22 **Abstract**

23 NH_3 is the most important alkaline gas in the atmosphere and one of the key
24 species affecting the behaviors of atmospheric aerosols. However, the impact of NH_3
25 on secondary organic aerosol (SOA) formation remains poorly understood, especially
26 the dynamic evolution of chemical compositions in the SOA formation process. In this
27 study, a series of chamber experiments were performed to probe the individual and
28 common effects of NH_3 and NO_x on toluene SOA formation through OH-
29 photooxidation. The chemical compositions of toluene SOA were characterized using
30 the Aerodyne high-resolution time-of-flight aerosol mass spectrometer (AMS). The
31 SOA yield increased from 28.1% in the absence of NH_3 to 34.7% in the presence of
32 NH_3 but decreased to 19.5% in the presence of NO_x . However, the highest SOA yield
33 of 42.7% and the lowest carbon oxidation state (OSC) occurred in the presence of both
34 NH_3 and NO_x , indicating that the higher volatility products that formed in the presence
35 of NO_x could partition into the particle-phase when NH_3 was added. This resulted in a
36 synergetic effect on SOA formation when NH_3 and NO_x co-existed. The heterogeneous
37 reaction was the main pathway by which NH_3 participated in SOA formation in the
38 photooxidation process. The synergetic effect of NH_3 and NO_x was also observed in
39 SOA optical absorption. A peak at 280 nm, which is characteristic of organonitrogen
40 imidazole compounds, was observed in the presence of NH_3 and its intensity increased
41 when NO_x was added into the chamber. This work improves our understanding of how
42 the synergistic interactions between NH_3 and NO_x influence SOA formation and offers
43 new insights into mitigating haze pollution.

45 effects

46

47 **1 Introduction**

48 Secondary organic aerosols (SOA) are an important component of atmospheric
49 particulate matter (Moise et al., 2015;Liu et al., 2017), and can significantly affect
50 atmospheric visibility, air quality, and human health (Paciga et al., 2014;Yang et al.,
51 2016;Liu et al., 2017). Optical properties of SOA have been directly and indirectly
52 linked to their effects on the climate (Laskin et al., 2015;Xie et al., 2017;Peng et al.,
53 2020). Because of the complexity of their chemical components, oxidation processes,
54 and environmental factors, SOA formation mechanisms are very complex and the
55 current understanding of SOA formation is incomplete. This limited understanding
56 hampers the ability of models to predict the magnitudes, dynamics, and distributions of
57 atmospheric aerosols from particulate and precursor emissions (Ortiz-Montalvo et al.,
58 2014). In the past decades, although our understanding of SOA formation mechanisms
59 has been constantly improving, there is still a gap between the simulated SOA
60 concentration in large-scale atmospheric models and field observations (Volkamer et
61 al., 2006;Yang et al., 2018).

62 Ammonia (NH₃) is the most abundant and ubiquitous alkaline inorganic gas in the
63 atmosphere and one of the critical factors influencing SOA formation (Wang et al.,
64 2016;Wang et al., 2018b;Chen et al., 2019). Some studies have noted that the presence
65 of NH₃ can contribute to the formation of more aerosol mass through photooxidation
66 (Na et al., 2007;Li et al., 2018). Na et al. (2007) observed that aerosol yields in the α -
67 pinene-ozone oxidation system increased by 8% when NH₃ was added. Li et al. (2018)
68 reported that the presence of NH₃ in the aromatic hydrocarbon photooxidation system

69 increased aerosol size growth potentials (by 7%–108%), and resulted in enhanced SOA
70 formation. Qi et al. (2020) found that the concentration and average diameter of SOA
71 showed an immediate and rapid increase after adding NH₃. Furthermore, the acid-base
72 reactions between NH₃/NH₄⁺ and the carboxyl groups in SOA molecules might enhance
73 SOA formation (Qi et al., 2020;Liu et al., 2015). The condensable ammonium salts
74 formed from the reaction between NH₃ and organic acids reduce the volatility of the
75 organic acids by several orders of magnitude (Paciga et al., 2014), and act as particle-
76 phase organics that further promote SOA formation (Na et al., 2007;Huang et al.,
77 2012;Chen et al., 2019;Qi et al., 2020;Wu et al., 2020). In addition, carbonyls can
78 undergo nucleophilic attack by NH₃ through the Maillard reactions and form the
79 corresponding iminium intermediates (Noziere et al., 2009;Laskin et al., 2015;Liu et
80 al., 2015). The iminium intermediates can continue to react with carbonyls, which
81 activates further transformations such as the formation of heterocyclic compounds and
82 oligomerization reactions and forms condensation (oligomeric) products with more
83 stable secondary imines (Schiff bases) (Laskin et al., 2014). Both Noziere et al. (2009)
84 and Ortiz-Montalvo et al. (2014) reported NH₃ is an efficient catalyst for reactions with
85 carbonyl compounds to form nitrogen-containing organic aerosols (NOA). The reaction
86 between carbonyl and NH₃ can significantly decrease the volatility of oxidation
87 products, which further increases the yield of SOA (Lee et al., 2013;Zhang et al.,
88 2015a;Qi et al., 2020). Babar et al. (2017) found that the substantial formation of
89 secondary imines in the presence of NH₃ was responsible for the higher α -pinene SOA
90 yields. However, not all studies have shown that the presence of NH₃ increases SOA

91 yields. One study observed that NH_3 suppressed SOA formation under certain
92 ozonation conditions (Ma et al., 2018b). Furthermore, the consumption of NH_3 by
93 Criegee intermediates was reported to decrease the secondary ozonide yield and thus
94 affect SOA formation.

95 Nitrogen oxides ($\text{NO}_x = \text{NO} + \text{NO}_2$), which are mainly emitted from the
96 combustion of fossil-fuels, have received significant attention due to their effects on the
97 photooxidation process of volatile organic compounds (VOCs) and SOA formation
98 (Surratt et al., 2006;Ng et al., 2007b;Draper et al., 2015;Berkemeier et al.,
99 2016;Sarrafzadeh et al., 2016;Zhao et al., 2018). A clear increase at first and then a
100 decrease in the SOA yield was found with increasing NO_x concentration from the
101 laboratory experiments with both anthropogenic (trimethylbenzene) and biogenic (β -
102 pinene) VOCs (Sarrafzadeh et al., 2016;Yang et al., 2020). The competitive chemistry
103 of organic peroxy radicals (RO_2) with hydroperoxy radicals (HO_2) and NO was
104 responsible for the variability in SOA formation (Ng et al., 2007a;Xu et al., 2014;Jiang
105 et al., 2020). RO_2 mainly reacts with HO_2 under low- NO_x conditions to form oxidation
106 products with lower volatility, which may enable it to partition into the particle-phase
107 and contribute to the SOA mass (Ng et al., 2007a). While the $\text{RO}_2 + \text{NO}$ reaction is
108 dominant in high- NO_x conditions, the increase in volatile products formed through
109 fragmentation was responsible for the decrease in SOA yield with increasing NO_x
110 (Zhao et al., 2018;Liu et al., 2019a;Xu et al., 2020). In addition, the increase of OH
111 concentration formed through $\text{NO} + \text{HO}_2 \rightarrow \text{NO}_2 + \text{OH}$ reaction at low- NO_x conditions,
112 and a suppressing effect of NO_x on OH formation under high- NO_x conditions was

113 partly responsible for the first increasing and then decreasing trend of SOA yield with
114 NO_x concentration (Sarrafzadeh et al., 2016; Bates et al., 2021).

