## Abstract

Increasing the resolution of chemical transport model (CTM) predictions in urban areas is important to capture sharp spatial gradients in atmospheric pollutant concentrations and better inform air quality and emissions controls policies that protect public health. The chemical transport model PMCAMx was used to assess the impact of increasing model resolution on the ability to predict the source-resolved variability and population exposure to $PM_{2.5}$ at 36 x 36, 12 x 12, 4 x 4, and 1 x 1 km resolutions over the city of Pittsburgh during typical winter and summer periods (February and July 2017). At the coarse resolution, county-level differences can be observed, while increasing the resolution to 12 x 12 km resolves the urban-rural gradient. Increasing resolution to 4 x 4 km resolves large stationary sources such as power plants and the 1 x 1 km resolution reveals intra-urban variations and individual roadways within the simulation domain. Regional pollutants that exhibit low spatial variability such as $PM_{2.5}$ nitrate show modest changes when increasing the resolution beyond 12 x 12 km. Predominantly local pollutants such as elemental carbon

Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

and organic aerosol have gradients that can only be resolved at the 1 x 1 km scale. Contributions from some local sources are enhanced by weighting the average contribution from each source by the population in each grid cell. The average population weighted $PM_{2.5}$ concentration does not change significantly with resolution, suggesting that extremely high resolution $PM_{2.5}$ predictions may not be necessary for effective urban epidemiological analysis.

## 1. Introduction

Particulate matter with aerodynamic diameter less than 2.5 μm ($PM_{2.5}$) contributes to poor air quality throughout large parts of the United States. These particles directly affect visibility (Seinfeld and Pandis, 2006) and have been associated with long and short-term health effects such as premature death due to cardiovascular disease, increased chance of heart attacks and strokes, reduced lung development and function in children and people with lung diseases such as asthma and increases in hospital admissions due to heart and lung disease (Dockery and Pope, 1994).

At high resolutions, emissions from local sources such as commercial cooking, on-road traffic, residential wood combustion, and industrial activities can have sharp gradients that influence the geographical distribution of $PM_{2.5}$ concentrations. High-resolution measurements of $PM_1$ have found gradients of up to ~2 μg $m^{-3}$ between urban background sites and those with high local emissions (Gu et al., 2018; Robinson et al., 2018).

A key limiting factor on the modeling of particulate matter at high resolutions is the geographical distribution of emissions. Previous studies have found that coarse grid emissions interpolated to higher resolutions lead to small to modest improvements in model predictive ability for ozone (Kumar and Russell, 1996; Arunachalam et al., 2006), secondary organic aerosol (Stroud et al., 2011; Fountoukis et al., 2013) and nitrate (Zakoura and Pandis, 2018; Zakoura and Pandis, 2019). Pan et al., (2017) used the default approach from the U.S. Environmental Protection Agency (EPA) National Emissions Inventory (NEI) to allocate county-based emissions to model grid cells at 4 x 4 and 1 x 1 km and found only small changes to model performance for $NO_x$ and $O_3$, while the 1 x 1 km case showed more detailed features of emissions and concentrations in heavily polluted areas.

Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

Improvements in the resolution of emission inventories have been focused on traffic as this source exhibits significant variability at high resolutions. Recent approaches to building high-resolution traffic inventories include origin-destination by vehicle class (Ma et al., 2020), synthetic population mobility (Elessa Etuman and Coll, 2018) and fuel sales combined with traffic counts (McDonald and McBride, 2014). Other sectors such as biomass burning for residential heating and commercial cooking have been identified as very uncertain in current inventories (Day et al., 2019). Recent versions of the NEI have made progress addressing the total emissions and temporal distributions of biomass burning and commercial cooking (Eyth and Vukovich, 2016), but there is still significant uncertainty on their geographical location at a sub-county scale. Robinson et al. (2018) found greatly elevated organic aerosol concentrations in the vicinity of numerous individual restaurants and commercial districts containing groups of restaurants indicating that commercial cooking is a source of large gradients on the urban scale.

Population density and socio-economic indicators of that population, such as income or access to healthcare, show large gradients in the urban scale. It is important to assess the exposure of different sub-populations to air pollutants and the resulting health effects, a concept known as Environmental Justice (Anand, 2002).

