processes, large biomass burning events, and anthropogenic activities (Millet et al.,  
160 2008; Fu et al., 2008; Stavrakou et al., 2009; Bauwens et al., 2016; Chan Miller et al., 2016). They are mostly produced  
161 as secondary products from oxidation of other NMVOCs but are also directly emitted from combustion and industrial  
162 processes, although to a lesser extent. In general, the relative production of CHOCHO from such combustion processes  
163 and from the oxidation of aromatics, originating mostly from the industrial sector, is higher than for HCHO. Thus, the  
164 CHOCHO response to changes in anthropogenic emissions is expected to be stronger (Chan Miller et al., 2016; Cao  
165 et al., 2018).

166 It is important to note that the retrievals provide information on the tropospheric or total column amount of these  
167 gases, because the spectra contain limited information on their vertical distribution in the atmosphere. TROPOMI  
168 observations thus provide a two-dimensional representation of the three-dimensional atmosphere. The vertical profiles  
169 of each trace gas vary significantly depending on the injection height of the emissions and atmospheric lifetime (see  
170 Table 1). For example, NOx emissions at the surface result in NO<sub>2</sub> vertical profiles that peak in the near-surface layer  
171 (lowest 1-2 km of the troposphere), due to the short lifetime of NO<sub>2</sub>. Similarly, SO<sub>2</sub> has a vertical profile which  
172 generally peaks in the lower troposphere. CO on the other hand, has a lifetime of weeks to a month (depending on the  
173 reaction with the hydroxyl radical) and can be transported over great distances, both horizontally and vertically.  
174 Therefore, CO even though it is often co-emitted with NO<sub>2</sub>, has a significantly higher background concentration  
175 throughout the troposphere as compared to NO<sub>2</sub>. HCHO and CHOCHO have lifetimes of a few hours but are generally  
176 formed in the atmosphere via secondary production processes, which leads to an intermediate profile shape as  
177 compared to NO<sub>2</sub> and CO.

178 In addition to vertical profiles that vary per trace gas species, the vertical sensitivity of the TROPOMI measurements  
179 also varies per species. For the trace gases retrieved in the UV and VIS ranges, the sensitivity decreases towards the  
180 surface so that the accuracy of the retrieved column depends on a well-characterized a priori knowledge of the vertical  
181 distribution. Due to scattering, the near-surface sensitivity is lower in the UV (SO<sub>2</sub>, HCHO) than in the VIS (NO<sub>2</sub> and  
182 CHOCHO). In the SWIR range, the vertical sensitivity is more constant. As part of the retrieval process, a priori  
183 vertical profiles of each trace gas are scaled to match the measured tropospheric column. An uncertainty in the  
184 retrieved column amount or vertical column density (VCD) is associated with inherent differences between the true  
185 and a priori vertical profiles. However, the averaging kernels, which are reported in the data products, can be used to  
186 replace the a priori profiles with custom profiles (e.g. Eskes and Boersma, 2003; Eskes et al., 2020) thereby reducing  
187 the corresponding uncertainty. In this study, we mostly focus on relative changes in VCDs and use standard a priori  
188 profiles for each data product. Therefore, the uncertainty related to the vertical profile is rather small (as detailed in  
189 Sect. 2.2 through 2.6). Another contribution to this error is the use of partly cloudy scenes by each retrieval which

190 increases the amount of data available but does change the vertical sensitivity. The cloud fraction threshold for each  
191 trace gas is described in Sect. 2.2 through 2.6. In future studies, the averaging kernels could be used for inversion  
192 modelling of emissions. As explained in Eskes and Boersma 2003, relative comparisons between the observations and  
193 the model used in the inverse modelling system, and therefore the resulting emissions, no longer depend on the  
194 retrieval a-priori profile shape when the kernel is applied to the model.In future studies, the averaging kernels could  
195 be used for inversion modelling of emissions thus eliminating this error completely.

196 ~~TROPOMI observes atmospheric concentrations of trace gases averaged over a vertical column, which is not the same as a direct measurement of the (near surface) emission. The column averaged amount of a given trace gas measured at a certain location depends not only on emission and deposition, but also on atmospheric transport and (photo)chemical reactions.~~ TROPOMI observes atmospheric concentrations of trace gases integrated over a vertical column, which is not the same as a direct measurement of the (near-surface) emission. The amount of a given trace gas integrated over a vertical column at a certain location depends not only on emission and deposition, but also on atmospheric transport and (photo)chemical reactions. Note that the background concentration is higher for trace gases with a longer atmospheric lifetime. In turn, enhanced background concentrations will increase the relative importance of atmospheric transport versus local emissions. Local NO<sub>2</sub> emissions have a relatively large impact on the measured column amounts, while for CO the contribution of remote sources can in some cases be superimposed on local emissions thus making the interpretation more difficult. To attribute a change in concentration to a corresponding change in local emissions, the effects of meteorology and chemical lifetime must be accounted for as well.

200 While emissions can be estimated from satellite observations using data-driven methods (Beirle et al., 2019, Beirle  
201 et al., 2021; Fioletov et al., 2016; Goldberg et al., 2019) or using complex inverse modelling techniques (e.g. Millet  
202 et al., 2008; Stavrakou et al., 2009; Bauwens et al., 2016; Ding et al., 2020; Miyazaki et al., 2020; Borsdorff et al.,  
203 2019; Borsdorff et al., 2020), here we use a more qualitative approach to probe emission changes. First we compare  
204 the ~~concentrations-column amounts~~ in 2020 with those from the same period from earlier years and then carry out  
205 additional analysis to separate the lockdown-driven variability from seasonal and meteorological variability ~~taking~~  
206 ~~into account local information about lockdown and anticipated impacts from different source sectors, taking in account~~  
207 ~~emission changes driven by mechanisms.~~

## 216 2.2 Nitrogen dioxide (NO<sub>2</sub>)

217 The tropospheric column of nitrogen dioxide (NO<sub>2</sub>) is a TROPOMI operational data product (Veefkind et al., 2012;  
218 doi.org/10.5270/S5P-s4ljg54). Product versions are listed in the Product Readme File (PRF, Eskes and Eichmann,  
219 2019a). The retrieval method is described in detail in the NO<sub>2</sub> Algorithm Theoretical Basis Document (ATBD, van  
220 Geffen et al., 2019). The data product and data usage are described in the NO<sub>2</sub> Product User Manual (PUM, Eskes  
221 et al., 2020). The dataset used for most of NO<sub>2</sub> analyses cover the period from 1 January 2018 to 30 May 2020. For  
222 Europe, the dataset was extended through 31 August 2020.

223 The retrieval algorithm derives NO<sub>2</sub> information from spectral range 405–465 nm and is largely based on the OMI  
224 NO<sub>2</sub> retrieval developments implemented during the EU QA4ECV project (Boersma et al., 2018). The retrieval  
225 consists of three steps. The first step is based on the DOAS approach, in which the total slant column of NO<sub>2</sub> is

226 retrieved from the TROPOMI spectra, as discussed in van Geffen et al. (2020). The second step is the estimation of  
227 the 3-D stratospheric distribution of NO<sub>2</sub> based on an assimilation of the TROPOMI slant column data of previous  
228 days using the chemistry-transport model TM5-MP (Williams et al., 2017) run at 1° x 1°. This assimilation is set up  
229 to predominantly make use of measurements over clean areas (e.g. ocean and remote land regions) with limited  
230 tropospheric NO<sub>2</sub>. The third step is the conversion of the tropospheric slant column (total minus stratosphere) into a  
231 tropospheric vertical column by combining radiative transfer calculations with a priori profile shapes from the TM5-  
232 MP model. The data product is very comprehensive and provides all the input (such as surface and cloud information)  
233 and intermediate products.

234 The tropospheric column is delivered with corresponding averaging kernels and a detailed error estimate. The  
235 random error on the slant column is discussed in van Geffen et al. (2020), and is on the order of 0.56x10<sup>15</sup> molec cm<sup>-2</sup>  
236 for individual measurements after 6 August 2019 (for pixel size 3.5 x 5.5 km<sup>2</sup>). This translates to only small random  
237 errors in the total columns on the order of 0.2x10<sup>15</sup> molec cm<sup>-2</sup>. Uncertainties in the estimate of the local stratospheric  
238 column amount is of the same order of magnitude. The uncertainty related to the computation of the air mass factor  
239 (AMF) is much more significant for tropospheric columns over polluted areas. The AMF uncertainties are driven by  
240 the treatment of surface albedo, clouds, aerosols, and profile shape. Such errors are multiplicative, and are of the order  
241 of 20-60% depending on the geographical location, time of day, and season ([van Geffen et al., 2021](#)). These  
242 uncertainties are modelled for individual observations and are provided in the data product.

243 As for all operational TROPOMI data products, a quality assurance value (qa\_value) is provided to filter the data  
244 and remove lower quality data where, the recommended threshold value depends on the application ([see also Appendix](#)  
245 [A, Table A1](#)). For direct visualization or gridding applications a qa\_value greater than 0.75 is recommended. For  
246 comparisons with models and data assimilation through the use of the averaging kernels, a relaxed qa\_value of greater  
247 than 0.5 may be used. In this study we use NO<sub>2</sub> retrievals with a qa\_value greater than 0.75. Application of this  
248 qa\_value threshold corresponds to data with mostly clear-sky conditions (cloud radiance fractions < 0.5) and implies  
249 that the data is filtered to remove retrievals which do not meet certain quality criteria as described van Geffen et al.  
250 (2019).

251 Several recent papers discuss the validation of the NO<sub>2</sub> product against independent observations (Verhoelst et al.,  
252 2021; Tack et al., 2021; Judd et al., 2020; Dimitropoulou et al., 2020; Ialongo et al., 2020). The main findings can be  
253 summarized as follows: the stratospheric and slant columns are in good overall agreement with other satellite  
254 measurements (van Geffen et al., 2020) and with ground-based observations (Verhoelst et al., 2021). However, the  
255 tropospheric column presents a negative bias of the order of 30% with respect to ground-based remote sensing  
256 reference observations (Verhoelst et al., 2021; Dimitropoulou et al., 2020), as well as with imaging data from airborne  
257 measurements (Judd et al., 2020; Tack et al., 2021). Although the origin of this bias remains unclear and may be due  
258 to several causes, validation results indicate that it scales linearly with the retrieved tropospheric column amount  
259 (Verhoelst et al., 2021; see Fig. C1). As a result, (COVID-related) relative changes in the NO<sub>2</sub> column, e.g., (2020-  
260 2019)/2019, should be largely insensitive to this bias.

261      **2.3    Sulphur dioxide (SO<sub>2</sub>)**

262    Initial analyses were performed using the TROPOMI operational data product for SO<sub>2</sub> (Theys et al., 2017). However,  
263    biases present in those data (Fioletov et al., 2020) hamper the detection of the type of small changes in SO<sub>2</sub>, typically  
264    on the order of -0.1 DU, that are under investigation in this work. Therefore, an alternative retrieval scheme was  
265    applied, the so-called COvariance-Based Retrieval Algorithm (COBRA; Theys et al., 2021). In brief, the approach  
266    considers a set of SO<sub>2</sub>-free spectra in the wavelength range 310.5-326.0 nm (from TROPOMI band 3) to represent the  
267    radiance background variability, in the form of a covariance matrix. The latter is updated for each orbit, TROPOMI  
268    row, and per latitude band. The covariance matrix is used to determine the SO<sub>2</sub> slant columns from individual spectral  
269    measurements using an optimally weighted single parameter retrieval (see Walker et al., 2011). We note that COBRA  
270    does not recalculate air mass factors (AMF). These are simply extracted from the operational product to convert SO<sub>2</sub>  
271    slant columns into vertical columns (VCDs). Compared to the operational DOAS results, COBRA significantly  
272    improves the SO<sub>2</sub> VCDs, both in terms of precision and accuracy. Because the approach empirically accounts for all  
273    sources of systematic variability in the measured signal, large-scale biases typically observed with the DOAS approach  
274    are efficiently removed leading to a large gain in sensitivity (see Fig. C2).

275    In this study, we use SO<sub>2</sub> retrievals under clear-sky conditions (cloud fractions less than 30%) with solar zenith  
276    angles lower than 60°, and we eliminate 25 swath edge pixels from each side of the orbit swath (450 pixels wide). The  
277    random error in the SO<sub>2</sub> vertical columns is rather small in the range of 0.5-1.0 DU, and can be largely reduced by  
278    data averaging. Errors due to spectral interferences are estimated to be very low, about 0.05 DU [\(Theys et al., 2021\)](#).  
279    Remaining systematic uncertainties are mostly from the auxiliary data used in the AMF calculation, and are in the 30-  
280    50% range. The dataset used for this analysis covers the period from May 2018 to June 2020.

281      **2.4    Carbon monoxide (CO)**

282    The total column of carbon monoxide (CO) is a TROPOMI operational data product obtained using TROPOMI 2.3  
283    micron measurements (Veefkind et al., 2012; doi.org/10.5270/S5P-1hkp7rp). Product versions are listed in the Product  
284    Readme File (Landgraf et al., 2020). The data product and data usage are described in in the CO Product User Manual  
285    (Apituley et al., 2018). This CO retrieval uses the Shortwave Infrared CO retrieval (SICOR) algorithm method and is  
286    described in detail in the CO Algorithm Theoretical Basis Document (Landgraf et al., 2018). The algorithm software  
287    is based on a scattering forward model and retrieves trace gas columns simultaneously with effective cloud parameters  
288    (cloud height, cloud optical thickness) from the SWIR channel to account for cloud contaminated measurements  
289    (Landgraf et al., 2016, 2018). The inversion deploys a profile scaling approach by which a vertical CO reference  
290    profile is scaled to obtain agreement between the forward simulation and the spectral measurement (Borsdorff et al.,  
291    2014). The reference profile is based on a monthly averaged simulation from the global chemical transport model  
292    TM5 and thus varies spatially and temporally (Krol et al., 2005). The vertical sensitivity of the retrieval for clear-sky  
293    conditions is good throughout the atmosphere while measurements for cloudy conditions have reduced sensitivity  
294    under the cloud (Borsdorff et al., 2018).

295    In this study, we use the CO retrieval for measurements under clear-sky and cloudy atmospheric conditions (cloud  
296    altitude less than 5000m). This corresponds to filtering the dataset by using the quality assurance values (qa\_value

297 greater than 0.5) that are supplied with the data product. CO retrievals under low cloud conditions perform well for  
298 unpolluted scenes however can lead to e.g. lower CO values when pollution hot spots are present below the cloud due  
299 to optical shielding and scattering (Borsdorff et al., 2018). Consequently, retrievals under cloudy conditions must be  
300 considered with care, however they are essential to improve the data coverage especially over the oceans where clear-  
301 sky measurements are hampered by the low reflectivity of water in the SWIR spectral range.

302 The CO retrieval skill lies well within the requirements of the TROPOMI mission (Veefkind et al., 2012) on accuracy  
303 (< 15%) and precision (< 10%). This was shown by validation with ground-based FTIR measurements operated by  
304 the Total Carbon Column Observing Network (TCCON). TROPOMI CO is biased high compared to TCCON by  
305 about 6 ppb with a station to station variability of about 4 ppb (Borsdorff et al., 2018; Lambert et al., 2020). The  
306 dataset used for this analysis covers the period from 1 January 2018 to 30 May 2020.

### 307 2.5 Formaldehyde (HCHO)

308 The tropospheric column of formaldehyde (HCHO) is a TROPOMI operational data product (Veefkind et al., 2012;  
309 doi:10.5270/S5P-tjlxfd2). Product versions are listed in the HCHO Product Readme File (De Smedt et al., 2020a).  
310 The data product and data usage are described in in the HCHO Product User Manual (PUM, Romahn et al., 2020).  
311 The TROPOMI HCHO retrieval algorithm has been fully described in De Smedt et al. (2018) and in the HCHO ATBD  
312 (De Smedt et al., 2020b). It is based on the DOAS method, and is directly inherited from the OMI QA4ECV product  
313 (<https://doi.org/10.18758/71021031>). The fit of the slant columns is performed in the spectral interval of 328.5-359.0  
314 nm. Reference spectra are updated daily using an average of Earth radiances selected in the Equatorial Pacific region.  
315 The conversion from total slant to tropospheric vertical columns is performed using a look-up table of vertically  
316 resolved air mass factors calculated at 340 nm. A priori vertical profiles are provided by the TM5-MP daily forecast  
317 with a spatial resolution of 1 x 1 degree (Williams et al., 2017). Cloud properties are taken from the S5P operational  
318 product Cloud as Reflecting Boundary (CRB; Loyola et al., 2018). In order to correct for any remaining offset and  
319 striping due to instrumental artefacts or unknown misfits in the spectral retrieval, a background correction is applied  
320 based on HCHO slant columns selected in the emission-free Pacific Ocean. The background HCHO vertical column,  
321 due to the methane oxidation, is added using data from the TM5 model in the reference region. We use the quality  
322 assurance values (qa\_value greater than 0.5) to filter out observations presenting a solar zenith angle larger than 70°  
323 or cloud fractions larger than 0.4.

324 The HCHO retrieval fulfils the requirements of the TROPOMI mission (Veefkind et al., 2012) on accuracy (40-  
325 80%) and precision ( $12 \times 10^{15}$  molec cm $^{-2}$ ). The precision of a single observation is estimated to be  $5 \times 10^{15}$  molec cm $^{-2}$   
326 in remote locations. The dispersion is naturally larger over polluted sites (from  $7-10 \times 10^{15}$  molec cm $^{-2}$ ). Validation  
327 using a global network of FTIR measurements indicates that TROPOMI HCHO columns present a negative bias over  
328 high emission sites (-30% for HCHO columns larger than  $7.5 \times 10^{15}$  molec cm $^{-2}$ ) and a positive bias for clean sites  
329 (+20% for HCHO columns lower than  $2.5 \times 10^{15}$  molec cm $^{-2}$ ) (Lambert et al., 2020; Vigouroux et al., 2020).

330 To characterize the HCHO interannual and seasonal variability, we have used the QA4ECV OMI dataset to construct  
331 a climatology based on recent years (2010-2018). This is justified the good agreement between OMI and TROPOMI

332 HCHO columns which is better than 10% for most regions (Lambert et al., 2020). For our analysis, we use two-week  
333 averaged columns. This reduces the random uncertainty to about 10%.