115 In the last decade, atmospheric pollutants in China have changed significantly in
116 their concentrations and composition (Wang et al., 2015; Xia et al., 2016) with the
117 emissions of SO₂ and NO_x decreased by 75% from 2007–2015 and 10% from 2011–
118 2015, respectively (de Foy et al., 2016; Vu et al., 2019; Wang et al., 2020). However,
119 owing to the lack of regulation regarding NH₃ emissions, NH₃ emissions increased by
120 ~30 % from 2008–2016 over the North China Plain (Liu et al., 2018). As has been
121 pointed out in previous research, the promoting effect of NH₃ on the formation of SOA
122 may counteract the decreases in aerosol formation due to reductions in SO₂ and NO_x
123 (Zhang et al., 2021a). Indeed, field observation and model simulation have pointed out
124 that the simultaneous control of NH₃ emissions in conjunction with SO₂ emission is
125 more effective in reducing PM_{2.5} than the process without NH₃ emissions control, and
126 PM_{2.5} concentration can be more effectively reduced if NH₃ emission is decreased as
127 much as that of SO₂ (Erisman and Schaap, 2004). Hence, the mechanism by which NH₃
128 affects SOA formation has attracted more and more attention (Wang et al., 2018a; Ge et
129 al., 2019; Zhang et al., 2021b). However, previous studies have not paid sufficient
130 attention to the joint impacts of NH₃ and NO_x on the formation of SOA and its
131 corresponding optical properties. Due to the lack of real time detection methods for
132 SOA chemical composition, the dynamic characteristics of how NH₃ participates in
133 SOA formation via photooxidation have not been extensively studied.

134 Toluene is one of the most abundant aromatic VOCs in the urban atmosphere,

135 which is also an important source of brown carbon (Laskin et al., 2010;Ma et al., 2018a).
136 The effects of NH₃ and NO_x on SOA formation through the toluene photooxidation
137 process were investigated in this study. The chemical composition of toluene SOA was
138 characterized on-line with an aerosol mass spectrometer and the characteristics of SOA
139 chemical composition under different conditions were further explored by applying a
140 positive matrix factorization (PMF) analysis. The optical properties of toluene SOA
141 particles were determined based on a UV-vis spectrum analysis. Possible mechanisms
142 of the effects of both NH₃ and NO_x on SOA formation were discussed. The results will
143 help us to better understand SOA formation mechanisms under complex pollution
144 conditions with elevated NH₃ and NO_x concentrations in an urban atmospheric
145 environment.

146 **2 Materials and Methods**

147 **2.1 Photooxidation chamber experiments**

148 All toluene photooxidation experiments were performed in a 4 m³ chamber. The
149 chamber has been described in detail in our previous study (Liu et al., 2021). Briefly,
150 the chamber was constructed with a 0.08 mm-thick FEP-Teflon film. 50 UV-B lamps
151 (TUV36W, Philips) with peak wavelengths of 254 nm were set up around the chamber
152 and used as the light source to drive OH radical formation through hydrogen peroxide
153 (H₂O₂) photolysis. Mirror surfaced stainless steel was used as the interior wall of the
154 enclosure to maximize and homogenize the interior light intensity. All experiments

155 were performed at room temperature (293~298 K) and atmospheric pressure was
156 maintained in the chamber at all times.

157 Before each experiment, the chamber was flushed with zero air for at least 18 hours,
158 after which the concentration of particles was less than 1 cm^{-3} . Zero air was generated
159 by a zero air supply (111-D3N, Thermo ScientificTM, USA). The flow rate of zero air
160 was controlled at 20 L min^{-1} by a mass flow controller (D088C/ZM, Beijing Sevenstar
161 Electron Corporation) during the process of chamber reaction bag inflating. The relative
162 humidity (RH) of zero air was about 20%. For each experiment, measured amounts of
163 toluene (Sigma-Aldrich, analytically pure) and H_2O_2 solution (Sigma-Aldrich, 30 wt%
164 in H_2O) were injected into a Teflon bulb with micro syringes. Zero air was passed
165 through the injection tube to make sure all the liquids had evaporated to the gas-phase
166 and were blown into the chamber. Toluene concentration was measured with a Proton
167 Transfer Reaction-Mass Spectrometry (PTR-ToF-MS, Ionicon Analytik, Austria). The
168 evolution of toluene concentration for different experiments was shown in Fig. S1. The
169 OH concentration in the chamber was calculated based on the first order decay of
170 toluene concentration. There was no obvious difference of OH concentrations in the
171 different NO_x and NH_3 levels (Fig. S2). The average OH concentration over the entire
172 reaction period was $5.87 \times 10^7 \text{ molecule cm}^{-3}$. NO_x (Air Liquid Shanghai, 510 ppm
173 NO_2 in N_2) and/or NH_3 (Air Liquid Shanghai, 502 ppm NH_3 in N_2) were introduced
174 directly into the chamber to reach the required concentrations. For experiments with
175 NO_x , although only NO_2 was introduced into the chamber before photooxidation, NO
176 could be formed through NO_2 photolysis under the UV light irradiation, so NO always

177 coexisted with NO₂ in the photooxidation system (Zhao et al., 2018). NO_x
178 concentration was measured online by the NO-NO₂-NO_x analyzer (Model 42C,
179 Thermo Electron Corporation, USA). Each experiment was performed without seed
180 aerosols. After all the reactants were added, the chamber stood quietly for 10 min
181 without turning on the light to ensure that the reactant gases in the chamber were evenly
182 mixed. The photooxidation started when the UV light was turn on.

183 The experimental conditions for the toluene photooxidation are listed in Table 1.
184 In our work, the OH and toluene concentrations were higher than those of urban
185 conditions. The purpose of the high OH and toluene concentrations is to obtain enough
186 particle production samples for off-line collections and accurate measurements. The
187 toluene concentrations remained stable under the different experimental conditions, the
188 variations of toluene-derived SOA mass concentration and yield were only affected by
189 the different NO₂ and/or NH₃ concentrations in this study. Toluene was studied here as
190 the representative of total aromatic VOCs in the urban atmosphere, thus its
191 concentration used in this study was much higher than that in the real atmosphere.
192 However, the concentration ratio of toluene to OH in this study is similar to that under
193 the real atmospheric conditions (Prinn et al., 1995;Zou et al., 2015).

194 **2.2 Particle concentration measurements**

195 For each experiment, a scanning mobility particle sizer (SMPS) was used to record
196 the particle size distribution and volume concentration of the toluene-derived SOA. The
197 SMPS was composed of a differential mobility analyzer (DMA model 3081, TSI Inc.,

198 USA) and a condensation particle counter (CPC model 3776, TSI Inc., USA) which
199 were used for screening particles with specific electrical mobility diameter (from 14.1
200 nm to 736.5 nm) and for counting the number of the selected particles, respectively.
201 The sheath gas velocity was 3 L min⁻¹ and the sample gas velocity was 0.3 L min⁻¹. The
202 size scan was repeated every 5 min. During each scan circle, the scan time was 240 s,
203 and the particle sizes ranged from 13.6 nm to 726.5 nm. A density of 1.4 g m⁻³, which
204 was measured by Ng et al. (2007), was used for the calculation of toluene SOA mass
205 concentration from the particle volume concentration (Ng et al., 2007b).

206 **2.3 Chemical characterization**

207 In this study, the toluene SOA chemical compositions were characterized with an
208 on-line high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS,
209 Aerodyne Research Inc. USA). The sample flow passed through a Nafion dryer and the
210 RH of the sample gas was reduced to below 20% before entering the AMS. In the
211 injection port, an aerodynamic lens focused particles with a vacuum aerodynamic
212 diameter below 1 µm into a narrow beam. Particles impacted a flash vaporizer (600°C)
213 at the rear of the sizing region under high vacuum ($\sim 10^{-7}$ Torr) and were subsequently
214 ionized by electron impact ionization (70 eV). Then, the positively charged ions entered
215 the ToF section and were separated. V-mode ($m/\Delta m = \sim 2000$) was used in the AMS
216 ToF section to achieve the high signal-to-noise ratio. The separated ion fragments were
217 analyzed by a mass spectrometer with scans from 1 to 300 m/z. The composition-
218 dependent collection efficiency (CE) was applied to the data based on the methods

219 established by Middlebrook et al. (2012). For mass concentration calculations, 1.1, 1.2,
220 and 1.4 were applied as the default relative ionization efficiency (RIE) values of nitrate,
221 sulfate, and organic compounds, respectively. The standard AMS data analysis software
222 SQUIRREL 1.63B coupled with PIKA 1.23B in the Igor Pro (WaveMetrics, Inc.,
223 Portland, Oregon), which were retrieved from [http://cires1.colorado.edu/jimenez-](http://cires1.colorado.edu/jimenez-group/ToFAMSResources/ToFSoftware/)
224 [group/ToFAMSResources/ToFSoftware/](http://cires1.colorado.edu/jimenez-group/ToFAMSResources/ToFSoftware/), were used for the analysis of elemental ratios
225 and the ion speciated compositions of toluene SOA in the chamber. Note that the
226 elemental ratios (i.e., O/C, H/C, and N/C) and mass-to-carbon ratio (OM/OC) were all
227 calculated using the Aiken-Ambient method for comparability with previous studies
228 (Aiken et al., 2008). In order to further explore the changes in SOA chemical
229 composition, a PMF of the high-resolution mass spectra was performed to determine
230 the different organic aerosol (OA) factors during the toluene photooxidation process.
231 We performed the PMF analysis in the same way as Zhang et al. (2011), the details of
232 which are provided in the Supporting Information.

233 **2.4 Absorption measurements**

234 The changes of absorption spectra and the absorbance of the toluene derived SOA
235 under different conditions were determined using a UV spectrophotometer (UV-3600,
236 Shimadzu, Japan) with a 1 cm cuvette. The SOA was collected from a 3 m³ sample gas
237 onto the 46.2 mm PTFE filter (Whatman™, UK). The collected SOA sample was
238 dissolved in 5 mL of methanol (HPLC grade, > 99.8%) with 30 min of sonication. As
239 reported by Chen and Bond (2010), > 92 % of SOA is extractable by organic solvents

240 (e.g., methanol), which means that almost all organic matter was extracted in this study.
241 The filter extracts were filtered through 0.2 μm PTFE syringe filters to remove
242 suspended insoluble particles. Before detection of the optical absorbance, a cuvette
243 filled with pure methanol was scanned as a blank to provide a spectral background. The
244 absorption was detected over the range of 200 to 800 nm with a resolution of 0.5 nm⁻¹.
245 The light absorption coefficient of the particles at a specific wavelength λ (Abs_λ , M/m)
246 was calculated according to Eq. R1:

$$\text{Abs}_\lambda = (A_\lambda - A_{700}) \cdot \frac{V_1}{V_a \cdot L} \cdot \ln(10) \quad (\text{R1})$$

247 where, A_{700} is the background value of light absorption intensity, calculated as the
248 average value of light absorption intensity from 695–705 nm to reduce the limits of
249 error in measurement; V_1 and V_a are the volumes of methanol with dissolved particles
250 and sampled air, respectively; and L is the optical path length. Because Abs_λ was
251 strongly dependent on the amount of SOA, all Abs_λ results were normalized based on
252 the SOA mass collected on the filter. The normalized result was defined as the mass
253 absorption coefficient (MAC , $\text{m}^2 \text{g}^{-1}$), calculated using Eq. R2:

$$\text{MAC}_\lambda = \frac{\text{Abs}_\lambda}{M} \quad (\text{R2})$$

254 where, M ($\mu\text{g m}^{-3}$) represents the concentration of methanol-soluble organic carbon.