334 One of the main drivers of the observed HCHO variability is temperature, which has a direct impact on NMVOC  
335 emissions and on the chemical production of HCHO (Stavrakou et al., 2018). It results in a strong correlation between  
336 HCHO columns and surface temperatures. For this paper, we correct the HCHO ~~concentrations column amounts~~ for  
337 this meteorological impact prior to using the data in the analyses. We introduce a temperature correction method (Zhu  
338 et al., 2017) based on data from OMI for 2005-2020, and from TROPOMI for 2018-2020. In brief, this correction  
339 entails fitting a second-order polynomial through daily HCHO columns reported as a function of the temperature. This  
340 ~~novel analysis temperature correction~~ is performed for each region and on the OMI and TROPOMI time series  
341 separately. On this basis, the temperature-induced variations in HCHO are removed from the time series using local  
342 daily temperatures specified by ERA5-Land 2m meteorological datasets (Muñoz Sabater, 2019a; See Fig. C3). This  
343 correction is designed to minimize the impact of temperature fluctuations on the HCHO anomalies. Finally, a  
344 polynomial obtained using a climatology of surface temperatures is added to the differential HCHO columns, in order  
345 to reintroduce the natural seasonal cycle, assuming the same temperature every year. These temperature-corrected  
346 HCHO columns are used throughout this paper. Note that the difference with uncorrected HCHO columns is generally  
347 small (less than 10%), but can be significant when looking for small effects such as those induced by COVID-19  
348 related emission changes. The dataset used for this analysis covers the period from May 2018 to June 2020.

## 349 2.6 Glyoxal (CHOCHO)

350 Glyoxal (CHOCHO) is not one of the TROPOMI operational ~~als~~ data products. For this study we used the prototype  
351 data product developed as part of the ESA S5p+I GLYRETRO project, which relies on scientific developments  
352 performed using the GOME-2 and OMI instruments (Lerot et al., 2010). The algorithm is described in detail in the  
353 GLYRETRO ATBD (Lerot et al., 2020). In brief, the retrieval approach consists of a DOAS-type spectral fit for the  
354 observed optical depth with reference absorption cross-sections for glyoxal and other absorbing species (NO<sub>2</sub>, O<sub>3</sub>, O<sub>2</sub>-  
355 O<sub>2</sub>, liquid water and water vapor, and the Ring effect) in the spectral interval of 435-460 nm to derive glyoxal slant  
356 column densities. The latter are converted into tropospheric columns using calculated air mass factors, after application  
357 of a background correction procedure aimed at reducing possible remaining (row-dependent) systematic biases. ~~Air~~  
358 ~~mass factors are calculated following the formulation of Palmer et al. (2001), which combines altitude-dependent air~~  
359 ~~mass factors (or Box-AMFs) with a priori glyoxal concentration profiles. The Box-AMFs represent the instrumental~~  
360 ~~sensitivity to changes in concentration at any altitude and are precomputed using the radiative transfer model~~  
361 ~~VLIDORT v2.7 (Spurr and Christi, 2019), while the a priori profiles are provided by the MAGRITTE chemistry-~~  
362 ~~transport model (Müller et al., 2018, 2019). Air mass factors are calculated following the formulation of Palmer et al.~~  
363 ~~(2001), which combines box air mass factors precomputed with the radiative transfer model VLIDORT v2.7 (Spurr~~  
364 ~~and Christi, 2019) and a priori glyoxal concentration profiles provided by the MAGRITTE chemistry transport model~~  
365 ~~(Müller et al., 2018, 2019).~~

366 The glyoxal optical depth is very small ( $< 5 \times 10^{-4}$ ), which makes its retrieval very sensitive to instrumental noise and  
367 to interferences with spectral signatures of species absorbing more significantly in the same spectral region. The first

368 factor introduces large random errors, in the range  $6\text{-}10 \times 10^{14}$  molec  $\text{cm}^{-2}$ , which can however be reduced by spatial-  
369 temporal averaging, that is, using multiple observations averaged time and/or space. Systematic uncertainties are  
370 dominated by spectral interferences, but also by uncertainties associated with the auxiliary data used as an input for  
371 the AMF calculation. These uncertainties are estimated to be  $2\text{-}3 \times 10^{14}$  molec  $\text{cm}^{-2}$  ( $\sim 50\%$  for source regions). To limit  
372 uncertainties related to cloud contamination, glyoxal observations are only provided for scenes with effective cloud  
373 fractions smaller than 20% (taken from the operational  $\text{NO}_2$  product). As with  $\text{HCHO}$ , to account for seasonal and  
374 interannual variability, a climatology of OMI CHOCHO columns was built to further delineate sources of variability  
375 for glyoxal column amounts.

376 Validation of satellite glyoxal column observations is generally limited, mostly due to the scarcity of independent  
377 ground-based data. However, a preliminary validation based on a few MAX-DOAS stations in Asia and Europe,  
378 indicates that the satellite and ground instruments measure consistent glyoxal tropospheric column amounts with mean  
379 differences generally less than  $2 \times 10^{14}$  molec  $\text{cm}^{-2}$ , except in particular conditions such as low sun elevation or for  
380 stations that are frequently covered by clouds (Alvarado et al., 2020). The dataset used for this analysis covers the  
381 period from May 2018 to June 2020.

### 382 3 Global Observations of Nitrogen Dioxide

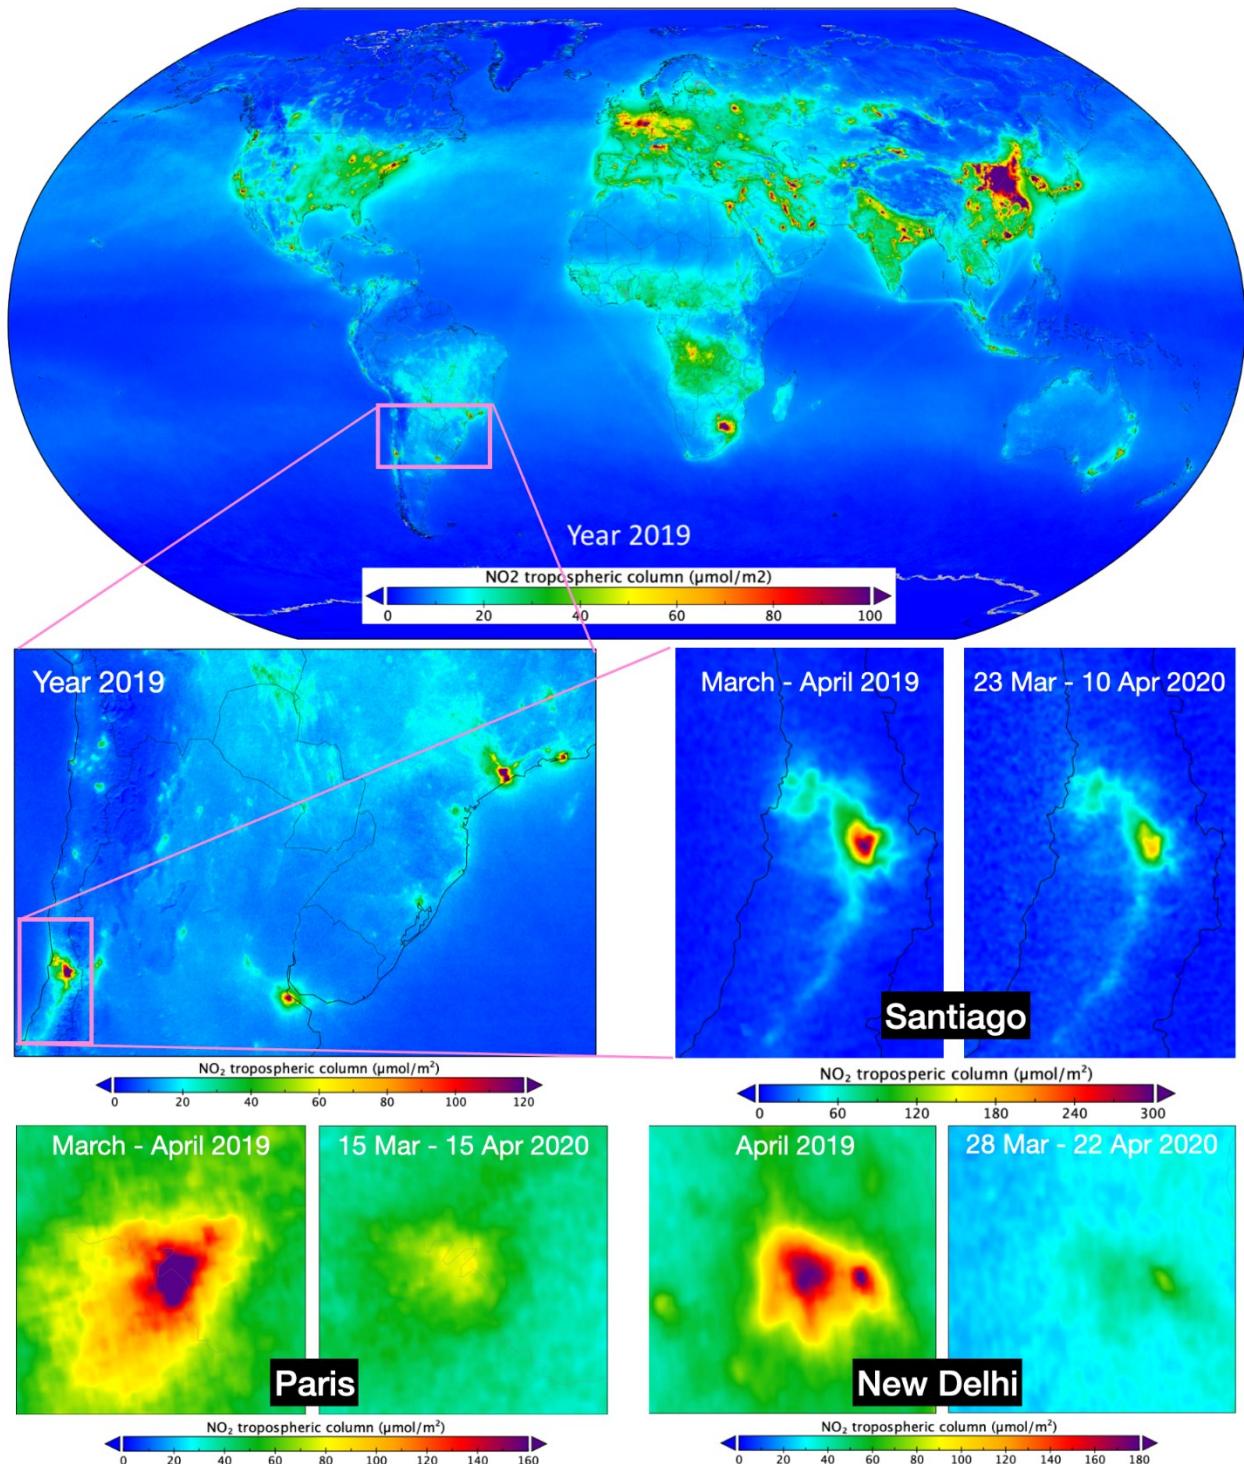

383 Numerous papers have shown that TROPOMI measurements of tropospheric  $\text{NO}_2$  column amount are well-suited for  
384 detecting emission from a variety of anthropogenic sources including traffic, power plants, and industry (van der A et  
385 al., 2020; Goldberg et al., 2019). The atmospheric lifetime of  $\text{NO}_2$  and its vertical profile shape dictate that the high  
386 spatial resolution measurements from TROPOMI can readily capture rapid week-to-week changes in near-surface  
387 emissions from COVID-19 impacted cities and point sources (Sekiya et al., 2021; Fioletov et al., 2021; Stavrakou et  
388 al., 2021; Gkatzelis et al., 2021). To give context and overview, the global distribution of tropospheric  $\text{NO}_2$  based on  
389 an annual average for 2019 with an oversampling resolution of approximately  $0.02^\circ \times 0.02^\circ$  is illustrated in [Figure 1](#).  
390 The high resolution of these measurements enables further zooming to the regional, suburban, and city scale providing  
391 detailed information about spatial distributions. Three further zoom-in cases for central Chile and its capital Santiago,  
392 for Paris, and for New Delhi are shown in A regional zoom in over central South America reveals high  $\text{NO}_2$  levels  
393 over the megacities of Rio de Janeiro, São Paulo, Buenos Aires, and Santiago. A further zoom in to central Chile and  
394 its capital Santiago is shown in Figure 1<sub>z</sub>. These cases focusing on a shorter periods coinciding with region-specific  
395 COVID-19 lockdowns (see Appendix B). Observed column amounts of  $\text{NO}_2$  are compared to similar periods in 2019,  
396 which are chosen to be longer than the 2020 period in order to reduce the effects of natural variability. Strong  
397 reductions in the  $\text{NO}_2$  tropospheric column amounts are observed during lockdown periods (Bauwens et al., 2020;  
398 Barré et al., 2021; Griffin et al., 2020; Qu et al., 2021). Interestingly, further zoom in shows that the relative reduction  
399 is not uniform over a city, reflecting differences in the mix of source contributions for different quarters of a given  
400 city, from 23 March to 10 April 2020, which coincides with a region specific COVID-19 lockdown (Figure 2k), as  
401 compared to the mean tropospheric  $\text{NO}_2$  column for March–April 2019. Note that the period in 2019 is chosen to be  
402 longer than 2020 in order to reduce the effects of natural variability, but the period is centered at the beginning of  
403 April to avoid the influence of the seasonal  $\text{NO}_2$  cycle. A strong reduction in the  $\text{NO}_2$  tropospheric concentration of

404 ~~about 40% is observed over Santiago during this period, and a 28% reduction is observed between 23 March and 15~~  
405 ~~May corresponding to the period when restrictions were eased (Figure 2k). Interestingly, a further zoom shows that~~  
406 ~~the relative reduction is not uniform over the city, reflecting differences in the mix of source contributions for the~~  
407 ~~different quarters of the city.~~

408

409

410

411

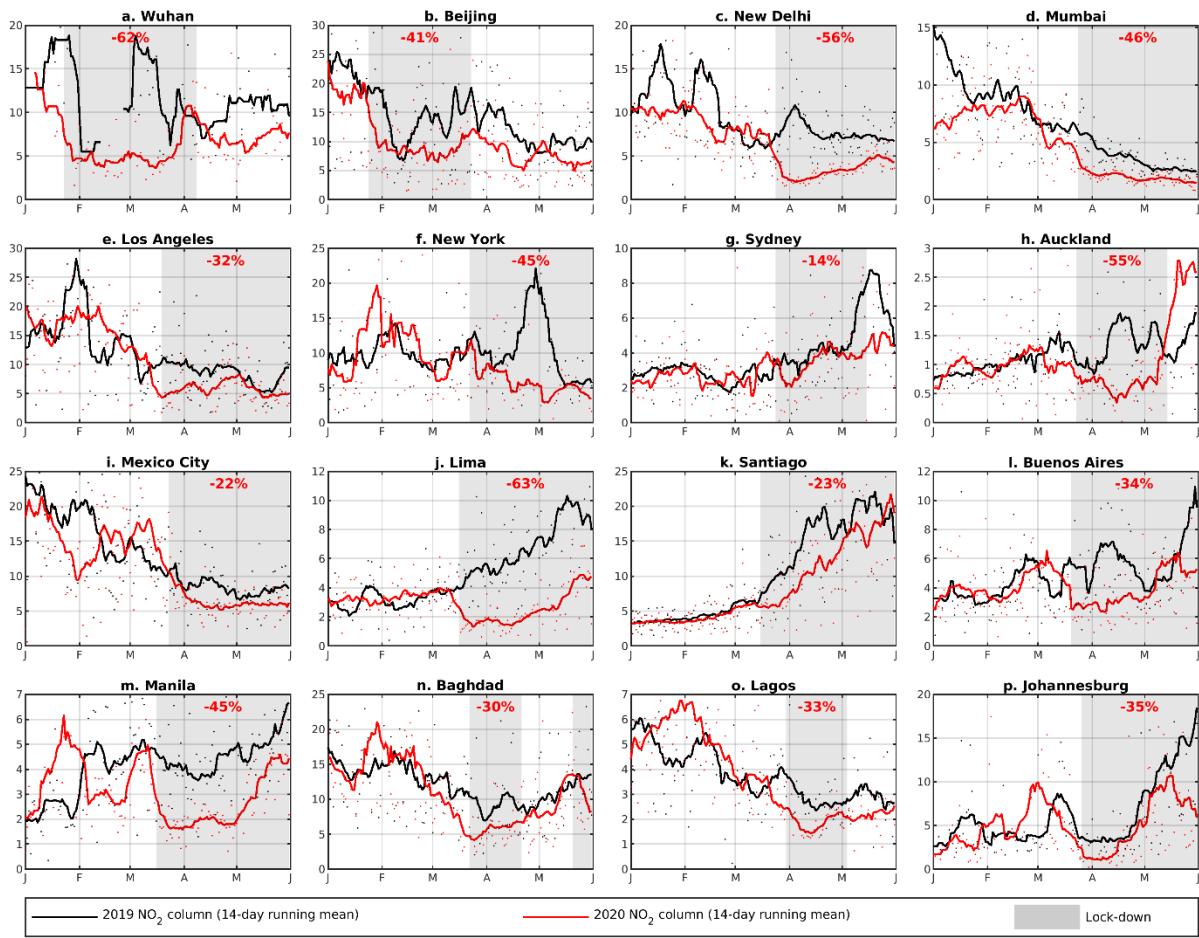

412 **Figure 1:** Global distribution of NO<sub>2</sub> based on the annual average of tropospheric column amounts of NO<sub>2</sub> measured by  
 413 TROPOMI for 2019 (top panel) shown in units of micromole per m<sup>2</sup>. Using the same data, several zoom-in plots are shown  
 414 in the middle and bottom panels: regional zoom-in for central South America (middle left) and a city-scale zoom-in over  
 415 Santiago, Chile (middle right panels, comparing 23 March to 10 April 2020 with March-April 2019), over Paris (lower left,  
 416 comparing 15 March to 15 April 2020 with March-April 2019) and over New Delhi (lower right, comparing 28 March to 22  
 417 April 2020 with April 2019). Note the different color scales in the three subpanels. The domain size of the panels is 1.5 x 1.0  
 418 degree for Paris, and 1.1 x 1.0 degree for New Delhi.

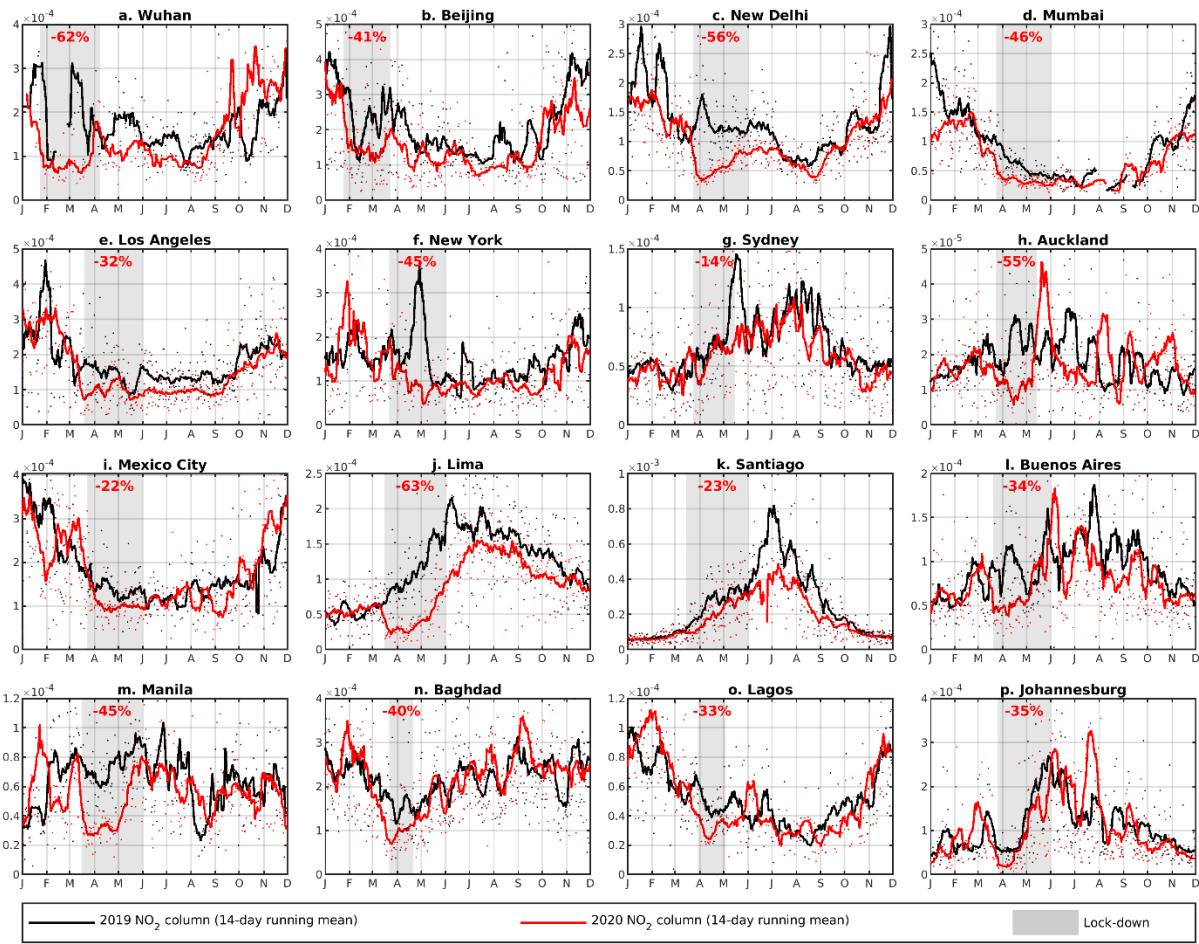

419

420

421 The lockdown periods and the measures taken to mitigate the spread of COVID-19 were rolled out on country- and  
422 often city-specific basis. Figure 2 illustrates the temporal evolution of NO<sub>2</sub> tropospheric column amounts from January  
423 to May over large cities across different continents. The observed reductions in China and India are discussed in more  
424 detail in Sections 4 and 5. Detailed information about the lockdown measures adopted for those cities is given in Table  
425 B2. Appendix B provides a detailed description of the observed reductions during the specific lockdowns for  
426 individual (mega)cities shown in Figure 2 and Figure 3. The TROPOMI observations indicate substantial decreases  
427 in NO<sub>2</sub> during the lockdowns in all studied cities, but the reductions vary significantly from one city to another. Two  
428 more examples of lockdown related NO<sub>2</sub> column reductions in major cities are shown for Paris and New Delhi in  
429 Figure 1 with time windows selected to reflect region specific lockdown periods. In Paris, the NO<sub>2</sub> levels for the  
430 period 15 March to 15 April 2020 are about a factor of two lower than in March–April 2019 (see also Figure 4). For  
431 New Delhi the reduction is even more striking in comparison to April 2019 (about a factor of 3, Figure 2c). Both Paris  
432 and New Delhi also show significant reductions in background values around the cities. Background locations are  
433 subject to a variety of wind directions and sometimes downwind of city plumes thus influencing background  
434 concentrations. Such plumes are typically on the order of 100 km long, and, given the atmospheric residence time of  
435 NO<sub>2</sub> (2–12 hours), these plumes can fill the small domains around Paris and New Delhi shown in Figure 1.

436

439 **Figure 2: Time series of TROPOMI NO<sub>2</sub> column amounts (in  $10^{15}$  meleemol em $^{-2}$ ) for selected cities for the period 1 January**

440 to 11 June December in 2019 (black dots) and 2020 (red dots). TROPOMI observations are averaged over a  $25 \times 25$  km $^2$  box

441 around the city center. The lines indicate the two-week running mean for 2019 (black) and 2020 (red). The grey zones

442 indicate the official lockdown period for each city. The reduction of the average NO<sub>2</sub> column during the lockdown period

443 relative to the same period in 2019 is given inset. Details about the lockdown dates are summarized in Table BC2.

444

445 The lockdown periods and the measures taken to mitigate the spread of the COVID-19 were rolled out on a country-

446 and often city-specific basis. Figure 2 and Figure 3 illustrates the temporal evolution of NO<sub>2</sub> tropospheric

447 columns from January to May over large cities for different continents. The observed reductions in China and India

448 are discussed in more detail in Sect. 4 and 5. Detailed information about the lockdown measures adopted for those

449 cities is given in Table BC2. The TROPOMI observations indicate substantial decreases in NO<sub>2</sub> during the lockdowns

450 in all studied cities, but the reductions vary significantly from one city to another.

451 ~~In Wuhan, the first city to issue quarantines and lockdown measures, the observed NO<sub>2</sub> column drastically declined~~

452 ~~(-60%) between 23 January and 8 April 2020 compared to the same period in 2019 (Table C2). This decrease is in~~

453 ~~good agreement with estimated reductions for the period 11 February to 2 March 2020 based on TROPOMI NO<sub>2</sub> (-~~

454 ~~43%, Bauwens et al., 2020) and in situ NO<sub>2</sub> observations in Wuhan (-55%, Shi and Brasseur, 2020). However, it~~

455 ~~should be noted that there was strong day to day variability in the NO<sub>2</sub> column amount due to meteorological factors,~~

456 as well as missing data over Wuhan in February 2019 due to clouds. Model calculations by Liu et al. (2020) indicate  
457 that meteorological variability could have led to increased  $\text{NO}_2$  columns in 2020 compared to 2019, suggesting that  
458 the observed  $\text{NO}_2$  reductions underestimate the impact of emission reductions due to COVID-19. The partial lifting  
459 of the restrictions on 8 April led to a progressive increase in  $\text{NO}_2$  levels, yet remained lower than in 2019, likely  
460 because the population was still advised to stay at home and schools remained closed. A similar response in  $\text{NO}_2$   
461 levels was observed in Beijing. The decreases were less pronounced ( 40%) and are in excellent agreement with the  
462 reported decrease based on in situ  $\text{NO}_2$  measurements ( 40%, Shi and Brasseur, 2020). The weaker response could be  
463 due to the less drastic measures adopted in Beijing, because locally sustained COVID-19 cases were lower than in the  
464 Hubei province (Leung et al., 2020). Strong  $\text{NO}_2$  reductions were observed for other Chinese cities, like Nanjing,  
465 Qingdao, and Zhengzhou, based on TROPOMI  $\text{NO}_2$  observations (Bauwens et al., 2020).

466 India enforced strict restrictions of human activities on 24 March 2020 to tackle the spread of COVID-19. In New  
467 Delhi and Mumbai, the onset of the lockdown induced a sharp decline in the observed  $\text{NO}_2$  columns (by a factor of  
468 2). The columns remained low during the entire lockdown period ( 56% and 46%, respectively) (see Table 2 for  
469 timing of lockdown phases). This is very much in line with the decreases reported in New Delhi based on  $\text{NO}_2$  data  
470 from monitoring stations, 53% (Mahato et al., 2020) and 48% (Jain and Sharma, 2020).

471 As compared to other cities, a very strong  $\text{NO}_2$  decrease was observed in Lima ( 63%), where strict regulations to  
472 stay indoors were enforced (Collins, 2020). A drastic drop in  $\text{NO}_2$  compared to the 2019 levels marked the start of  
473 the lockdown, and the levels remained very low throughout the entire lockdown period. The gradual increase of  $\text{NO}_2$   
474 columns in Lima and other Southern Hemispheric cities from January to May (Figure 2) reflects the natural seasonal  
475 variation when levels peak during the Southern Hemispheric winter, as temperatures decrease and  $\text{NO}_2$  lifetime  
476 increases.

477 In Buenos Aires, the observed reduction was not as strong compared to Lima for the entire lockdown period ( 34%,  
478 Table C2), but was particularly marked during the first month of the lockdown (20 March through 20 April 2020),  
479 due to a compulsory quarantine period and strict limitation of activities for many sectors. Although partial lifting of  
480 measures was issued after 10 April for many provinces in Argentina, the measures in the Buenos Aires agglomeration  
481 were maintained due to the elevated number of cases (Raszewski and Garrison, 2020). More moderate reductions are  
482 found for Mexico City ( 22%) and Santiago ( 23%) during the lockdown in comparison to the same period in 2019,  
483 that could be attributed to less strict adherence to and enforcement of lockdown measures (Ueho, 2020; Pasley, 2020).

484 Strong reductions were observed over the entire lockdown period in the heavily hit cities in southwest Europe, Los  
485 Angeles, and New York, with reductions ranging between 32% and 54% (Bauwens et al., 2020). It should be noted  
486 however, that in these regions, the start of the lockdown period is generally less marked partly because the lockdowns  
487 were not as strictly enforced in Europe and the U.S. as in China and India. Moreover, the observed TROPOMI data  
488 displays a strong variability attributable to meteorology, e.g. over Paris, New York and Los Angeles in 2019.

489 In Sydney, the reduction was moderate ( 14%) and delayed with respect to the onset of the measures (Figure 2).  
490 This could be related to observations of less strict compliance in the early period of lockdown measures (New South  
491 Wales Public Health, 2020). A rapid and strong decrease was observed for  $\text{NO}_2$  column amount as a result of lockdown  
492 measures in Auckland, New Zealand ( 55%). Similarly, the lockdown measures in New Zealand were implemented

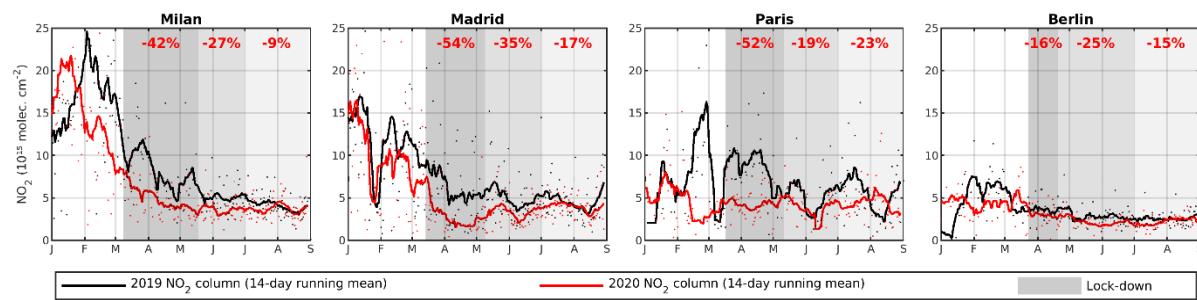

493 swiftly with high levels of compliance (Matthews, 2020). The end of the lockdown coincided with a strong increase  
494 in  $\text{NO}_2$  pollution, from  $1.8 \times 10^{15}$  molec  $\text{cm}^{-2}$  to  $3 \times 10^{15}$  molec  $\text{cm}^{-2}$  in the last three weeks of May.  
495 In Africa, Nigeria is among the countries most affected by COVID-19 and reported the first confirmed case in sub-  
496 Saharan Africa (Odunsi, 2020; Adigun and Anna, 2020). A two week lockdown period was put in place for Lagos  
497 starting 30 March. The  $\text{NO}_2$  column amount decreased by 33% during the lockdown (Figure 2) with respect to the  
498 same period of 2019 and remained lower even after the lifting of restrictions on 4 May (Table C2). An  $\text{NO}_2$  column  
499 decrease of similar magnitude ( 35%) was observed in Johannesburg, where a national lockdown was issued on 26  
500 March 2020, with a gradual easing of restrictions starting 1 May. In Sub Saharan Africa, the emission reductions in  
501 April were significant for larger populous and industrialized areas, whereas no noticeable drop was found in less  
502 developed regions (Masaki et al., 2020).

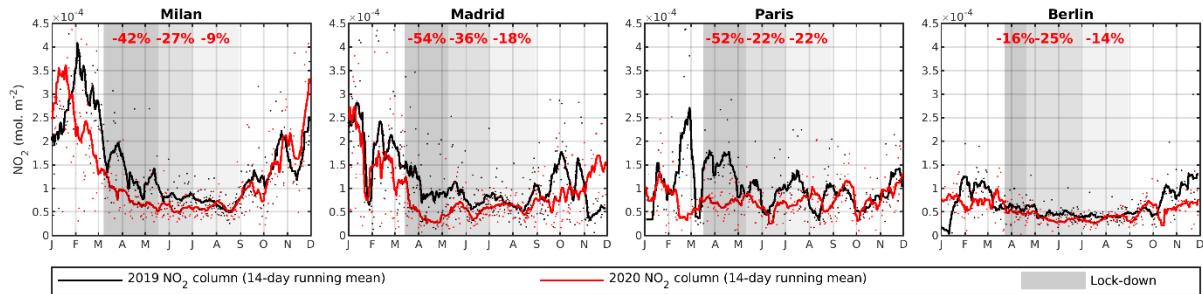

503 Finally, the Iraqi capital of Baghdad faced an initial lockdown from 22 March through 21 April. A second partial  
504 lockdown was issued starting 20 May in response to a sharp increase in COVID-19 cases due to the temporary  
505 relaxation of restrictions to allow the celebration of Ramadan in late April (Table C2). The  $\text{NO}_2$  column responded  
506 quickly (Figure 2n) as confirmed by the rapid decrease once curfew measures were issued in late May.

507 Figure 3 and Figure 4 illustrate the tropospheric concentration of  $\text{NO}_2$  over Europe, focusing on Milan, Madrid,  
508 Paris and Berlin (Figure 3), extending the analysis to include summer months. In France, Spain and Italy we detect  
509 strong reductions of  $\text{NO}_2$ , which can be largely attributed to the lockdown measures. In Berlin, the measured  
510 differences are smaller, and a more detailed analysis of the meteorological variability is needed to quantify the impact  
511 of the lockdown (see Figure 3). The extended time series shows a recovery of the  $\text{NO}_2$  pollution levels to pre COVID-  
512 19 values. However, the recovery is not complete, suggesting that remaining restrictions, new stay at home life and  
513 working practices, together with a downturn in industrial and service based activities have contributed to a longer  
514 lasting impact.

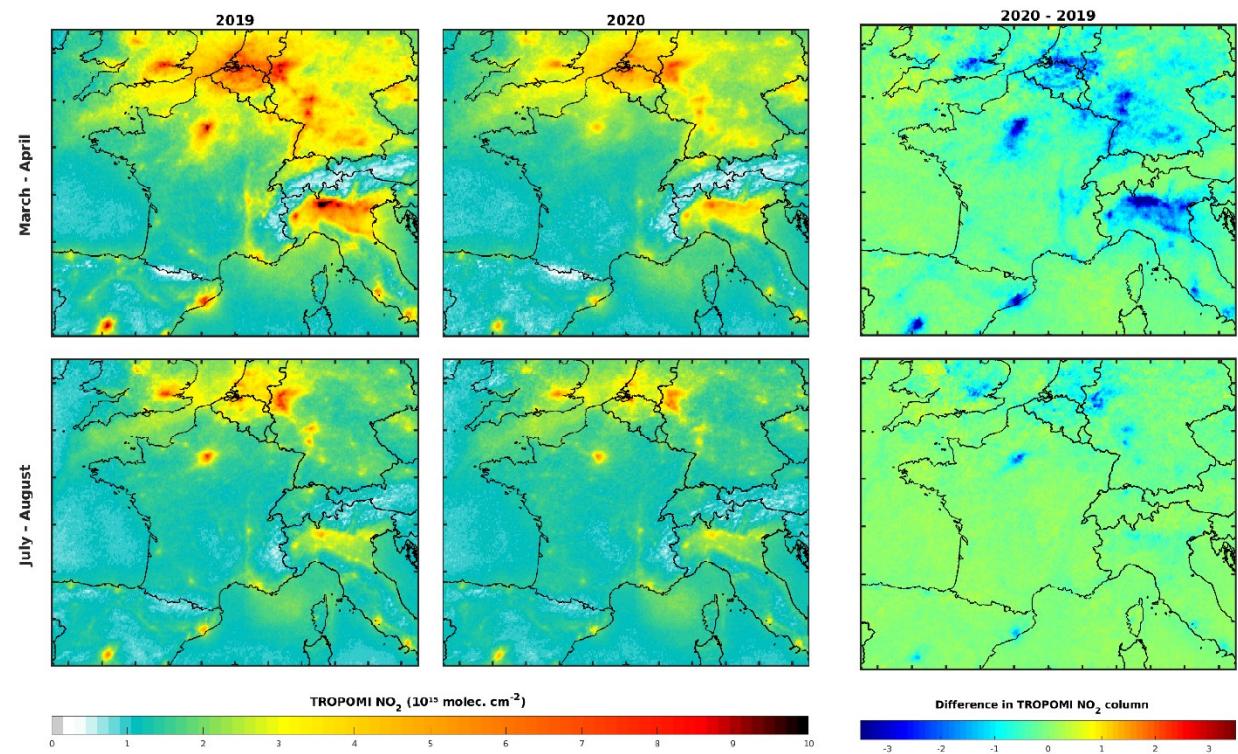

515

516

 521 **period of 1 January to 14 September December in units of mol m<sup>-2</sup>.** Additional shading indicates the lockdown period (dark  
 522 **lockdown**)