255 **3 Result and Discussion**

256 **3.1 SOA formation**

257 In order to investigate the effect of NH_3 and NO_x on SOA formation from toluene
258 photooxidation, a control test was carried out. SOA yield (Y) is defined as $Y =$

259 $\Delta M_0/\Delta HC$, where ΔM_0 is the produced organic aerosol mass concentration ($\mu\text{g m}^{-3}$),
260 and ΔHC is the mass concentration of reacted toluene ($\mu\text{g m}^{-3}$). The evolution of SOA
261 mass concentrations and SOA yield at different conditions during the photooxidation
262 process were shown in Fig. 1. Recent experiments showed that the wall loss of organic
263 vapors to the Teflon walls should not be ignored (Zhang et al., 2014; Zhang et al.,
264 2015b), and represented a major challenge in investigating SOA formation with
265 environmental chambers (Krechmer et al., 2020). The formation of SOA in laboratory
266 chambers may be substantially suppressed due to losses of SOA-forming vapors to
267 chamber walls, but this effect on SOA formation have not yet been quantitatively
268 established. However, the particle wall loss rates were detected at the end of the
269 chamber experiment after the UV-lamps were turned off, and the mass concentration
270 was corrected with the same way of Jiang et al. (2020) and Pathak et al. (2007). After
271 the wall loss correction, the particle mass concentration was almost constant, the
272 different wall loss effect caused by gaseous oxidation products formed in the different
273 experiment conditions was considered remedied. There was a noticeable increase in the
274 SOA mass concentration in the presence of NH_3 , which was consistent with previous
275 studies (Qi et al., 2020; Chu et al., 2016). The mass concentration of SOA increased
276 from $637 \pm 14.6 \mu\text{g m}^{-3}$ without NH_3 to a maximum of $867 \pm 12.7 \mu\text{g m}^{-3}$ with 200 ppb
277 NH_3 . Previous studies attributed the enhancement of SOA to the formation of NOA
278 from acid-base reactions between $\text{NH}_3/\text{NH}_4^+$ and carboxyl groups, or Maillard reactions
279 of $\text{NH}_3/\text{NH}_4^+$ with carbonyl functional groups (Noziere et al., 2009; Ortiz-Montalvo et
280 al., 2014; Liu et al., 2015; Qi et al., 2020). In contrast, SOA concentrations were lower

281 in the presence of NO_x , and the maximum mass concentration of toluene SOA was only
282 $452 \pm 18.9 \mu\text{g m}^{-3}$ with 63 ppb initial NO_x . The branching of RO_2 loss among different
283 pathways has an important influence on the product distribution and SOA formation.
284 The fate of RO_2 mainly depends on the concentrations of NO_x (Zhao et al., 2018; Liu et
285 al., 2019a; Xu et al., 2020). Several studies have shown that, instead of RO_2 reacting
286 with RO_2/HO_2 , NO would react with RO_2 to form the RO intermediate and produces
287 more oxidation products with higher volatilities through fragmentation in the presence
288 of NO_x (Zhao et al., 2018; Liu et al., 2019a; Xu et al., 2020). Highly volatile compounds
289 cannot readily partition into the particle-phase, so this substantially suppresses the
290 formation of SOA.

291 The NO_x and NH_3 had opposite effects on toluene SOA formation in this study.
292 Interestingly, however, the highest SOA mass concentration ($1020 \pm 10.6 \mu\text{g m}^{-3}$)
293 occurred in the presence of both NO_x and NH_3 , which was nearly 1.6 times higher than
294 that observed in the absence of NO_x or NH_3 . Although inorganic aerosol (i.e., NH_4NO_3)
295 was formed from the interaction of NH_3 and NO_x in the chamber, the upper limit of the
296 inorganic matter only accounted for 6.6% of the total mass of particulate matter (Table
297 S1) in the $\text{NH}_3 + \text{NO}_x$ experiment. Therefore, NH_4NO_3 was not the main cause of the
298 increase in particulate matter; the co-occurrence of NH_3 and NO_x had a synergistic
299 effect on the SOA formation, because their combined effect on SOA formation was
300 greater than the sum of their separate effects. Qi et al. (2020) found that the promotion
301 of NH_3 on toluene SOA formation was more obviously under high NO_x concentration,
302 SOA yield increased 3.7% and 4.6% for 70 ppb and 160 ppb initial NO_x concentration,

303 respectively, when 200 ppb NH₃ was added into the chamber. Li et al. (2018) showed
304 that the presence NH₃ can promote the particle size growth of SOA; at the same time,
305 this particle growth rate was higher under low VOC/NO_x (or high NO_x) conditions. All
306 in all, the joint effect of multiple environmental factors on SOA formation is not the
307 simple summation of the influences of various factors on SOA formation. This may at
308 least partly explain why predictions of SOA concentrations in large-scale atmospheric
309 models, which typically describe SOA formation from data derived from chamber
310 experiments, are frequently lower than field observations (Volkamer et al., 2006).

311 **3.2 SOA chemical composition**

312 The traditional SOA formation mechanism is based on the chemical compositions
313 obtained through off-line detection of the chemical composition of SOA (Jang et al.,
314 2002;Liu et al., 2019a;Xu et al., 2020). SOA is continually evolving in the atmosphere
315 and the ageing process of SOA co-occurs with its formation process, resulting in the
316 transformation of SOA chemical composition continuously proceeding during the
317 photooxidation process. Therefore, the AMS was used for on-line measurement of the
318 SOA chemical composition and how the chemical composition evolved in the
319 photooxidation process will be discussed in the following section.

320 Chemical composition of SOA is very complex. The average carbon oxidation
321 state (OS_C) has been shown to be an ideal conceptual framework to describe changes
322 in the degree of oxidation undergone by SOA (Kroll et al., 2011), and has been widely
323 applied in field and laboratory studies (Chen et al., 2018;Mandariya et al., 2019).

324 Average OS_C calculation was shown in Supporting Information. Fig. 2 shows the
325 changes in the OS_C of toluene SOA formed in different experiments. Notably, toluene
326 SOA OS_C values was in the range between -0.5 and 0, which is consistent with that of
327 semi-volatile oxygenated organic aerosols (SV-OOA). However, the different OS_C
328 values and the change trends observed for the toluene SOA formed in different
329 conditions (with and without NH_3/NO_x) in Fig. 2 indicated that there was a
330 photooxidation mechanism active during SOA formation, which ultimately changed the
331 SOA chemical compositions.