524

525  
 526 **Figure 4: TROPOMI NO<sub>2</sub> tropospheric columns over Europe in the lockdown months March-April (top) and the post-**  
 527 **lockdown months July-August (bottom), comparing 2019 (left) with 2020 (middle) in units of mol m<sup>-2</sup>. The difference is**  
 528 **shown in the right panel.**

529  
 530 ~~Relative concentration changes between 2019 and 2020, as mentioned previously, should not be fully attributed to~~  
 531 ~~COVID-19 lockdown measures and the subsequent reduction of emissions. Daily changes in the weather have a strong~~  
 532 ~~influence on the NO<sub>2</sub>-concentrations, even when the data is averaged over a month. In order to estimate the impact of~~  
 533 ~~meteorological variability on TROPOMI-based NO<sub>2</sub>-observations, simulations were performed with the LOTOS-~~  
 534 ~~EUROS chemistry transport model over Europe at a resolution of 0.1° x 0.1°. Using the same emissions for 2019 and~~  
 535 ~~2020, the simulations show that meteorological variability is responsible for changes in the monthly mean, city-~~  
 536 ~~averaged NO<sub>2</sub> columns with a 1-sigma standard deviation of about 13%. This variability is clearly illustrated in e.g.~~  
 537 ~~the individual daily observations in Figure 2. The drastic changes in the range of 30-60% observed in the TROPOMI~~  
 538 ~~data and shown in Figure 1 through Figure 4 clearly fall outside this range and cannot be attributed to weather alone.~~  
 539 ~~Relative concentration changes between 2019 and 2020 (as shown in Figure 4), as mentioned previously, should not~~  
 540 ~~be fully attributed to COVID-19 lockdown measures and the subsequent reduction of emissions. Daily changes in the~~  
 541 ~~weather have a strong influence on the NO<sub>2</sub> concentrations, even when the data is averaged over a month. In order to~~  
 542 ~~estimate the impact of meteorological variability on TROPOMI-based NO<sub>2</sub> observations, simulations were performed~~  
 543 ~~with the LOTOS-EUROS chemistry-transport model over Europe at a resolution of 0.1° x 0.1°. Using the same~~  
 544 ~~emissions for 2019 and 2020, the simulations show that meteorological variability is responsible for changes in the~~  
 545 ~~monthly-mean, city-averaged NO<sub>2</sub> columns with a 1-sigma standard deviation of about 13%. This variability is clearly~~  
 546 ~~illustrated in e.g. the individual daily observations in Figure 2. The drastic changes in the range of 30-60% observed~~

547 [in the TROPOMI data and shown in Figure 1 through Figure 4 clearly fall outside this range and cannot be attributed](#)  
548 [to weather alone.](#)

549 A second complication is the presence of clouds. Months with persistent local cloud cover will therefore have a  
550 reduced number of tropospheric column observations and will exhibit more natural variability. For quantitative  
551 estimates of the COVID-19 measures, these factors should be carefully taken into account. This can be done through  
552 (i) daily-based analysis of the NO<sub>2</sub> plumes from cities using wind speed fields from meteorological models and  
553 subsequent emission derivation (Lorente et al., 2019; Goldberg et al., 2019); (ii) [combining NO<sub>2</sub> observations with](#)  
554 [analyzed wind fields \(Beirle et al., 2019, 2021\);](#) (iii) regression models to estimate the impact of natural variability  
555 and emission trends in the observations (Diamond and Wood, 2020); (iv) chemistry-transport modelling (Chang et  
556 al., 2020; Liu et al., 2020; Barré et al., 2021); and (v) inverse modelling and data assimilation approaches (Ding et  
557 al., 2020; Miyazaki et al., 2020).

#### 558 4 Regional Observations for China

559 China was the first country to impose measures to limit the spread of the SARS-CoV-2 virus. Although no national  
560 lockdown was declared, strict local lockdown measures were implemented in many cities and provinces. In Wuhan,  
561 the epicenter of the virus outbreak, the lockdown period lasted from 23 January 2020 until 8 April 2020, while in other  
562 regions, it generally started in early February with measures being eased and lifted through March. In addition to the  
563 lockdown measures, the yearly Chinese New Year holidays also affected the amount of anthropogenic emissions (Tan  
564 et al., 2009), and so needs to be considered for proper interpretation of the observations. The timing of the holiday  
565 period differs from year to year and took place from 24 January to 2 February in 2020, and in the periods 4-10 February  
566 and 15-21 February for 2019 and 2018, respectively.

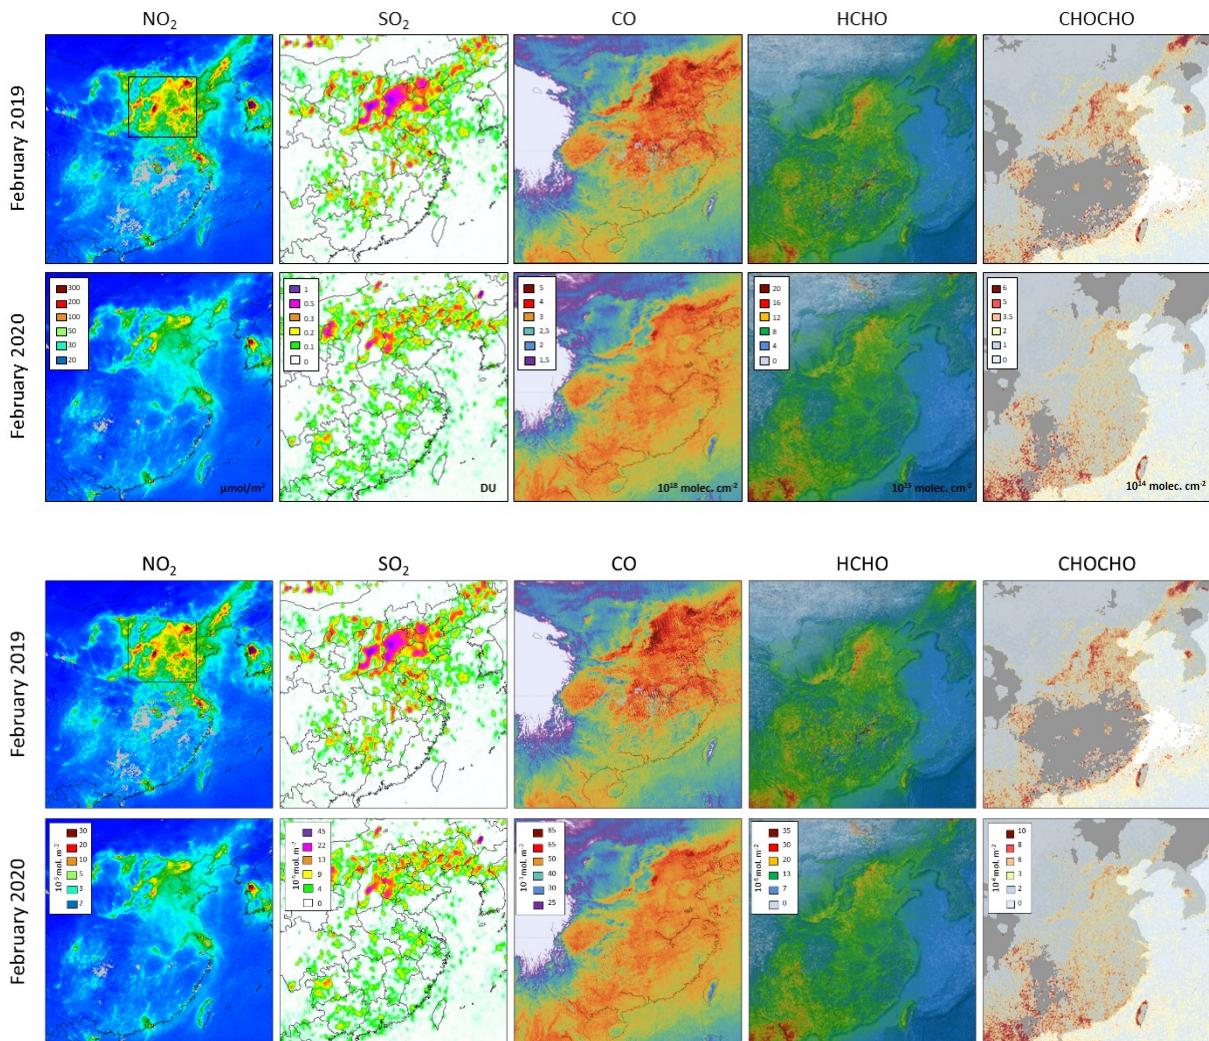

567 The impact of the COVID-19 crisis on air quality in China has already been investigated in several studies. Bauwens  
568 et al. (2020) reported that tropospheric NO<sub>2</sub> column amounts observed by TROPOMI during the lockdown dropped  
569 by 40-50% in the most impacted cities compared to the same period in 2019 (see Sect. 3). Accordingly, top-down  
570 estimated NO<sub>x</sub> emissions exhibited sharp reductions of up to 50% during the strict lockdown period in late January  
571 through early February (Ding et al., 2020; Liu et al., 2020; Zhang, R. et al., 2020).

572 In situ data indicate significant reductions of ground concentrations for NO<sub>2</sub>, but also for PM, SO<sub>2</sub>, and CO (Shi and  
573 Brasseur, 2020; Wang et al., 2020; Zhang, Z. et al., 2020; Zhao, Y. et al., 2020). On the other hand, those studies  
574 consistently reported increases of ozone concentrations. With the support of models, Zhao, Y. et al. (2020) have shown  
575 that the observed decreases in NO<sub>2</sub> concentration were mostly caused by emissions reductions. They also show that  
576 the contribution of meteorological changes to the observed concentration reductions of other species depends on the  
577 exact location. Based on OMI observations, Zhang, Z. et al. (2020) observed reductions in East Asia of about 33%  
578 and 41% for NO<sub>2</sub> and SO<sub>2</sub>, respectively.

579 City-scale impacts of lockdown on NO<sub>2</sub> tropospheric column amounts for Wuhan and Beijing [are presented](#) in Sect.  
580 3. Here, we investigate whether a lockdown signature can be detected from space at the regional scale for other key  
581 pollutants by focusing on TROPOMI tropospheric column measurement of SO<sub>2</sub>, CO, HCHO, and CHOCHO. We also  
582 compare the identified changes with the marked changes in NO<sub>2</sub> concentration. Figure 5 compares monthly mean

583 tropospheric columns of those different species for February 2019 and 2020. The  $\text{NO}_2$  and  $\text{SO}_2$  tropospheric column  
 584 amounts are clearly lower in February 2020 compared to 2019. A small general reduction is also visible in the CO,  
 585 HCHO and glyoxal column amounts. As discussed before, many factors other than the lockdown measures may  
 586 explain changes in pollutant concentrations, such as the meteorology or emission reduction related to the timing of  
 587 holidays. Another difficulty to compare different years is the data sampling. In February 2019, large parts of Southern  
 588 China were covered by clouds, preventing space-based observation of the lowermost atmospheric layers. This is  
 589 clearly illustrated in the upper panel of Figure 5 showing CHOCHO ~~concentrations~~ column amounts, where data is  
 590 missing over large regions since this product uses the most stringent cloud filtering as compared to the other trace  
 591 gases. Therefore, the following detailed discussion only focuses on the northern part of China (black box in Figure 5  
 592 top left panel), even though the lockdown measures were stricter in the region of Wuhan.