332 The OS_C increased over time for all SOAs that were formed in the absence of NH_3 .
333 There are several possible reasons for the increasing trend of OS_C values. Firstly, a
334 dynamic equilibrium of semi-volatile vapors may have been achieved between the
335 particle-phase and gas-phase during the earlier toluene oxidation process. The increase
336 of SOA led to a reduction in the concentration of gas-phase semi-volatile organic
337 products. A decreasing concentration of gas-phase semi-volatile organic compound
338 products would suppress their transformation from gas-phase to particulate-phase.
339 More lower volatility gas-phase oxidation products with higher OS_C values would then
340 be shifted to the particle phase, which would be responsible for the continuing increase
341 of SOA and its OS_C . Secondly, the formed SOA could have further been oxidized by
342 OH radical through heterogeneous reactions (Kourtchev et al., 2015; Liu et al., 2019b).
343 This could be the main reason for the increase in the OS_C when the SOA concentration
344 was no longer increasing. Finally, as pointed by Malecha and Nizkorodov (2016), even
345 if there was no OH radical in the chamber, the photodegradation of SOA can produce

346 small oxygenated volatile organic compounds (e.g. acetaldehyde $OS_C = -1$, and acetone
347 $OS_C \approx -1.3$) under UV light irradiation. The photoproduction of OVOCs from SOA had
348 a lower OS_C value than that of SOA. Although the loss of SOA through
349 photodegradation is small, the OS_C value of SOA still had increased to a certain extent
350 (Malecha and Nizkorodov, 2016).

351 The fact that additional photochemical processing results in the dynamic evolution
352 of the OS_C over time has been demonstrated in both field and laboratory experiments
353 (Jimenez et al., 2009). The atmospheric oxidation of OA tends towards higher OS_C
354 regardless of the original OA source (Herndon et al., 2008). However, when NH_3 was
355 present, the OS_C of total SOA was almost unchanged for the whole photooxidation
356 period. Carboxyl and carbonyl are the main oxygen-containing functional groups
357 responsible for the toluene photooxidation production (Ji et al., 2017). An organic
358 ammonium salt with four H atoms can offset an increase in OS_C value caused by the
359 formation of organic acids/carboxy group with two O atoms through acid-base reactions
360 (Kuwata and Martin, 2012; Liu et al., 2015). In addition, NH_3/NH_4^+ may react with
361 carbonyl functional groups through Maillard reactions, consuming the oxygen atom in
362 the carbonyl group and leading to the formation of species with covalent carbon-
363 nitrogen bonds (Lee et al., 2013; Zhang et al., 2015a; Qi et al., 2020). Xu et al. (2018)
364 showed that imidazole compounds ($OS_C \approx -1.3$) generated through heterogeneous
365 reaction between NH_3 and carbonyl compounds might contribute to the decrease in the
366 OS_C of SOA. It is clear that an increase in OS_C caused by the formation of oxygen-
367 containing functional groups (e.g., carboxyl, carbonyl, etc.) would be counteracted

368 through acid-base reactions or Maillard reactions in the presence of NH_3 . After 60 min
369 of UV light irradiation, there was no more SOA formation; however, the OS_C did
370 decrease slightly in Exp.2 and 3, illustrating that the NH_3 could continue to react with
371 SOA through heterogeneous processes. Huang et al. (2016) also pointed out that the
372 portion of semi-volatile products with low OS_C formed at the later stage of
373 photooxidation also contributed to the decreased OS_C .

374 The OS_C of the toluene SOA formed with NO_X was lower than that formed in the
375 absence of NO_X , no matter whether NH_3 was present in the chamber or not. This
376 indicated that an increased NO_X concentration benefits the formation of high volatility
377 oxidation products with lower OS_C values (Kroll et al., 2011; Jimenez et al., 2009).
378 However, the relationships between OS_C and SOA mass concentration with and without
379 NH_3 were the opposite to each other. Predictably, the SOA formation mechanism in the
380 presence of NO_X is different from that with $\text{NO}_X + \text{NH}_3$. In the absence of NH_3 , the RO
381 intermediate, which is easily fragmented to produce relatively high-volatility
382 compounds, was the dominant product of the $\text{NO}_X + \text{RO}_2$ reaction (Zhao et al., 2018; Liu
383 et al., 2019a; Xu et al., 2020). Highly volatile compounds cannot readily partition into
384 the particle-phase, which subsequently results in a lower SOA yield in the presence of
385 NO_X (Yang et al., 2020). Thereby, both OS_C and the SOA mass concentration were
386 lower when 60 ppb NO_X was added into the chamber. However, when both NO_X and
387 NH_3 were present, the toluene derived SOA had the lowest OS_C value, but the highest
388 mass concentration. This result suggested that although NO_X promotes the formation
389 of higher volatility compounds, these higher volatility compounds (e.g. glyoxal) can

390 react with NH_3 and partition into the particle-phase, which could contribute to the
391 increase in SOA formation. Huffman et al. (2009) observed that aerosol volatility was
392 inversely correlated with the extent of oxidation of OA components. The low value of
393 OS_C in the presence of NO_X indicated that NO_X would promote the formation of the
394 relatively high-volatility compounds. However, the lower OS_C value in the presence of
395 NH_3 indicated that the high-volatility compounds would promote partitioning into the
396 particle-phase when reacting with NH_3 .

397 Fragments derived from the AMS data have also been widely used to explore the
398 bulk compositions and properties of SOA (Ng et al., 2010; Ng et al., 2017). The m/z 43
399 (f43) frequency was dominated by ion $\text{C}_2\text{H}_3\text{O}^+$, which is the tracer for organic
400 compounds with alcohol and carbonyl functional groups (Alfarra et al., 2006).
401 Meanwhile, the m/z 44 (f44) signal was dominated by CO_2^+ ions, which is the tracer
402 for organic compounds with carboxyl functional groups and an indicator of highly
403 oxygenated organic aerosols (Ng et al., 2010). Here, we use the approach of Ng et al.
404 (2010) by plotting the fractions of the total organic signal at m/z 43 vs. m/z 44 (f43 vs.
405 f44). The change of f43 vs. f44, which has an inflection point during the photooxidation
406 process, is shown in Fig. 3 and Fig. S3. In our study, the change before the inflection
407 point was defined as the formation stage, and the linear fit of f43 vs. f44 for the
408 formation stage is shown by the dashed lines. The change in f43 vs. f44 after the
409 inflection point was defined as the stable stage, and the linear fit of f43 vs. f44 in this
410 stage is shown by the solid lines. The formation and stable stages of the f43 vs. f44
411 relationship during the experiment are discussed separately here.