593  
594

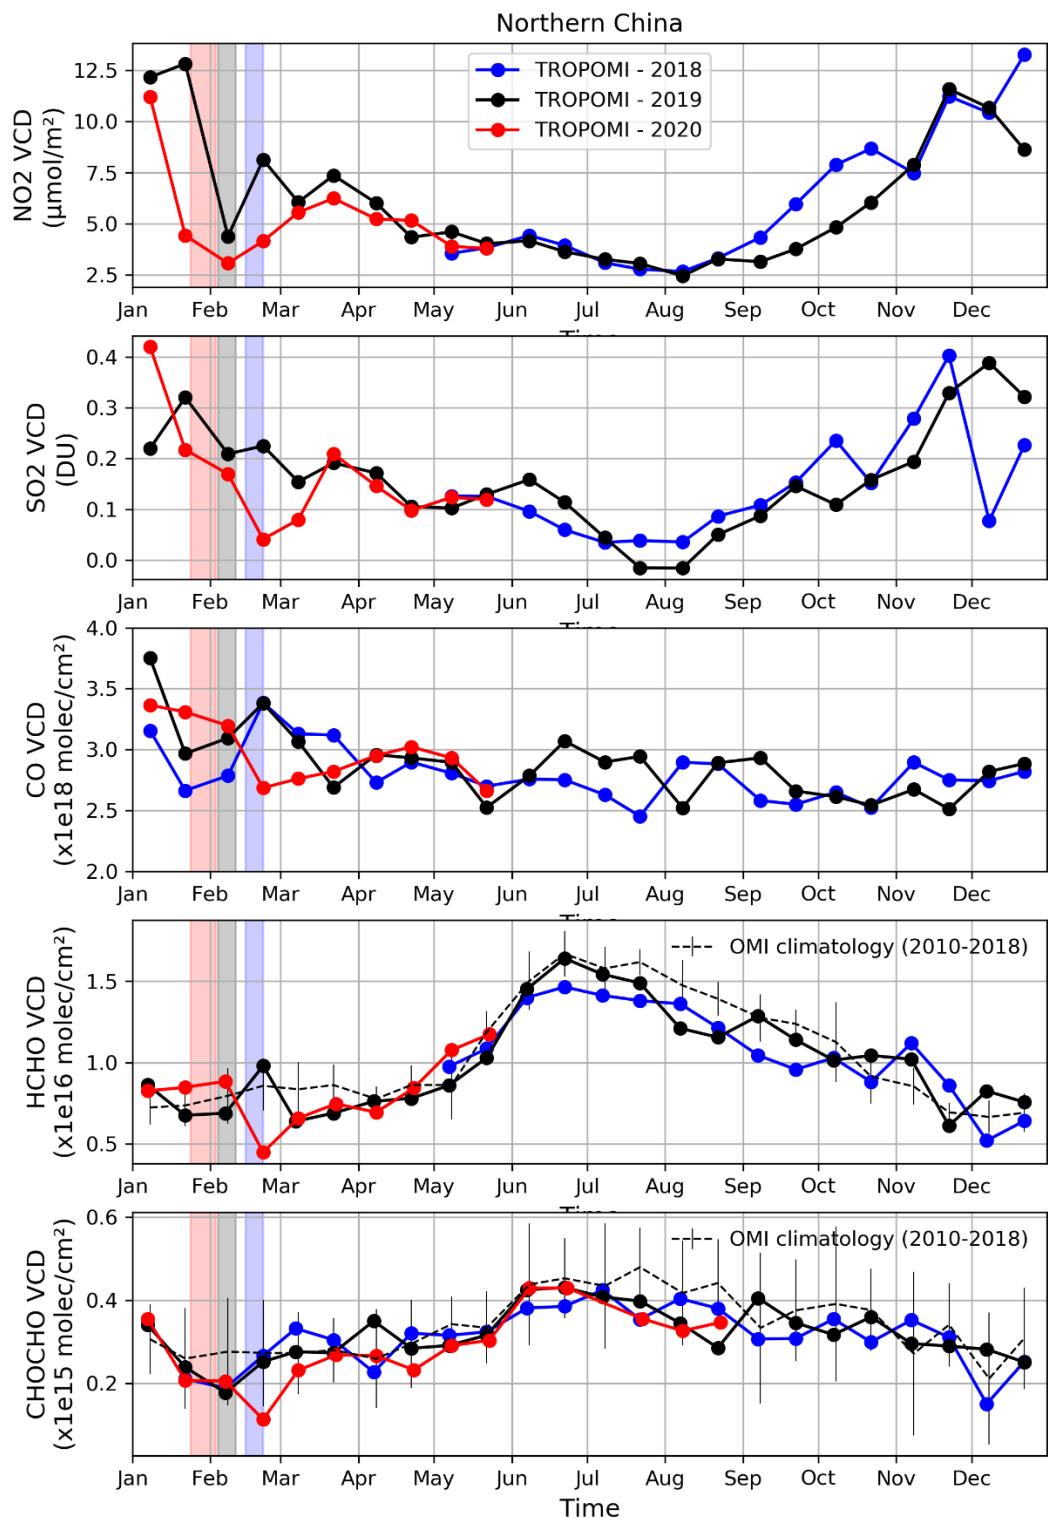

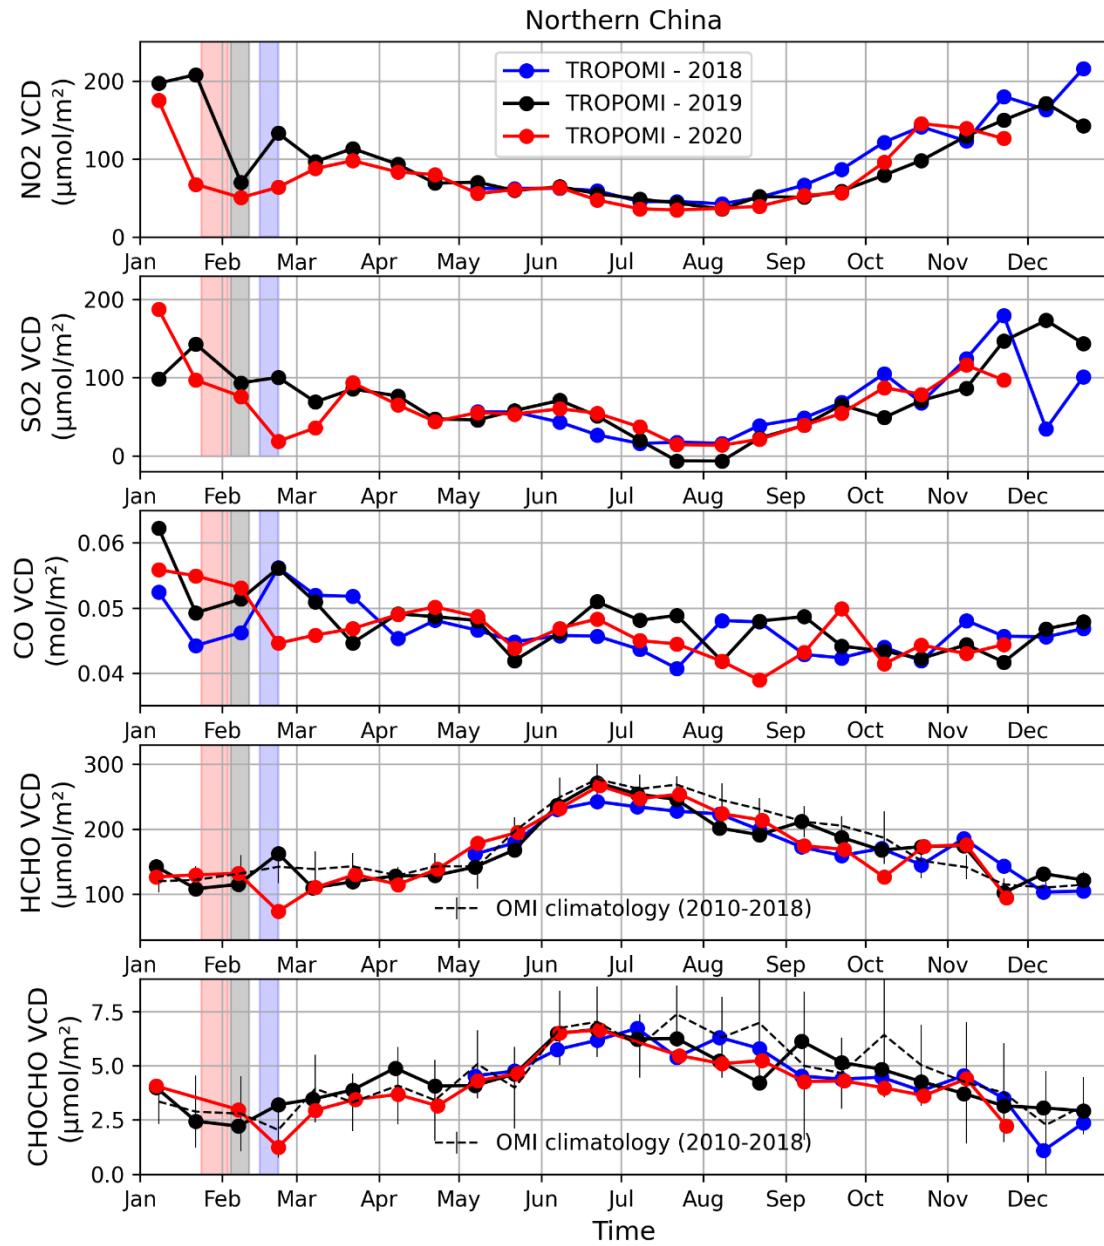

597 **Figure 5: Tropospheric and total columns for various trace gases over China as observed by TROPOMI over China in**  
 598 **February 2019 (upper panels) and 2020 (lower panels) in units of mol m<sup>-2</sup>. The black box indicates the geographical region**

599 used in the time series analysis (Figure 6). Note: the grey-shaded regions in NO<sub>2</sub> and CHOCHO panels (far left and far  
600 right, respectively) indicate areas with little or no data available due to persistent local cloud cover.

601  
602 Figure 6 shows the seasonal cycles for tropospheric column amounts of TROPOMI NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO, and  
603 CHOCHO for different years in northern China (region in black box highlighted in Figure 5) starting at the beginning  
604 of the operational phase of the S5P/TROPOMI mission (30 April 2018). The different colored curves show two-week  
605 medians of the daily mean tropospheric columns. In order to focus on the effect of COVID-19 lockdown measures for  
606 HCHO and CHOCHO, the TROPOMI-based time series are compared with an OMI-based climatology for these  
607 species using OMI data from 2010 to 2018, and shown by the black dashed curves. The associated uncertainties  
608 represent the interannual variability as estimated from OMI. This type of climatological reference based on a longer  
609 time series is not available for CO. Therefore, Figure 6 shows CO columns starting from 1 January 2018, which have  
610 been added to extend the time series even though the data sampling was more limited in the early phase of the mission.  
611 The light vertical boxes in January and February indicate the period of Chinese New Year holidays. Note that the 2020  
612 holiday period was slightly extended as a first measure against the COVID-19 spread.

613  
614

616  
617 **Figure 6:** Two-week median tropospheric column concentrations amounts of NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO and CHOCHO (from  
618 top to bottom) for northern China (34°N-40°N; 110°E-120°E) in units of (micro)mol m<sup>-2</sup>. The year 2020 is represented in  
619 red (2018 in blue, 2019 in black) and The different curves represent different years as indicated in the legend. The colored  
620 boxes represent correspond to the yearly Chinese New Year holidays for those same years. The dashed black lines in the  
621 HCHO and CHOCHO panels represent a climatological seasonality as obtained using the OMI data sets from 2010 to 2018  
622 and the error bars represent the interannual variability (1-sigma standard deviation).

623  
624 Superimposed on the overall seasonal cycle of NO<sub>2</sub> (maximum during wintertime caused by a longer atmospheric  
625 lifetime), a clear reduction of the NO<sub>2</sub> columns is systematically observed which corresponds to the New Year  
626 festivities. While a quick return to higher values is usually observed after that period (Tan et al., 2009), the NO<sub>2</sub>  
627 columns remained lower for several weeks in 2020 likely as a consequence of the reduced traffic and industrial

628 activities. For example, NO<sub>2</sub> column amounts at the end of February were about 45% lower than those of 2019. In  
629 March 2020, NO<sub>2</sub> columns return progressively to a similar level as compared to other years.

630 SO<sub>2</sub> emissions in China mostly originate from fossil fuel burning of coal and oil (Wang et al., 2018). Although  
631 Chinese SO<sub>2</sub> emissions have dropped significantly in the last decade (van der A et al., 2017; Zheng et al., 2018a),  
632 enhanced SO<sub>2</sub> columns are still observed in some regions of northern China (Figure 5). As illustrated in Figure 6, SO<sub>2</sub>  
633 column amounts are larger during wintertime mostly due to its longer atmospheric lifetime (Lee et al., 2011). No clear  
634 reduction could be related to the yearly holidays. However, in 2020 a sharp drop is observed starting in late January  
635 through mid-March with a reduction of up to 77% as compared to 2019. By late-March/early-April values returned to  
636 levels similar to previous years, which is consistent with the NO<sub>2</sub> lockdown signature.

637 In northern China the residential sector, consisting of mostly of emissions from heating and cooking, accounts for  
638 nearly half of the anthropogenic CO emissions, while the rest is distributed between traffic, power generation, and  
639 industry (Zheng et al., 2018b). Since the impact of lockdown measures is more limited for the residential sector as  
640 compared to the transport or industrial sectors, the response of CO to the lockdown measures is expected to be less  
641 distinct. Also, due to the longer atmospheric lifetime of CO (weeks to a month), the observed column amounts result  
642 from the accumulation of the trace gas over source regions and from long-range transport from regional and global  
643 sources. As such, meteorology significantly influences CO concentrations. The observed day-to-day variability is  
644 indeed large, leading to more scatter in the two-week median time series shown in Figure 6. The CO columns observed  
645 in late February/early March are lower than those observed in the last two years, which might be partly caused by the  
646 lockdown measures. However, the high temporal and spatial natural variability of the CO column amount is of the  
647 same magnitude as the possible COVID-19 lockdown signal, and the large, year-to-year interannual differences  
648 prevent firm conclusions from being drawn. Dedicated model simulations or a longer time series of the TROPOMI  
649 CO data may help to disentangle these effects in the future.

650 There are difficulties associated with the investigation of a possible lockdown signature in the satellite HCHO and  
651 CHOCHO data sets. Large uncertainties are associated with both of these column retrievals owing to their low optical  
652 depth. Moreover, HCHO and CHOCHO columns are dominated by biogenic emissions, which explains the observed  
653 seasonal pattern of HCHO and CHOCHO column values with a maximum during summertime as illustrated in Figure  
654 6. Variability in meteorology (temperature changes, winds, precipitation) may lead to changes in column amounts on  
655 the same order of magnitude as the expected lockdown-related reduction in anthropogenic emission changes. The  
656 interannual variability as inferred from the OMI data sets is estimated to be in the range of  $1 \times 10^{14}$  molec cm<sup>-2</sup> (~30%)  
657 and  $1.2 \times 10^{15}$  molec cm<sup>-2</sup> (~12%) for CHOCHO and HCHO, respectively. Despite those issues, a clear minimum is  
658 visible for both HCHO and CHOCHO in late February 2020, with columns significantly lower than 2019 and lower  
659 than the OMI climatology (about -40% and -50% for HCHO and CHOCHO, respectively). The differences are also  
660 larger than what can be explained by the typical interannual variability. This is in agreement with Sun et al. (2021),  
661 who finds a significant HCHO decrease in the Northern China Plain. For glyoxal, a reduction of the column amounts  
662 starts already in late January but similar reductions are observed in other years and might be related to a holiday effect  
663 similar to that observed for NO<sub>2</sub>.

664 It is interesting to note that local minima are observed simultaneously in late February 2020 for all species except  
665 NO<sub>2</sub>, despite the data products being generated using independent retrieval algorithms. This gives confidence into the  
666 detected reductions and their anthropogenic origin. The small delay between the initial decrease in NO<sub>2</sub> ~~concentration~~  
667 ~~column amount~~ and the observed decreases in the other trace gases ~~signals~~ is related to a combination of longer  
668 atmospheric lifetimes and production being dominated by secondary processes as compared to NO<sub>2</sub> ([Stavrakou et al.,](#)  
669 [2021](#)) and is also likely tied to the early timing of the Chinese New Year in 2020.

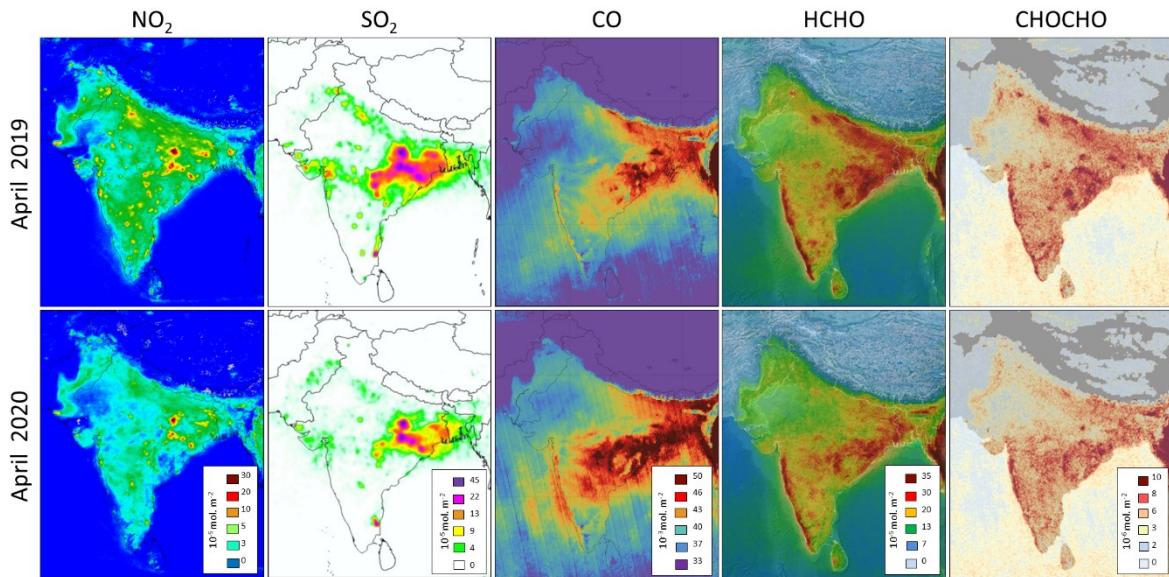

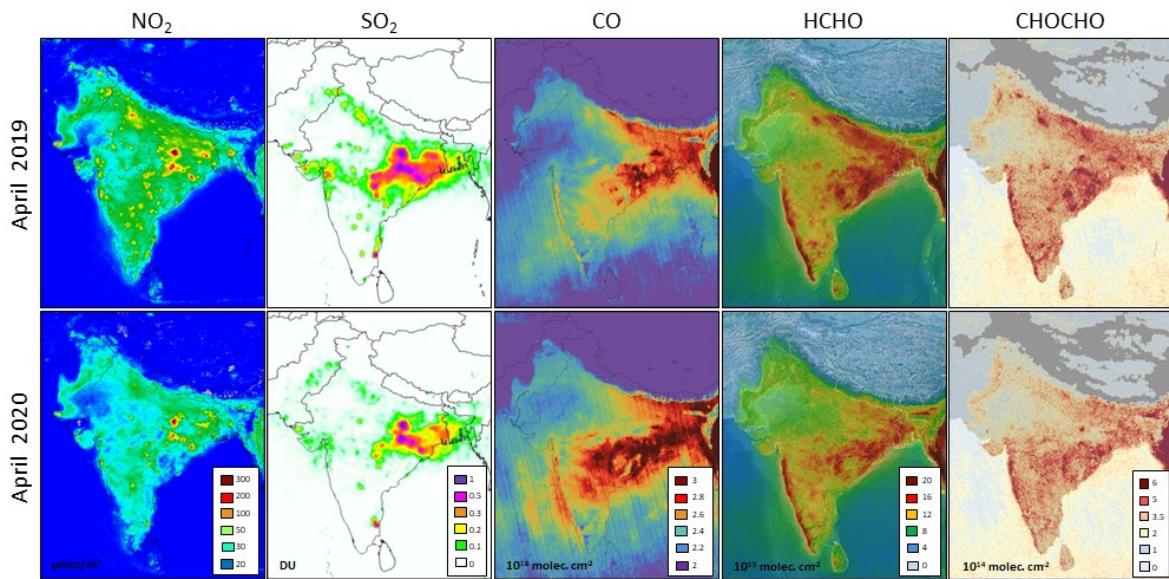

670 **5 Regional Observations for India**

671 India implemented strict national lockdown measures limiting activities across the country starting 24 March 2020 for  
672 a period of 21 days in order to tackle the spread of the SARS-CoV-2 virus amongst its 1.3 billion inhabitants. The  
673 initial stringent phase 1 restrictions were followed by careful region-based relaxations in three subsequent phases  
674 carried out through the end of May as shown in Table 2.

675  
676 **Table 2: Lockdown phases in India.**

	<b>Dates</b>	<b>Measures</b>	<b>Reference</b>
<b>Phase 1</b>	24 Mar to 14 Apr	Nearly all services and factories suspended.	Singh et al. (2020)
<b>Phase 2</b>	15 Apr to 3 May	Extension of lockdown with relaxations, reopening of agricultural businesses and small shops at half capacity.	BBC News (2020)
<b>Phase 3</b>	4 May to 17 May	Country split in 3 zones: (i) lockdown zone, (ii) zone with movement with private and hired vehicles, and (iii) normal movement zone.	India today (2020)
<b>Phase 4</b>	17 May to 31 May	Additional relaxations, more authority given to local bodies.	The Economic Times, 2020

677  
678  
679 Figure 7 gives an overview of TROPOMI observations of NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO, and CHOCHO, over India for  
680 April 2020, thus covering most of phase 1 and 2 of the Indian lockdown, as compared to the same month in 2019. For  
681 NO<sub>2</sub> and SO<sub>2</sub> the ~~concentrations column amounts~~ are clearly lower across the country in 2020 as compared to 2019.  
682 Although less prominent, ~~concentrations column amounts~~ of CO, HCHO, and CHOCHO appear to be lower in April  
683 2020 over the domain of the Indo-Gangetic Plain (IGP), which is one of the most densely populated areas of the world  
684 with roughly 900 million people.