412 In the stable stage, the increase in f44 and decrease in f43 with increasing OH
413 exposure indicated that the carbonyl groups in toluene SOA were oxidized to carboxyl
414 groups by the ageing process. For the experiments without NH₃ and NO_x, the slope
415 ratio of f43 vs. f44 was -3.9. When there was 60 ppb initial NO_x, the f43 was almost
416 stable while the f44 increased with the oxidation process. There was a lower slope ratio
417 of f43 vs. f44, indicating that organic compounds with more alcohol and carbonyl
418 functional groups had formed in the presence of NO_x. But for the experiments with 200
419 ppb initial NH₃, the slope ratios of f43 vs. f44 were only -1.1 and -1.3 in the presence
420 and absence of NO_x, respectively. According to the above results, we can see that more
421 carbonyl groups are consumed as carboxyl groups are formed in the presence of NH₃.
422 The carbonyls can be oxidized to organic acids (Kawamura and Bikkina, 2016), but
423 unreacted carbonyl can be nucleophilically attacked by NH₃/NH₄⁺ to form nitrogen-
424 heterocyclic compounds, e.g., imidazole (Grace et al., 2019; Lian et al., 2020).
425 Meanwhile, the peak f44 value decreased from 0.13 to 0.10 when NH₃ was added into
426 the chamber. This suggested that the heterogeneous reaction of NH₃/NH₄⁺ could
427 promote the consumption of particle-phase carbonyl groups (Xu et al., 2018), and must
428 inhibit the formation of carboxyl groups in the SOA ageing process. According to the
429 changing trend of SOA concentration over time, the photooxidation process was
430 divided into formation stage and stable stage. As shown in Fig. 1, the first half hour of
431 photooxidation when SOA concentration increased linearly with time was defined as
432 SOA formation stage. After 60 min of photooxidation, SOA concentration was not
433 changed with reaction time, and it was defined as stable stage. The differences in spectra

434 of toluene SOA in the formation stage and stable stage are shown in Fig. 4. A lower
435 signal intensity variation of CO_2^+ in the presence of NH_3 also illustrated that NH_3 would
436 inhibit heterogeneous reactions that form carboxyl groups.

437 In the formation stage, the slope ratios of f43 vs. f44 were almost the same for both
438 experiments without NO_x . It can thus be seen that the presence or absence of NH_3 does
439 not affect the change trend of f43 vs. f44 in the SOA formation stage. Therefore, the
440 gas-phase homogeneous reaction of NH_3 on SOA formation is not important. Clearly,
441 the particle-phase heterogeneous reaction was the main reaction pathway by which NH_3
442 participated in the photooxidation process and toluene SOA formation. However,
443 negative correlations were observed between f43 and f44 in the presence of NO_x . Based
444 on this, we concluded that NO_x not only affects the SOA formation through the particle-
445 phase heterogeneous reactions, but also through gas-phase homogeneous reactions.

446 **3.3 PMF results**

447 A temporal evaluation of the toluene SOA chemical composition during
448 photooxidation is vital to the analysis of the NOA formation mechanism in the presence
449 of NH_3 and/or NO_x . Therefore, this study further compared the chemical properties of
450 the SOA generated under different experimental conditions by applying a PMF analysis
451 to the HR-ToF-AMS data (Chen et al., 2019). A summary of the PMF results is
452 presented in Fig. S4-S7. For the toluene OH-photooxidation experiments with NH_3
453 and/or NO_x presence, two factors were identified from the PMF analysis in the same
454 way of Chen et al. (2019). The H/C, O/C, and N/C values of these two factors are shown

455 in Fig. 5. The factor with higher N/C values was defined as high-nitrogen OA (Hi-NOA).
456 In contrast, the factor with lower N/C values was defined as low-nitrogen OA (Lo-
457 NOA). Fig. 6 exhibits the evolution of Hi-NOA and Lo-NOA during the photooxidation
458 process as resolved from the PMF analysis of different initial NO_x/NH_3 concentrations.
459 While similar evolutionary trends were observed under different conditions, the relative
460 intensities and the chemical compositions of these two factors in each experiment were
461 not consistent.

462 For the toluene SOA formed under NH_3 conditions, both Lo-NOA and Hi-NOA
463 had similar O/C values, which were fully oxygenated with an average of 0.74 ± 0.04
464 (Fig. 5a). These O/C values were comparable to the low-volatility oxygenated organic
465 aerosols (LV-OOA) with an O/C value ranging from 0.6 to 1 (Jimenez et al., 2009). The
466 main difference between these two OA sources was the N/C ratio. The N/C ratio of Hi-
467 NOA (N/C = 0.032) was about three times higher than that of Lo-NOA (N/C = 0.010)
468 (Fig. 5a). The evolution of these two OA sources during the photooxidation process is
469 shown in Fig. 6a. The components of toluene SOA were mostly Lo-NOA during the
470 initial phase of SOA formation, but Hi-NOA toluene SOA started forming after 10
471 minutes and continued to increase. The Lo-NOA reached the maximum mass
472 concentration after 30 min of the photooxidation, and then decreased. Such a declining
473 trend of Lo-NOA at longer reaction times reflected the conversion of Lo-NOA into
474 something else in the particle-phase. As the Lo-NOA decreased, the mass concentration
475 of Hi-NOA gradually increased. Thus, the Hi-NOA should be derived from the
476 heterogeneous reaction of Lo-NOA with $\text{NH}_3/\text{NH}_4^+$. At the same time, it was proved

477 that the formation pathway of Hi-NOA was not through reaction of NH_3 with later-
478 generation gas-phase products in the homogeneous gas phase. With the gradual
479 replacement of Lo-NOA by Hi-NOA, the ratio of $[\text{Hi-NOA}]/[\text{Lo-NOA}]$ stabilized at
480 5~6.

481 For the toluene SOA formed under NO_x conditions, there was not a large
482 difference between the N/C ratios of Hi-NOA (N/C = 0.019) and Lo-NOA (N/C = 0.014)
483 (Fig. 5c). At the end of the NO_x experiment, the ratio of $[\text{Hi-NOA}]/[\text{Lo-NOA}]$ was only
484 3:2 (Fig. 6c). It follows that the contribution of the heterogeneous NO_x reaction to the
485 N/C ratio of toluene SOA was not obvious. Therefore, the formation of NOA in the
486 presence of NO_x mainly occurred through gas-phase homogeneous reactions, which
487 was consistent with the results in section 3.3.

488 The changing trend of N/C with time in the presence of NH_3 was different to that
489 with NO_x present. The evolutions of the N/C of SOA in different experiments are shown
490 in Fig. 7. In the presence of NH_3 , the N/C value gradually increased throughout the
491 photooxidation process. The increased N/C value in the photooxidation process was
492 attributed to the heterogeneous NH_3 reaction with SOA. But in the presence of NO_x ,
493 the N/C increased rapidly to its maximum value where it was stable for the rest of the
494 reaction. This could mean that the heterogeneous reaction of toluene SOA with NO_x to
495 form NOA was not as important as the gas-phase homogeneous reaction.