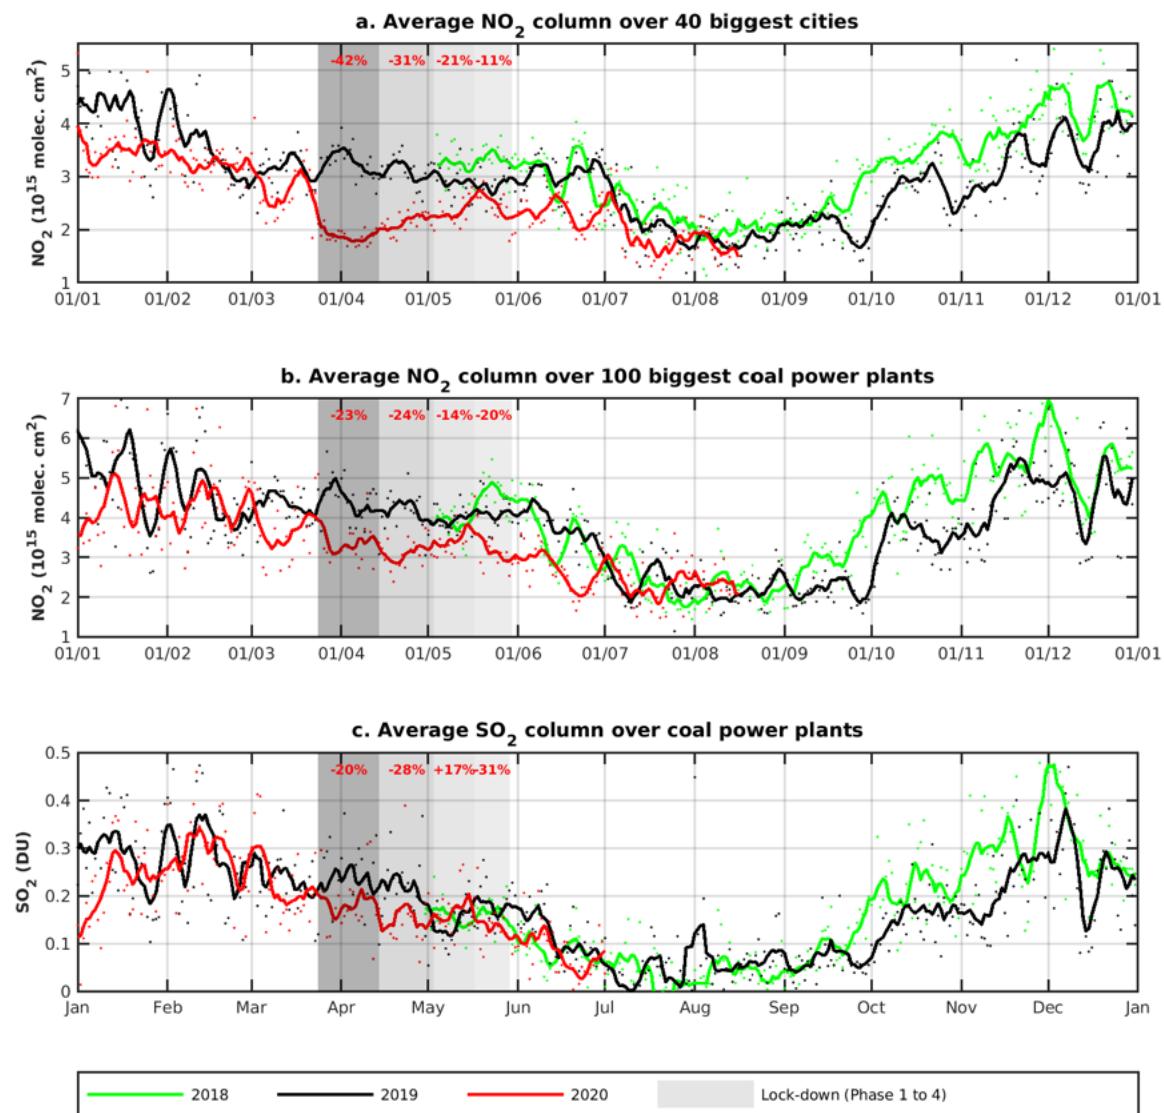

689 **Figure 7: Tropospheric and total columns Concentrations-maps for April 2019 (top row) and April 2020 (bottom row) for**  
 690 **the various trace gas species measured by TROPOMI from left to right, NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO and CHOCHO, shown in**  
 691 **units of mol m<sup>-2</sup>.**

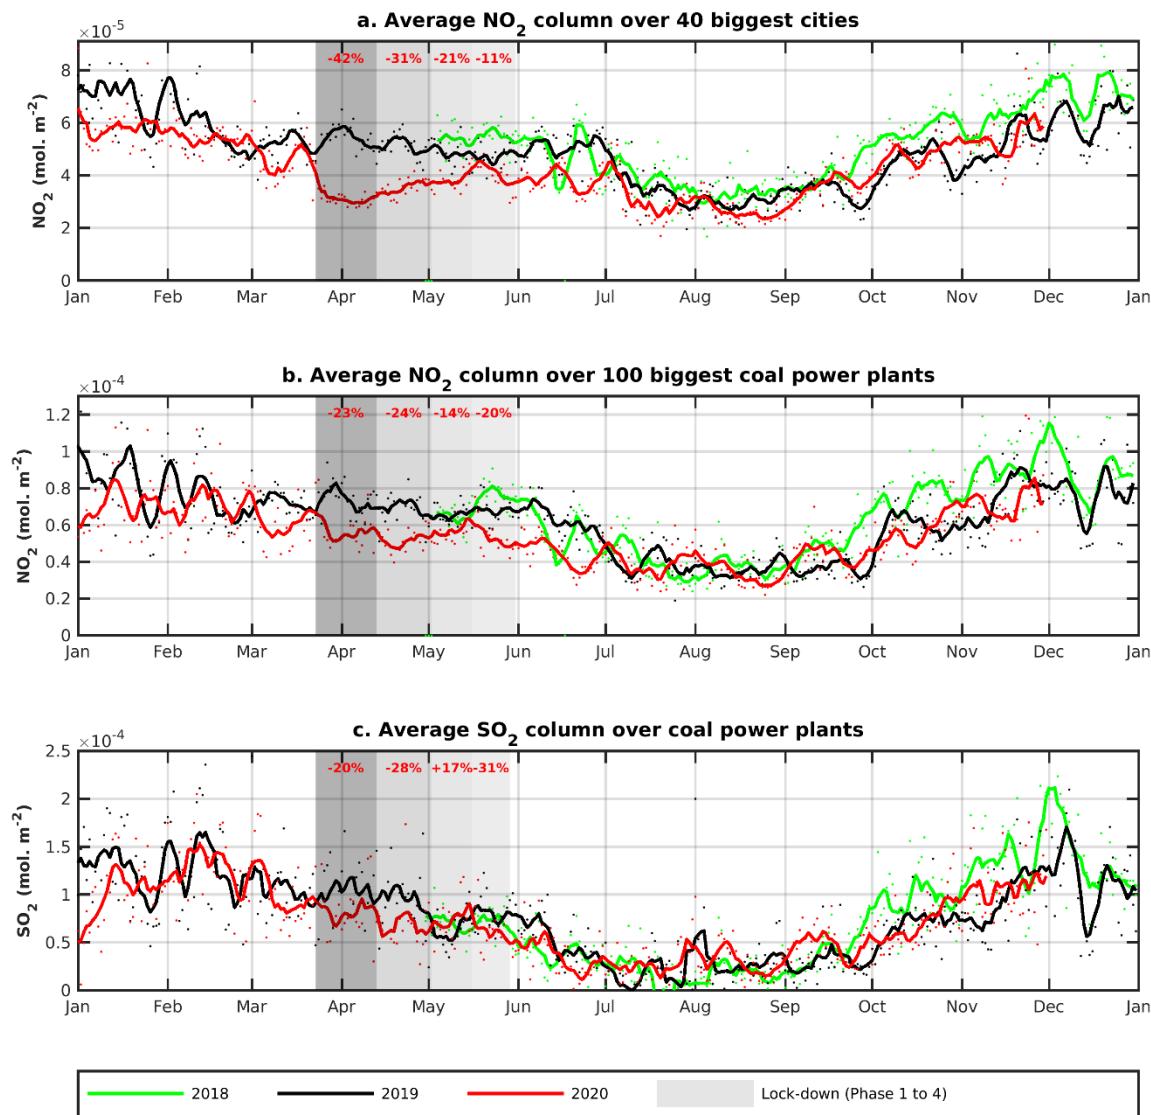

693 The two main sources of NO<sub>2</sub> are road transport and power generation, each accounting for about 30% of total  
 694 anthropogenic emissions in India (Granier et al., 2019). During phase 1 of the lockdown the Tom-Tom traffic index  
 695 dropped by 80% (Aloi et al., 2020; Prabhjote, 2020) and energy consumption dropped by 25% compared to 2019  
 696 (Dattakiran, 2020; POSOCO, 2021) (Fig. D1). As such, we expect a strong reduction in NO<sub>2</sub> particularly in urban

697 areas due to large decreases in transport sector activities and we expect a weaker reduction near power plants due to  
698 smaller decreases in energy demand.

699 Indeed, as indicated by the maps of NO<sub>2</sub> column ~~eonecentrations amounts~~ in Figure 7, a notable reduction in NO<sub>2</sub> can  
700 be seen in April 2020 as compared to April 2019. A clear reduction is observed over major cities as well as over the  
701 eastern part of India where most large power plants are located. Figure 8a shows the average NO<sub>2</sub> total column  
702 ~~eonecentrations amounts~~ as measured by TROPOMI for 2018, 2019 and 2020, for the 40 largest cities in India selected  
703 on the basis of the number of inhabitants ([www.geonames.org](http://www.geonames.org)) where NO<sub>2</sub> is averaged over a 15 x 15 km<sup>2</sup> area around  
704 each city center. When both city centers and power plants are located within a 45 x 45 km<sup>2</sup> box, this box is excluded  
705 from the averages to avoid potential outflow of one source to the other. A sharp reduction of 42% can be seen in the  
706 amount of NO<sub>2</sub> over cities during the first phase of the lockdown period starting at the end of March, as compared to  
707 the same period in 2019. This initial drop in NO<sub>2</sub> is then followed by a slow but gradual increase in line with the  
708 successive relaxation phases (Table 2). Power generation is a major source for NO<sub>2</sub> in India, in particular from coal-  
709 fired power plants. When examining the average amount of NO<sub>2</sub> over the 100 largest coal-fired power plants  
710 ([www.wri.org](http://www.wri.org)), we observe a significant drop in NO<sub>2</sub> during phase 1 of the lockdown period. This drop, observed  
711 over coal-fired power plants of 23% as compared to 2019 (Figure 8b), is less pronounced than the observed drop in  
712 NO<sub>2</sub> over cities (Figure 8a). The TROPOMI-observed reduction in NO<sub>2</sub> over coal-power plants is in line with the  
713 initial 25% decrease in maximum electricity demand reported by National Load Dispatch Centre (NLDC) during phase  
714 1 and tapering to an 8% decrease during phase 4 of the lockdown as compared to 2019 (Fig. D1, Dattakiran, 2020).

715

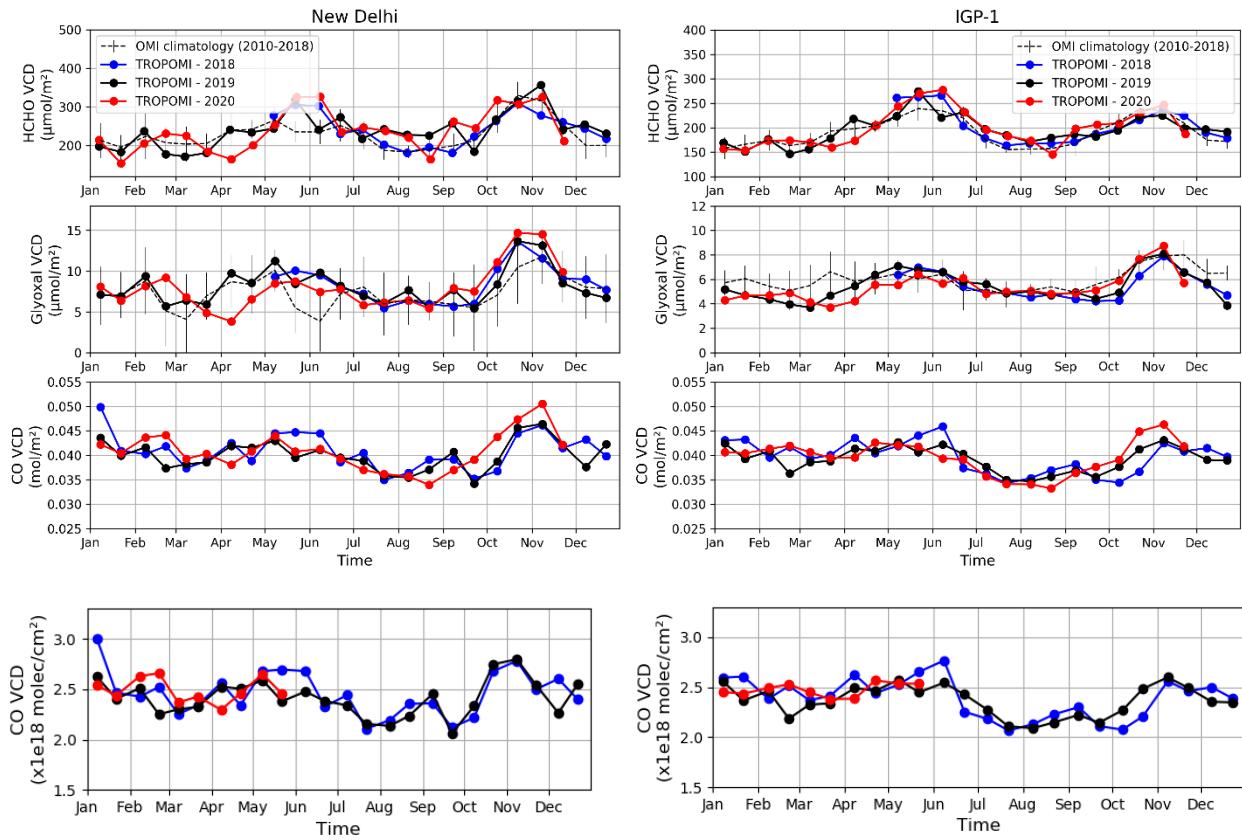

717  
718 **Figure 8: Average tropospheric NO<sub>2</sub> concentrations-column amounts for May 2018 (green), 2019 (black) up until June**  
719 **December 2020 (red) over the 40 largest Indian cities (top); over the 100 largest power plants in India (middle); and**  
720 **average SO<sub>2</sub> concentrations over the 59 largest SO<sub>2</sub>-emitting power plants in India (bottom). The four different phases of**  
721 **the lockdown period are denoted by the different grey shading. For each phase, the reductions in NO<sub>2</sub> (or SO<sub>2</sub>)**  
722 **concentrations are given relative to the same period in 2019. The dots are the daily means, and the solid lines represent**  
723 **the 7-day running means.**

724  
725 According to the CAMS-GLOB-ANT emission inventory for 2019 the major sources for SO<sub>2</sub> in India are power  
726 generation (65%) and industry (25%) (Granier et al., 2019). Since India largely relies on coal for producing energy, it  
727 is the world's top emitter of anthropogenic SO<sub>2</sub> (Li et al., 2017). So, most of the SO<sub>2</sub> signal we see in TROPOMI data  
728 for this region (Figure 7) is from coal-fired power plants, where contributions from oil and gas plants in India comprise  
729 a much smaller part of the signal (Fioletov et al., 2016). From Figure 7, a reduction in SO<sub>2</sub> is visible over most areas,  
730 and is especially noticeable for the easternmost part of India, which is India's largest SO<sub>2</sub>-emitting region with more  
731 than 20 coal-fired power plants.

732 We have investigated the SO<sub>2</sub> VCD amounts over the largest power plants, and adapted the selection method used  
733 for NO<sub>2</sub> by considering a larger area of 50 x 50 km<sup>2</sup> around each power plant. This is justified by (1) the longer lifetime  
734 of SO<sub>2</sub> compared to NO<sub>2</sub>, (2) the lower contamination by other sources, and (3) the need to reduce the noise on the  
735 SO<sub>2</sub> data to more clearly isolate the signal from the power plant. The results of the averaged SO<sub>2</sub> VCD time series are  
736 presented in Figure 8c. It should be noted that, compared to NO<sub>2</sub>, an additional selection of the power plants was  
737 applied. Based on the SO<sub>2</sub> VCD map for April 2019 (Figure 7), only the power plants with mean SO<sub>2</sub> columns larger  
738 than 0.15 DU were considered (59 power plants in total). Although the signal is relatively weak for SO<sub>2</sub>, we find very  
739 similar reductions in SO<sub>2</sub> as compared to NO<sub>2</sub>. Especially during the first two phases of the lockdown, a reduction of  
740 about 20% is found which is in line with the NO<sub>2</sub> observations and the reported reduction in energy demand. In May,  
741 for the different years, the consistency between NO<sub>2</sub> and SO<sub>2</sub> VCDs is less straightforward and the reason for this is  
742 not fully understood. It should however be noted that the NO<sub>2</sub> and SO<sub>2</sub> data products do not use the same cloud  
743 products for filtering and this might be a reason for discrepancy. Moreover, the possibility of a systematic  
744 contamination of the NO<sub>2</sub> signal over power plants by other sources cannot be ruled out completely. A noticeable  
745 feature of Figure 8b and Figure 8c is the overall excellent correspondence between NO<sub>2</sub> and SO<sub>2</sub> VCD evolution (on  
746 short-term/seasonal basis, and outside the lockdown periods) as well as from year to year. This further strengthens the  
747 observed COVID-19 related drop in both trace gases, although it is clear that meteorology and chemistry likely play  
748 a large role in the observed VCD variability. Also, ground-based studies in New Delhi find a more important reduction  
749 in NO<sub>2</sub> compared to SO<sub>2</sub> (Mahato et al., 2020; Kumari and Toshniwal, 2020).

750 For HCHO, CHOCHO, and CO, various regions over India have been investigated to detect a possible signal  
751 resulting from COVID-19 lockdown measures. We could only identify such a signal in the densely populated areas of  
752 the Indo-Gangetic Plain and New Delhi. These areas, due to the high intensity of traffic and industrial activities, are  
753 most likely to exhibit large impacts on atmospheric pollution levels due to COVID-19 lockdown measures.

754  
755 [Figure 9](#) shows two-week averaged column values for HCHO, CHOCHO, and CO over the IGP and New  
756 Delhi, based on TROPOMI data from January 2018 to June 2020. To support the interpretation of the observed  
757 seasonal and interannual variations, Fig. D2 presents the corresponding temperature, precipitation amount, and fire  
758 count. The temperature starts increasing in January and reaches a maximum in June. The period from July to  
759 September corresponds to the monsoon season with heavy rains and lower temperatures, and therefore lower pollution  
760 levels. Fire activity peaks around May with a second peak is observed in November for the IGP. The time series of  
761 the HCHO, CHOCHO, and CO columns correlate with these seasonal events, although with a different amplitude. For  
762 example, HCHO shows the strongest correlation with temperature (see Sect. 2.5), while CHOCHO mainly follows  
763 fire emissions. The smaller amplitude in CO variations is caused by its longer lifetime.

768 **Figure 9:** Time evolution of HCHO, CHOCHO, and CO over the densely populated Indo-Gangetic plain (**right panel**,  
 769 defined by the region within this 4 coordinates: 29.5°N 72°E, 21.5°N 86°E, 24.5°N 88.5°E, 32.5°N 74.5°E), and over the  
 770 megacity New Delhi (**left panel**, radius of 25 km, or 50 km for CHOCHO) as observed with TROPOMI. The year 2020 is  
 771 represented in red (2018 in blue, 2019 in black). With the HCHO and CHOCHO time series, the OMI climatology is shown  
 772 for comparison (dashed black line, 2010-2018), the error bars represent the interannual variability of the two-week  
 773 averaged columns. The HCHO columns have been corrected in order to assume the same temperature every year (see Sect.  
 774 2).

776 A large part of the observed HCHO and CHOCHO columns for India are due to natural emissions which can vary  
 777 significantly due to changes in meteorology, in particular temperature and precipitation. Hence a possible reduction  
 778 of the anthropogenic VOC emissions due to the lockdown measures is expected to have a small contribution to the  
 779 variability of the measured columns. During the most stringent phase 1 lockdown, a reduction in HCHO column  
 780 concentrations-amount is observed for the IGP and is even more pronounced over New Delhi (  
 781 Figure 9) top panels; respectively  $-2$  and  $-4 \times 10^{15}$  molec  $\text{cm}^{-2}$  [-20% and -40%] compared to the OMI  
 782 climatology for 2010-2018). In both cases, the anomaly is larger than the interannual variations observed during this  
 783 period (about  $1.5 \times 10^{15}$  molec  $\text{cm}^{-2}$ ), where changes in temperature or precipitation do not seem to explain the observed

784 column decrease during phase 1. The observed column decline is even more pronounced over New Delhi than over  
785 the IGP, suggesting that the origin of the reduction is mostly anthropogenic.