496 When both NO_x and NH_3 were added into the chamber, the N/C ratios of Hi-NOA
497 and Lo-NOA were 0.062 and 0.029, respectively (Fig. 5b). The N/C ratio of Hi-NOA,

498 which was comparable to the recently isolated nitrogen-enriched OA value (0.053)
499 observed by Sun et al. (2011), was much higher than that observed in the experiments
500 with only NH₃ or NO_x. It was even higher than the sum of the N/C ratios from both
501 Exp. 2 with NH₃ and Exp. 4 with NO_x. In order to calculate the relative contributions
502 of NH₃ and NO_x to N/C, it was assumed that the effects of NH₃ or NO_x on the N/C
503 ratio in the Hi-NOA and Lo-NOA factors did not change among different experimental
504 conditions. For Lo-NOA, the contributions of NH₃ and NO_x to the N/C value were
505 0.0126 and 0.0164, and their relative intensities were 43% and 57%, respectively. While
506 for the Hi-NOA, the contributions of NH₃ and NO_x to the N/C values were 0.0404 and
507 0.0216, and their relative intensities were 65% and 35%, respectively. For the
508 experiment with both NH₃ and NO_x, the contribution of NH₃ to N/C was higher by 26%,
509 and the contribution of NO_x to N/C was higher by 17% compared to the experiments
510 with the single pollutants. The co-existence of NH₃ and NO_x further enhanced the N/C
511 value of toluene SOA, indicating that a synergetic interaction between NH₃ and NO_x
512 further enhanced organic nitrogen formation.

513 **3.4 Optical absorption**

514 The optical characteristics of toluene SOA formed from different NH₃ and NO_x
515 conditions were investigated. The MAC of toluene derived SOA detected over the range
516 of 230–600 nm is displayed in Fig. 8. Over the entire UV detection range, an increase
517 in light absorption was observed when the toluene SOA formed in the presence of NO_x
518 or NH₃.

519 By looking at Fig. 8 in detail, one can see that the MAC of toluene SOA formed
520 with (red line) and without (black line) NH_3 overlapped at 250 nm, but when the UV
521 wavelength exceeded 250 nm the MAC of the toluene SOA formed in the presence of
522 NH_3 was higher. The red line reflects an obvious characteristic absorption peak at
523 270~280 nm, which was mainly due to the absorption of the $n \rightarrow \pi^*$ electronic
524 transitions. The imidazole compounds were formed through the Maillard reactions
525 between $\text{NH}_3/\text{NH}_4^+$ with carbonyl functional groups (Zhang et al., 2015a). The C=N
526 double bonds in the organonitrogen imidazole compounds can act as effective
527 chromophores since both $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions are chromatically active
528 (Nguyen et al., 2013). The UV/visible spectrum of imine and pyrrole show broad bands
529 at 270 nm (NIST, 2020), which was consistent with the UV absorption peak of the
530 $n \rightarrow \pi^*$ band observed here. According to the AMS results, carbonyl was the main
531 functional group of toluene SOA. The emergence of absorption peaks at 270~280 nm
532 demonstrated that some organonitrogen imidazole compounds (e.g. imines and pyrrole)
533 were formed through the heterogeneous reaction of toluene with NH_3 . Meanwhile, the
534 high-molecular weight nitrogen-containing organic species might have formed through
535 Maillard reactions in the particle-phase (Wang et al., 2010). This was also a reason for
536 the increase in SOA mass concentration in the presence of NH_3 .

537 The green line in Fig. 8 represents the MAC value of toluene-derived SOA in the
538 presence of NO_x , which was also higher than the black line (control) throughout the
539 UV detection range. When compared with the red line, the green line had no obvious
540 characteristic peak at 280 nm, but it had higher absorbance in the range between 240

541 and 280 nm. This indicated that both NO_x and NH_3 increased the absorbance of toluene
542 SOA, while the chromophores generated from the reactions between toluene-derived
543 SOA with NH_3 or NO_x did not behave in the same way.

544 The blue line in Fig. 8 represents the absorbance of toluene SOA formed in the
545 presence of both NO_x and NH_3 . The MAC of toluene SOA formed in the presence of
546 both NO_x and NH_3 was higher than the toluene SOA formed in the presence of either
547 NH_3 or NO_x . There might have been a synergetic effect between NO_x and NH_3 on the
548 absorbance of toluene SOA. Considering that the mass concentration of toluene SOA
549 formed in the presence of both NH_3 and NO_x was the highest, as described in section
550 3.1, the co-existence of NH_3 and NO_x may also result in the toluene SOA having
551 stronger light absorption and atmospheric radiative forcing. We also noted a higher
552 MAC value at 280 nm, which illustrated that the presence of NO_x could promote the
553 formation of imines and pyrrole in the photooxidation system of toluene with NH_3 .

554 **4 Conclusion**

555 Here we present the results of a study in which we characterized the mass
556 concentrations, chemical compositions, and optical properties of SOA formed from the
557 photooxidation of toluene under different NH_3 and NO_x concentrations. When
558 compared with the control experiment, the SOA mass concentration data showed that
559 the formation of toluene-derived SOA was enhanced in the presence of NH_3 , through
560 acid-base reactions between carboxyl groups or Maillard reactions with carbonyls, but
561 inhibited in the presence of NO_x . Meanwhile, the mass concentration of toluene SOA

562 formed in the presence of both NO_x and NH_3 was higher than those formed under either
563 NH_3 or NO_x alone. This result indicated that there was a synergistic interaction between
564 NH_3 and NO_x that further enhanced toluene-derived SOA formation. At the same time,
565 the lowest OS_C value was obtained when both NH_3 and NO_x were present. We
566 concluded that highly volatile compounds, which were formed from toluene
567 photooxidation in the presence of NO_x , could react with NH_3 to form products with
568 lower volatilities, and promoted the partitioning of these products into the particle-
569 phase.

570 Synergetic effects of NH_3 and NO_x on the formation of NOA and the optical
571 properties of SOA were also observed in this study. The heterogeneous reaction was
572 responsible for the formation of NOA in the presence of NH_3 . Meanwhile, an absorption
573 peak at 270~280 nm, which is characteristic of imine and pyrrole, was observed. In
574 contrast, the formation of NOA caused by NO_x alone was mainly due to a gas phase
575 homogeneous reaction.