786 The case for lockdown-driven reductions is further supported by the CHOCHO observations, which exhibit the  
787 clearest COVID-19 signal during phase 1 of the lockdown (

788 [Figure 9](#)[Figure 9](#)). The reduction of CHOCHO during the lockdown period over the IGP is slightly larger than the  
789 interannual variability of  $1 \times 10^{14}$  molec cm $^{-2}$  (or -25%) as determined from the OMI CHOCHO climatology. Similar  
790 to HCHO, the reduction in CHOCHO over New Delhi is twice as large (-50%) and well beyond the 1-sigma OMI  
791 climatology range. Phase 2 is also characterized by lower CHOCHO column amounts in 2020 as compared to 2019,  
792 but temperatures are also lower, unlike phase 1. Accounting for temperature-driven variability (Sect. 2.5) brings the  
793 HCHO columns close to the mean HCHO seasonal levels. The somewhat more pronounced effect of the lockdown on  
794 CHOCHO compared to HCHO in New Delhi is most likely due to the strong contribution of anthropogenic VOC  
795 precursors to CHOCHO amounts (Chan Miller et al., 2016). Interestingly, fire counts show that there were fewer fires  
796 in May 2020 compared to previous years (Fig. D2), most likely as a consequence of the lockdown measures, which  
797 may also contribute to the lower glyoxal columns.

798 As it was the case for China, it is more difficult to identify a signal in CO column data driven by the COVID-19  
799 lockdowns over India. An important reason for this is the much longer atmospheric residence time of CO that varies  
800 depending on the OH concentration (Holloway et al., 2000). Moreover, according to bottom-up inventories, the major  
801 anthropogenic CO source in India are due to the residential sector (42%), road transportation (21%), agricultural waste  
802 burning (18%) and the industrial sector (16%) (Granier et al., 2019). Hence, during a lockdown we expect that the  
803 main source of CO, residential, to be less affected. [Figure 7 shows that the CO amounts in southern India are higher](#)  
804 [in 2020 as compared to 2019. The enhanced CO values in 2019 and 2020 are detected above regions \(e.g. Madhya](#)  
805 [Pradesh, Odisha, and Chhattisgarh\) where seasonal forest fires commonly occur in April/May \(Chandra and Kumar](#)  
806 [Bhardwaj, 2015, Srikanta et al. 2020\). Thus, the enhancement of CO for the different years depends not only on the](#)  
807 [fire activity but also on how the meteorological situation prevents or permits the accumulation of CO in the](#)  
808 [atmosphere. To more fully address the reasons why CO is higher in 2020 than 2019, future studies could carry out](#)  
809 [calculations using a chemical transport model](#)[Figure 7 shows that the CO amounts in southern India are higher in 2020](#)  
810 [compared to 2019. The reason could be the accumulation of CO originating from elsewhere prior to the lockdown](#)  
811 [period.](#) The long atmospheric residence time of CO complicates the identification of COVID-19 lockdown signals.  
812 Also for CO we derived the full TROPOMI time series for the IGP and New Delhi as shown in  
813 [Figure 9](#)[Figure 9](#) (lower panel). The time series for New Delhi in mid-April shows somewhat lower CO values in 2020  
814 compared to 2019, but the large natural variability of CO prevents clear identification of a COVID-19 lockdown driven  
815 effect. In future, analysis of a longer TROPOMI CO time series or model experiments may help to quantify the  
816 COVID-19 effects.

817

818 **6 Conclusions**

819 In this paper, we have analyzed the impact of COVID-19 lockdown measures on air quality around the globe, based  
820 on observations of several trace gases from the Sentinel-5P/TROPOMI instrument. TROPOMI provides daily, global  
821 observations of multiple trace gases, where the measured vertical column amounts are driven by emissions as well as  
822 atmospheric and chemical processes of transport, transformation, and deposition. We compared the 2020 TROPOMI  
823 data with similar periods from previous years and carried out additional analysis to disentangle changes in emissions  
824 due to COVID-19 lockdown measures from meteorological variability, seasonal variability, and from other non-  
825 lockdown emission drivers. We analyzed time series of NO<sub>2</sub> measurements from city to regional scales for several  
826 locations around the globe, showing the potential of TROPOMI to globally monitor local to regional impacts of  
827 COVID-19 lockdown measures on air quality and anthropogenic emissions. Furthermore, for the first time, we used  
828 a combination of five trace gases observed by TROPOMI, specifically NO<sub>2</sub>, SO<sub>2</sub>, CO, HCHO and CHOCHO, to assess  
829 the impact of COVID-19 related lockdown measures on trace gas concentrations.

830 From the global to city scale, we have illustrated consistent, sharp decreases in NO<sub>2</sub> ~~concentrations column amount~~  
831 driven by the COVID-19-related lockdown measures. These findings are based on detailed analysis of the distribution  
832 of NO<sub>2</sub> using daily measurements from TROPOMI. For the city of Wuhan in China, the first city to issue a lockdown,  
833 NO<sub>2</sub> concentrations measured by TROPOMI were about 60% lower than the same period in February-March 2019.  
834 After China, lockdowns were issued across all continents and for the majority of countries from March through May  
835 2020. For megacities all over the world, reductions in column amounts of tropospheric NO<sub>2</sub> range between 14% and  
836 63%. The strength of the reduction depends on the type and efficiency of local measures carried out and on the relative  
837 contribution of traffic, industry, and power generation to NO<sub>2</sub> emissions for a given area. Owing to the unprecedented  
838 resolution of TROPOMI of about 5 km, reductions of different source contributions to NO<sub>2</sub> such as city traffic,  
839 highways (Liu et al., 2020), power plants (Miyazaki et al., 2020), industry, and shipping (Ding et al., 2020) can be  
840 estimated separately.

841 As demonstrated by time series analysis of the NO<sub>2</sub> observations, there is substantial variability even in two-week  
842 averages, which is attributable to meteorological variability. On average, we estimate the standard deviation of this  
843 variability to be about 13% (1-sigma standard deviation) for major cities in Europe, but locally the effect can  
844 sometimes be larger. The large and systematic reductions (30-60%) observed, however, cannot be explained by  
845 meteorological variability alone and are therefore attributed to the effect of the lockdown measures.

846 For SO<sub>2</sub>, we observe significant column reductions in China and India over coal-fired power plants, which are the  
847 primary sources of anthropogenic SO<sub>2</sub> in these areas. Over northeastern China in late February 2020, large reductions  
848 of SO<sub>2</sub> vertical column amounts were observed, as a result of lockdown measures, with a decrease up to 77% as  
849 compared to the same time period in 2019, which cannot be explained by interannual variability alone. An analysis of  
850 SO<sub>2</sub> vertical column amounts over the largest SO<sub>2</sub>-emitting power plants in India, reveals a reduction in SO<sub>2</sub> of about  
851 25% during the first two phases of the lockdown, as compared to 2019. For India, the reductions in SO<sub>2</sub> were highly  
852 correlated with NO<sub>2</sub> reductions for the same power plants and with the national energy demand for that period.

853 The natural variability of HCHO and CHOCHO does not allow detection of a significant decrease due to the COVID-  
854 19 measures in most regions of the world based on TROPOMI observations alone. Exceptions are northern China and  
855 New Delhi, where observed reductions could be attributed to the lockdown measures. For northeastern China, a 50%  
856 reduction in the CHOCHO concentration column amount is observed during the second half February, which is larger  
857 than the typical observed interannual variability of 30%. For HCHO, after correcting for the effect of seasonal and  
858 temperature variations, we observe a coincident 40% reduction. We analyzed column amounts of CO, CHOCHO, and  
859 HCHO over the Indo-Gangetic Plain, which is the most densely populated region of India. For CHOCHO and HCHO,  
860 we observed small reductions in column amount due the COVID-19 measures, where these observed effects are  
861 slightly larger than the interannual variability as determined using an OMI climatology (2010-2018). The observed  
862 reduction of 25% of CHOCHO in this region is of the same order as the typical interannual variability. A stronger  
863 reduction of 60% is observed for the city of New Delhi, which is similar to the reduction observed over northern China  
864 but occurs later due to the difference in lockdown timing. For HCHO, we also observe a significant 40% decrease  
865 over New Delhi in April, while over the whole Indo-Gangetic Plain, a decrease of 20% is observed.

866 For CO, reductions related to COVID-19 measures were much more difficult to identify, although over northern  
867 China we see that the reductions in CO correlate with those for HCHO and CHOCHO. We could not find a similar  
868 effect for CO over New Delhi. The fact that it is so hard to draw conclusions for CO based on the TROPOMI data  
869 alone is due to the high variability in CO driven by meteorological conditions, in combination with the difficulty of  
870 distinguishing localized emission changes from the high and variable background values, caused by the long  
871 atmospheric lifetime of CO.

872 TROPOMI data have already been used in many publications (Gkatzelis et al., 2021; Bauwens et al., 2020; Liu et  
873 al., 2020; Huang et al., 2020) aiming to analyze the impact of COVID-19 lockdown measures on air pollution levels.  
874 Predominantly, these studies have been based on the use of TROPOMI NO<sub>2</sub> observations alone. We anticipate that  
875 the combined use of multiple trace gases from TROPOMI together with the high spatial resolution of the  
876 measurements, has large potential for a significantly improved sector-specific analysis of the impact of the COVID-  
877 19 lockdown measures than previously possible. Such a multi-species analysis offers promise for in-depth  
878 understanding of changes in air quality, the chemical interplay of pollutants in the atmosphere and their relation to  
879 emissions. While keeping in mind the importance of accounting for interannual, seasonal, and meteorologically driven  
880 variability (e.g. Miyazaki et al., 2020), it is clear that a detailed analysis cannot be based on TROPOMI observations  
881 alone. For more quantitative estimates of the impact of COVID-19 lockdown measures on trace gas concentrations  
882 and emissions, we need (inverse) models driven by high-quality meteorological analyses, or at least wind information  
883 or statistical relationships to account for weather-driven variability (Goldberg et al., 2020; Miyazaki et al., 2020; Ding  
884 et al., 2020).

885 In summary, our analyses using the most recent operational and scientific retrieval techniques have shown that by  
886 taking emission sources, atmospheric lifetime as well the seasonal and meteorological variability into account for a  
887 variety of trace gases measured by TROPOMI, rapid changes in anthropogenic emissions can be observed as induced  
888 by the implementation of regional COVID-19 lockdown measures. It is our hope that this case study will serve as

889 reference for future analyses aimed at characterizing emission changes of not just NO<sub>2</sub>, but by utilizing the  
890 concomitant observation of the variety of trace gases measured by TROPOMI.

896 **Appendix B**897 Appendix B contains additional information [\(Table B2\) and description](#) supporting the timing of COVID-19 driven  
898 emissions changes for global cities evaluated in this study and shown in [Figure 2, Fig. 2.](#)

899

900 **Table B2. Details about the lockdown dates for the cities illustrated in [Figure 2, Figure 2.](#)**

City	Date (2020)	Comment	Reference
<b>Wuhan</b>	23 January	Lockdown Wuhan and Hubei province	Bloomberg (2020)
	8 April	Lockdown lifted	Bloomberg (2020)
<b>Mumbai and New Delhi</b>	24 March	Closure of schools, public transport and most businesses	BBC (2020a)
	31 May	Nationwide lockdown is extended until end of May	Aljazeera (2020a)
<b>Manila</b>	16 March	Philippines announced strict home quarantine	Calonzo and Jiao (2020)
	1 June	Most businesses allowed to re-open, but bars, restaurants and schools remain closed	Jennings (2020)
<b>Madrid</b>	14 March	Nationwide lockdown	Minder and Peltier (2020)
	9 May	Easing, stores and restaurants allowed to open	Goodman et al. (2020)
<b>Milan</b>	8 March	Locking down of Northern Italy including Milan	Horowitz (2020a)
	4 May	Loosening of strictest lockdown measures	Horowitz (2020b)
<b>Paris</b>	17 March	France imposes nationwide the restriction	Onishi and Méheut (2020)
	11 May	Gradually relaxed lockdown measures, most shops open	Makooi (2020)
<b>Los Angeles</b>	19 March	California enters lockdown	BBC (2020b)
	1 June	Reopening of some shops and restaurants	Patel (2020)

<b>New York</b>	22 March	New York state enters lockdown	BBC (2020b)
	13 June	Stay-at-home orders put in place until further notice	CBS News (2020)
<b>Sydney</b>	24 March	Strict lockdown measures adopted in Australia	Wahlquist (2020)
	15 May	New South Wales eases lockdown restrictions	Sonali (2020)
<b>Auckland</b>	23 March	In New Zealand stay-at-home orders are issued	Menon (2020)
	14 May	All businesses can open in New Zealand	Conforti (2020)
<b>Mexico City</b>	23 March	Most economic sectors stopped in Mexico	Pasley (2020)
	1 June	Gradual reopening of Mexico city	Associated Press (2020)
<b>Lima</b>	16 March	Stringent quarantine enforced by police and army	Collyns (2020)
	30 June	Peru extended nationwide lockdown through end of June	Aljazeera (2020b)
<b>Sao Paulo</b>	24 March	Start of lockdown, but measures were largely ignored	Uchoa (2020)
	31 May	Quarantine extended through May	CGTN (2020)
<b>Buenos Aires</b>	20 March	Argentina under mandatory lockdown	Do Rosario and Gillespie (2020)
	28 June	Lockdown extended	Misculin and Garrison (2020)
<b>Baghdad</b>	22 March	Iraq imposed a total nationwide lockdown	The Star (2020)
	21 April	Relaxed restrictions: shops reopen for limited hours	Saleh (2020)
	20 May	In Baghdad strict lockdown re-imposed for 6 districts	Saleh (2020)
<b>Lagos</b>	30 March	Stay-at-home order, markets open for limited hours	Orjinmo (2020)
	4 May	Easing of restrictions, but schools, bars, and cinemas remain closed	Mbah (2020)
<b>Johannesburg</b>	26 March	Stay-at-home orders issued in South Africa	Winter (2020)
	1 June	Most economic sectors permitted to operate	Aljazeera (2020c)

901

**Detailed observations of NO<sub>2</sub> reductions in major cities worldwide**

902

Three examples of lockdown-related NO<sub>2</sub> column reductions in major cities are shown for Santiago, Paris and New

903

Delhi in Figure 1 with time windows selected to reflect region-specific lockdown periods. A strong reduction in the

905 NO<sub>2</sub> tropospheric concentration of about 40% is observed over Santiago. In Paris, the NO<sub>2</sub> levels for the period 15  
906 March to 15 April 2020 are about a factor of two lower than in March-April 2019 (see also Figure 4). For New Delhi  
907 the reduction is even more striking in comparison to April 2019 (about a factor of 3, Figure 2c). Both Paris and New  
908 Delhi also show significant reductions in background values around the cities. Background locations are subject to a  
909 variety of wind directions and sometimes downwind of city plumes thus influencing background concentrations. Such  
910 plumes are typically on the order of 100 km long, and, given the atmospheric residence time of NO<sub>2</sub> (2-12 hours),  
911 these plumes can fill the small domains around Paris and New Delhi shown in Figure 1.

912 In Wuhan, the first city to issue quarantines and lockdown measures, the observed NO<sub>2</sub> column drastically declined  
913 (-60%) between 23 January and 8 April 2020 compared to the same period in 2019 (Figure 2a, Table B2). This decrease  
914 is in good agreement with estimated reductions for the period 11 February to 2 March 2020 based on TROPOMI NO<sub>2</sub>  
915 (-43%, Bauwens et al., 2020) and in situ NO<sub>2</sub> observations in Wuhan (-55%, Shi and Brasseur, 2020). However, it  
916 should be noted that there was strong day-to-day variability in the NO<sub>2</sub> column amount due to meteorological factors,  
917 as well as missing data over Wuhan in February 2019 due to clouds. Model calculations by Liu et al. (2020) indicate  
918 that meteorological variability could have led to increased NO<sub>2</sub> columns in 2020 compared to 2019, suggesting that  
919 the observed NO<sub>2</sub> reductions underestimate the impact of emission reductions due to COVID-19. The partial lifting  
920 of the restrictions on 8 April led to a progressive increase in NO<sub>2</sub> levels, yet remained lower than in 2019, likely  
921 because the population was still advised to stay at home and schools remained closed. A similar response in NO<sub>2</sub>  
922 levels was observed in Beijing. The decreases were less pronounced (-40%) and are in excellent agreement with the  
923 reported decrease based on in situ NO<sub>2</sub> measurements (-40%, Shi and Brasseur, 2020). The weaker response could be  
924 due to the less drastic measures adopted in Beijing, because locally sustained COVID-19 cases were lower than in the  
925 Hubei province (Leung et al., 2020). Strong NO<sub>2</sub> reductions were observed for other Chinese cities, like Nanjing,  
926 Qingdao, and Zhengzhou, based on TROPOMI NO<sub>2</sub> observations (Bauwens et al., 2020).

927 India enforced strict restrictions of human activities on 24 March 2020 to tackle the spread of COVID-19. In New  
928 Delhi and Mumbai, the onset of the lockdown induced a sharp decline in the observed NO<sub>2</sub> columns (by a factor of  
929 2). The columns remained low during the entire lockdown period (-56% and -46%, respectively) (see Table 2 for  
930 timing of Indian lockdown phases). This is very much in line with the decreases reported in New Delhi based on NO<sub>2</sub>  
931 data from monitoring stations, -53% (Mahato et al., 2020) and -48% (Jain and Sharma, 2020).

932 As compared to other cities, a very strong NO<sub>2</sub> decrease was observed in Lima (-63%), where strict regulations to  
933 stay indoors were enforced (Collyns, 2020). A drastic drop in NO<sub>2</sub> compared to the 2019 levels marked the start of  
934 the lockdown, and the levels remained very low throughout the entire lockdown period. The gradual increase of NO<sub>2</sub>  
935 columns in Lima and other Southern Hemispheric cities from January to May (Figure 2j) reflects the natural seasonal  
936 variation when levels peak during the Southern Hemispheric winter, as temperatures decrease and NO<sub>2</sub> lifetime  
937 increases.