576 In the actual atmosphere especially in Chinese urban atmosphere, NO_x and NH_3
577 abundantly co-exist. Therefore, the findings presented here clearly show that the
578 synergetic effects of NO_x and NH_3 should not be neglected. In the meantime, our work
579 provides a scientific basis for the consideration of synergistic emission reductions of
580 NH_3 and NO_x under the compound pollution conditions, which will contribute to
581 reducing the burden of aerosols in the atmosphere. It has to be noted that the
582 concentration of reactants used for the experiments is much higher than that observed
583 in polluted areas. Although the reactant concentrations including NH_3 used in this work

584 are much higher than those in the real urban environment, our results are applicable for
585 the polluted urban atmosphere. In the urban atmosphere aromatic VOCs consist of
586 numerous species and their total concentration is much higher than a single species such
587 as toluene. On the other hand, carboxylic acids and carbonyls in the urban polluted
588 atmosphere can be produced from aromatics and many other species. Therefore, it is
589 reasonable for our smog chamber experiments to use toluene as a single precursor with
590 a concentration much higher than that in the real atmosphere. Although the mechanisms
591 of SOA formed under high precursor concentrations is expected to be the same as that
592 under low concentrations, the kinetics are probably different. Thus, the effect of NH₃
593 and NO_x on the photooxidation of toluene with lower concentrations should be checked
594 in the further study.

903

904 **Tables**

905

906

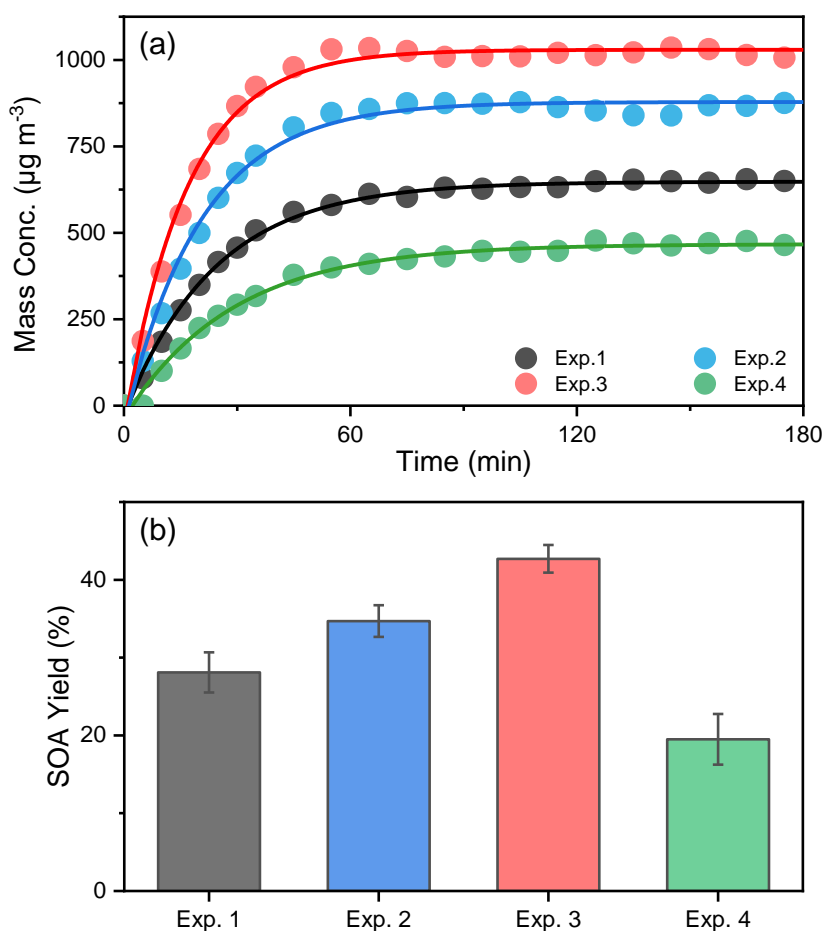

Table 1. Summary of experimental conditions in this study

No.	Tol ₀ (ppb)	Δ Tol (ppb)	NH ₃ ^a (ppb)	NO ₂ (ppb)	RH (%)	SOA mass conc. ^{b,c} (μg m ⁻³)	SOA yield ^b (%)
Exp.1	664.1	551.2	-	-	25 ± 1	637 ± 14.6	28.1
Exp.2	618.7	499.4	~200	-	23 ± 1	867 ± 12.7	34.7
Exp.3	620.9	526.1	~200	62	26 ± 1	1020 ± 10.6	42.7
Exp.4	645.7	539.5	-	63	25 ± 1	452 ± 18.9	19.5

907 ^a The concentration of NH₃ is estimated by the amount of NH₃ added and the volume of the smog
 908 chamber. ^b SOA concentration and yield were calculated after taking into account the wall loss. ^c
 909 The reported SOA mass concentrations was the peak values after the wall loss correction.

910

911 **Figures**

912

913

914 **Fig. 1.** The evolution of mass concentration (a) and yield (b) of toluene-derived SOA in different
 915 experiments. All the mass concentrations were wall-loss corrected. The error bars were calculated
 916 by the fluctuation of measured SOA concentration after the UV light was turn off at the end of
 917 each experiment

918

919 **Fig. 2.** The OSc values for the toluene SOA formed under different NH₃/NO_x conditions.

920

921

922

923

924 **Fig. 3.** The relationship between total organic signals at 43 m/z (f43) vs. 44 m/z (f44) from SOA
 925 data during the photooxidation process. The f43 vs. f44 plots exhibited inflection points during the
 926 photooxidation process. The dashed lines indicate the trends of f43 vs. f44 for the SOA formation
 927 stage (before the inflection point) and the solid lines for the stable stage.

928

929

930 **Fig. 4.** The differential spectra of toluene SOA in the formation and stable stages. Data were taken
 931 and analyzed at a high resolution but were summarized to a unit mass resolution for display. Only
 932 minimal N-containing fragments could be observed in the Exp.1 without added NH_3 and NO_x .
 933 These N-containing fragments could be attributed to the background NH_3 and NO_x in the chamber
 934 or the systematic errors from AMS.

935

936

937

938 **Fig. 5.** The H/C, O/C, and N/C values of Hi-NOA and Lo-NOA for each experiment. (a) Exp. 2
 939 with 200 ppb NH₃, (b) Exp. 3 with 200 ppb NH₃ and 62 ppb NO₂, and (c) Exp. 4 with 63 ppb
 940 NO₂.

941

942

943 **Fig. 6.** The evolution of high-nitrogen OA (Hi-NOA) and low-nitrogen OA (Lo-NOA) during the
 944 photooxidation process under different NO_x/NH_3 concentrations. Hi-NOA and Lo-NOA were not
 945 consistent among experiments. (a) Exp. 2 with 200 ppb NH_3 , (b) Exp. 3 with 200 ppb NH_3 and 62
 946 ppb NO_2 , and (c) Exp. 4 with 63 ppb NO_2 .

947

948

949 **Fig. 7.** The evolution of N/C in different experiments.

950

951

952

953

954 **Fig. 8.** The MAC over the range of 230 – 600 nm for the toluene SOA formed under different
955 experiment conditions.