938 In Buenos Aires, the observed reduction was not as strong compared to Lima for the entire lockdown period (-34%,  
939 Table B2), but was particularly marked during the first month of the lockdown (20 March through 20 April 2020),  
940 due to a compulsory quarantine period and strict limitation of activities for many sectors. Although partial lifting of  
941 measures was issued after 10 April for many provinces in Argentina, the measures in the Buenos Aires agglomeration

942 were maintained due to the elevated number of cases (Raszewski and Garrison, 2020). More moderate reductions are  
943 found for Mexico City (-22%) and Santiago (-23%) during the lockdown in comparison to the same period in 2019,  
944 that could be attributed to less strict adherence to and enforcement of lockdown measures (Uchoa, 2020; Pasley, 2020).

945 Strong reductions were observed over the entire lockdown period in the heavily hit cities in southwest Europe, Los  
946 Angeles, and New York, with reductions ranging between -32% and -54% (Bauwens et al., 2020). It should be noted  
947 however, that in these regions, the start of the lockdown period is generally less marked partly because the lockdowns  
948 were not as strictly enforced in Europe and the U.S. as in China and India. Moreover, the observed TROPOMI data  
949 displays a strong variability attributable to meteorology, e.g. over Paris, New York and Los Angeles in 2019.

950 In Sydney, the reduction was moderate (-14%) and delayed with respect to the onset of the measures (Figure 2g).  
951 This could be related to observations of less strict compliance in the early period of lockdown measures (New South  
952 Wales Public Health, 2020). A rapid and strong decrease was observed for NO<sub>2</sub> column amount as a result of lockdown  
953 measures in Auckland, New Zealand (-55%). Similarly, the lockdown measures in New Zealand were implemented  
954 swiftly with high levels of compliance (Matthews, 2020). The end of the lockdown coincided with a strong increase  
955 in NO<sub>2</sub> pollution, from  $1.8 \times 10^{15}$  molec cm<sup>-2</sup> to  $3 \times 10^{15}$  molec cm<sup>-2</sup> in the last three weeks of May.

956 In Africa, Nigeria is among the countries most affected by COVID-19 and reported the first confirmed case in sub-  
957 Saharan Africa (Odunsi, 2020; Adigun and Anna, 2020). A two-week lockdown period was put in place for Lagos  
958 starting 30 March. The NO<sub>2</sub> column amount decreased by 33% during the lockdown with respect to the same period  
959 of 2019 and remained lower even after the lifting of restrictions on 4 May (Table B2). An NO<sub>2</sub> column decrease of  
960 similar magnitude (-35%) was observed in Johannesburg (Figure 2p), where a national lockdown was issued on 26  
961 March 2020, with a gradual easing of restrictions starting 1 May. In Sub-Saharan Africa, the emission reductions in  
962 April were significant for larger populous and industrialized areas, whereas no noticeable drop was found in less  
963 developed regions (Masaki et al., 2020).

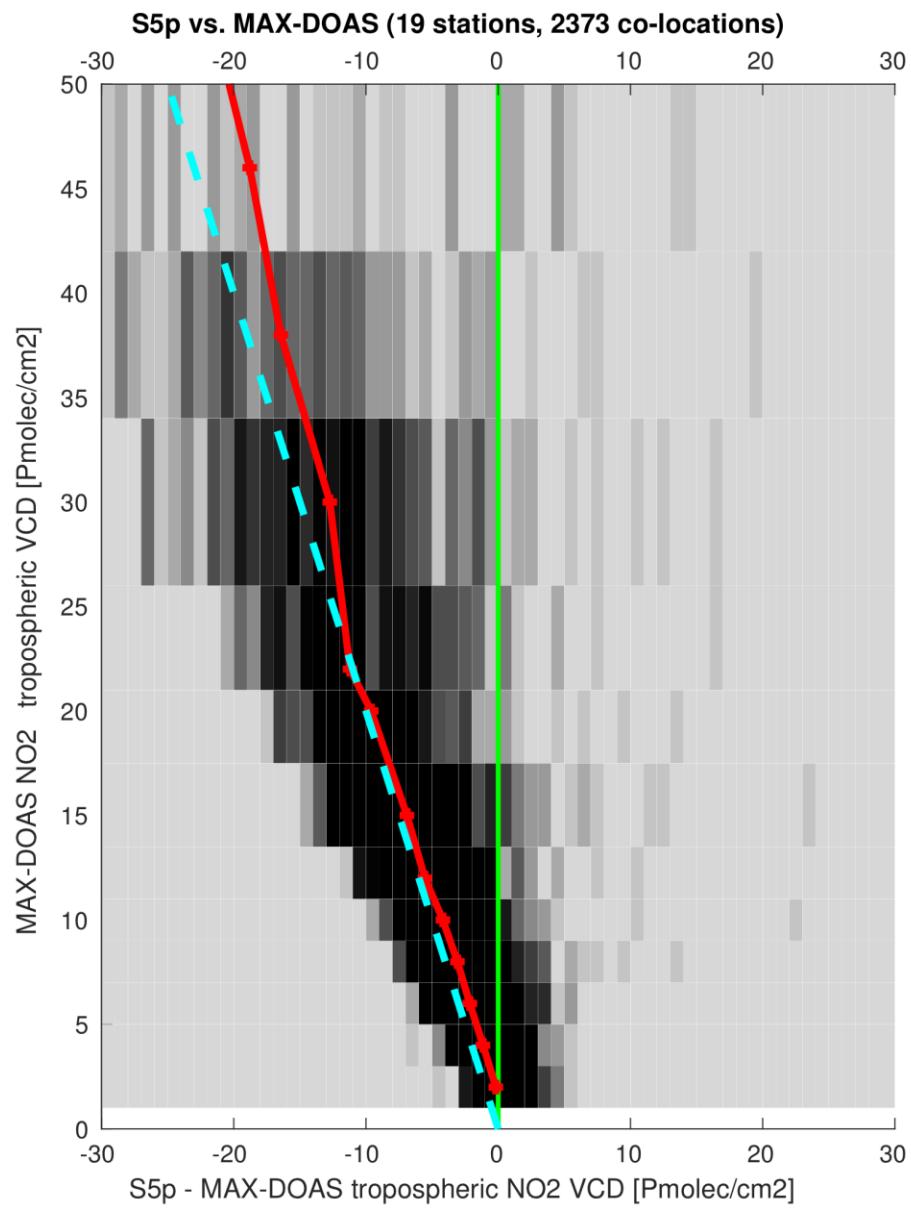

964 Finally, the Iraqi capital of Baghdad faced an initial lockdown from 22 March through 21 April. A second partial  
965 lockdown was issued starting 20 May in response to a sharp increase in COVID-19 cases due to the temporary  
966 relaxation of restrictions to allow the celebration of Ramadan in late April (Table B2). The NO<sub>2</sub> column responded  
967 quickly (Figure 2n) as confirmed by the rapid decrease once curfew measures were issued in late-May.

968 Figure 3 and Figure 4 illustrate the tropospheric column amount of NO<sub>2</sub> over Europe, focusing on Milan, Madrid,  
969 Paris and Berlin, extending the analysis up to 1 December. In France, Spain and Italy we detect strong reductions of  
970 NO<sub>2</sub>, which can be largely attributed to the lockdown measures. In Berlin, the measured differences are smaller, and  
971 a more detailed analysis of the meteorological variability is needed to quantify the impact of the lockdown (see Figure  
972 3). The extended time series shows a recovery of the NO<sub>2</sub> pollution levels to pre-COVID-19 values. However, the  
973 recovery is not complete, suggesting that remaining restrictions, new stay-at-home life and working practices, together  
974 with a downturn in industrial and service-based activities have contributed to a longer lasting impact.

975 **Appendix C**

976 Appendix C contains figures which support the technical understanding of individual retrieval algorithms.

977

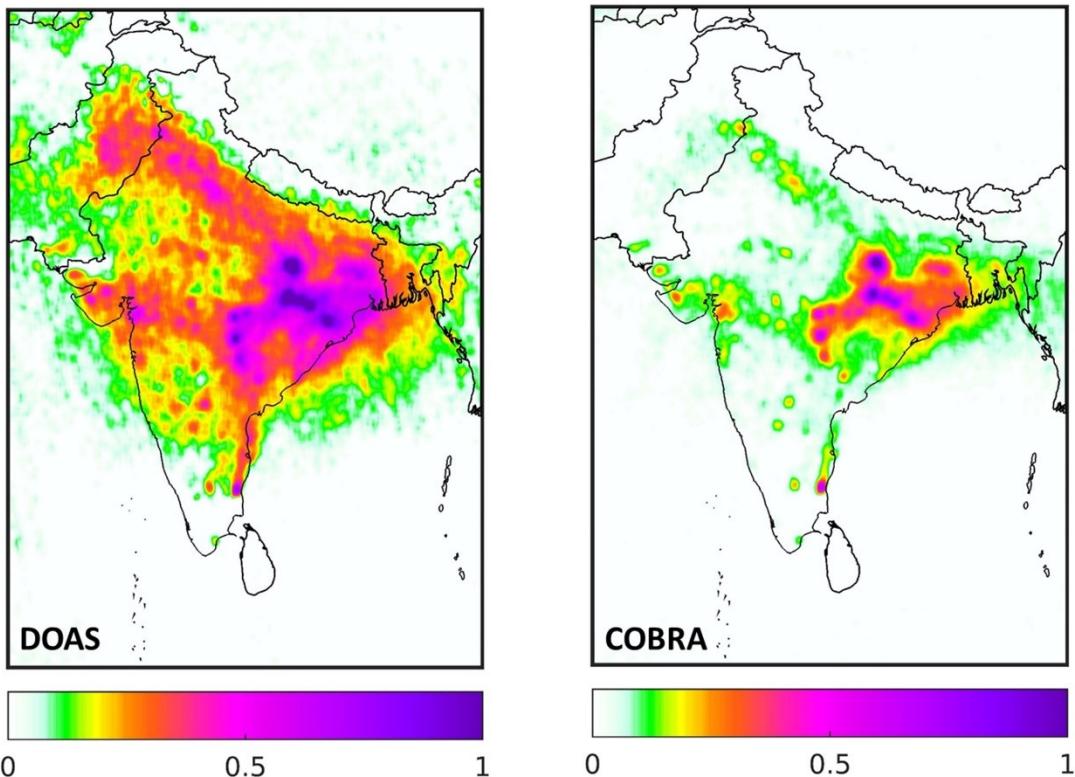

978

979      **Figure C1:** Bias in S5p-TROPOMI tropospheric NO<sub>2</sub> as estimated from comparisons to co-located ground-based MAX-  
980      DOAS measurements, presented as a function of the ground-based VCD measurement. The grey-scale background  
981      represents a 2-D histogram, where the median difference per MAX-DOAS VCD bin is shown as the red curve, and the blue  
982      dashed line shows a multiplicative bias (b) model with  $b \sim 0.5 \times \text{VCD}$ . More details on the ground-based data and co-  
983      location scheme can be found in Verhoelst et al., 2021.

984

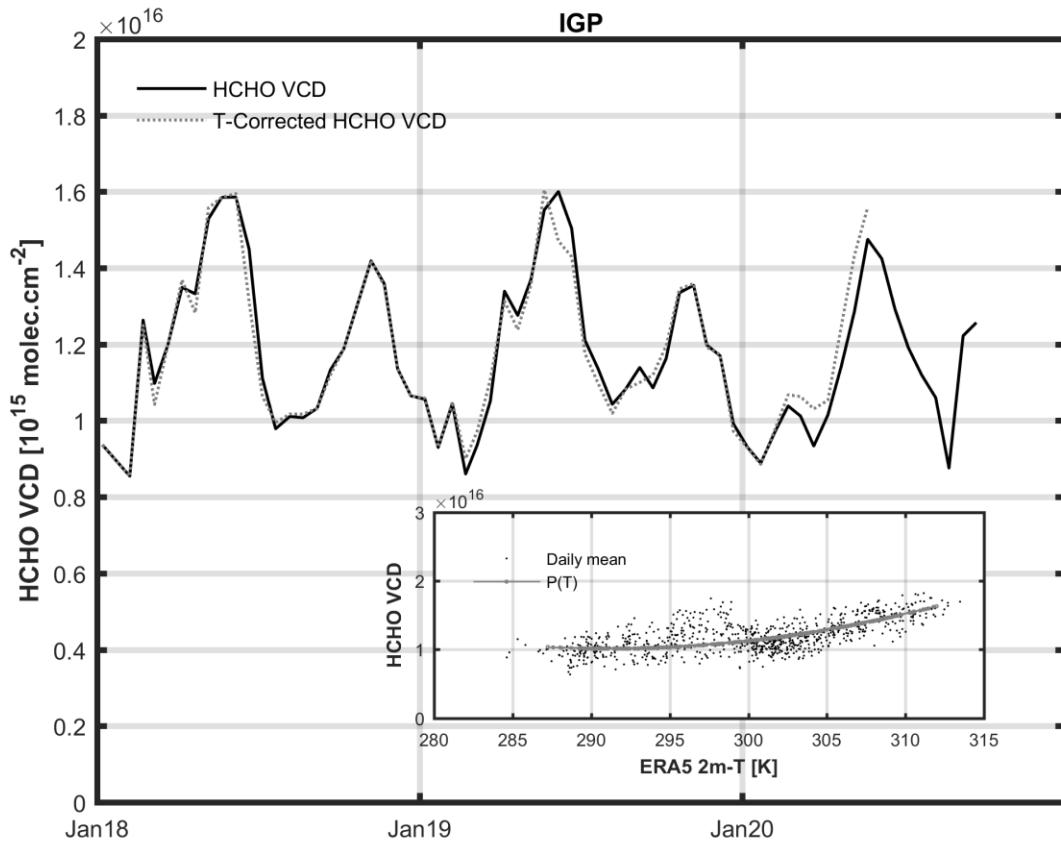

985

## SO<sub>2</sub> vertical column (DU) - April 2019

986  
987 Figure C2: Monthly averaged TROPOMI SO<sub>2</sub> columns over India for April 2019, from (left) DOAS operational product  
988 and (right) COBRA scientific product. The reduction in noise and offsets reductions described and illustrated in Theys et  
989 al. (2021) can also be seen here where there is more contrast between the maps is clear from the maps the background and the. The  
990 emissions from individual point sources (power plants, darker pink and purple) can be better discerned in the COBRA SO  
991 2 map.

992  
993

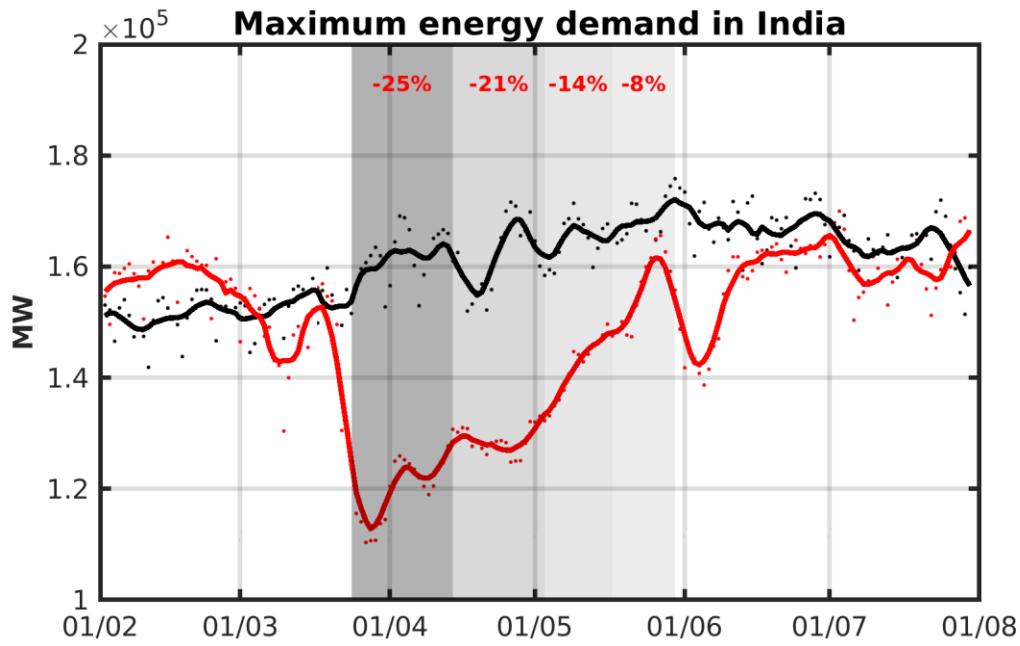

994

995 **Figure C3:** Example of temperature correction of the TROPOMI HCHO tropospheric columns in the Indogangetic Plain  
 996 region. The dashed line presents the HCHO columns after correction using climatological temperatures. The correlation  
 997 between the local daily temperatures from ERA5-Land 2m and the HCHO columns is shown inset for the entire period.

998 **Appendix D**

999 Appendix D contains additional figures that support the interpretation timing of observed changes in COVID-19  
 1000 driven emissions related to power generation (Fig. D1) and meteorological conditions (Fig. D2).

## 1024 **Data Availability**

1025 Operational versions of all Copernicus Sentinel 5-P Data TROPOMI data are freely available from the European  
1026 Union/ESA/Copernicus Sentinel-5P Pre-Operations Data Hub (<https://s5phub.copernicus.eu>; S5P Pre-Ops Data Hub,  
1027 2021). The TROPOMI COBRA SO<sub>2</sub> dataset is available on request as described in Theys et al., 2021. OMI HCHO  
1028 and NO<sub>2</sub> datasets are openly available on <http://www.qa4ecv.eu/ecvs>. TROPOMI Glyoxal data is available upon  
1029 request as a part of the ESA S5p+I GLYRETRO project as detailed on the project website:  
1030 <https://glyretro.aeronomic.be/>.

## 1031 **Author Contributions**

1032 PFL conceptualized, initiated, and managed this manuscript with contributions from IA, MB, TB, IDS, HE, CL, TS,  
1033 DSZ, NT, MVR, PV, and TV. Formal analysis was carried out by MB, TB, IDS, HE, CL, and NT. DL and FR provided  
1034 data curation and software support for TROPOMI HCHO data products. DSZ prepared, edited, and co-managed the  
1035 manuscript with contributions from IA, MB, TB, IDS, HE, CL, PFL, TS, NT, MVR, PV, and TV.

## 1036 **Competing Interests**

1037 The authors declare that they have no conflict of interest.

## 1038 **Acknowledgements**

1039 We acknowledge financial support from the following projects: ESA S5P MPC (4000117151/16/I-LG); Netherlands