We use the Particulate Matter Comprehensive Air quality Model with Extensions (PMCAMx) to study the impact of increasing model resolution on the model's ability to predict the variability, sources and population exposure of $PM_{2.5}$ concentrations on the urban scale in Pittsburgh. We compare predicted variability at 36 x 36, 12 x 12, 4 x 4 and 1 x 1 km resolutions over the city of Pittsburgh during one typical summer and one typical winter month of 2017. Additional sensitivity simulations were performed to determine contributions from selected sources to concentrations. The results of the simulations are used to estimate exposure to $PM_{2.5}$ at all resolutions and from the selected sources. A detailed evaluation of the PMCAMx predictions against measurements will be the topic of a future publication. Overall the model performance was similar to those in previous model applications in the Eastern US (Fountoukis et al., 2013).

Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

## 2. PMCAMx Description

The Particulate Matter Comprehensive Air quality Model with Extensions (PMCAMx) (Tsimpidi et al., 2009; Karydis et al., 2010; Murphy and Pandis, 2010), uses the framework of the CAMx model (Environ, 2006) to describe horizontal and vertical advection and diffusion, emissions, wet and dry deposition, gas, aqueous and aerosol-phase chemistry. A 10-size section aerosol sectional approach is used to dynamically track the evolution of the aerosol mass distribution. The aerosol species modeled include sulfate, nitrate, ammonium, sodium, chloride, elemental carbon, water, primary and secondary organics, and other non-volatile aerosol components. The SAPRC (Statewide Air Pollution Research Center) photochemical mechanism (Carter, 1999) is used for the simulation of gas-phase chemistry. The version of SAPRC used here includes 237 reactions and 91 individual and surrogate species. For inorganic growth, a bulk equilibrium approach was used, assuming equilibrium between the bulk inorganic aerosol and gas phases (Pandis et al., 1993). The partition of the various semivolatile inorganic aerosol components and aerosol water is determined using the ISORROPIA aerosol thermodynamics model (Nenes et al., 1998). The primary and secondary organic aerosol components are described using the volatility basis set approach (Donahue et al., 2006). For primary organic aerosol (POA) ten volatility bins, with effective saturation concentrations ranging from $10^{-3}$ to $10^{6}$ μg $m^{-3}$ at 298 K are used. Anthropogenic (aSOA) and biogenic (aSOA) are modeled with 4 volatility bins (1, 10, $10^{2}$, $10^{3}$ μg $m^{-3}$) (Murphy and Pandis, 2009) using $NO_x$ dependent yields (Lane et al., 2008). More detailed descriptions of PMCAMx can be found in Fountoukis et al. (2011) and Zakoura and Pandis (2018).

## 3. Model Application

PMCAMx was used to simulate air quality over the metropolitan area of Pittsburgh during February and July 2017. For the base-case simulation we used a one-way nested structure with a 36 x 36 km master grid covering the continental United States, with nested grids of 12 x 12 km, 4 x 4 km in South Western Pennsylvania and a 1 x 1 km grid covering the city of Pittsburgh, most of Allegheny County and the upper Ohio River valley (Figure 1a). The 1 x 1 km grid covers a 72 x 72 km area (Figure 1b).

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

The surface concentrations at the boundaries of the 36 x 36 km grid are shown in Table S1 in the Supplementary Information. These values were applied to all upper air layers assuming a constant mixing ratio. Horizontal wind components, vertical diffusivity, temperature, pressure, water vapor, clouds, and rainfall were generated using the Weather Research and Forecasting (WRF v3.6.1) model over the whole modeling domain with horizontal resolution of 12 km. The data was interpolated to higher resolutions when needed. Initial and boundary meteorological conditions for the WRF simulations were generated from the ERA-Interim global climate re-analysis database, together with the terrestrial data sets for terrain height, land-use, soil categories, etc. from the United States Geological Survey (USGS) database. The WRF modeling system was prepared and configured in a similar way as described by Gilliam and Pleim (2010). This configuration is recommended for air quality simulations (Hogrefe et al., 2015; Rogers et al., 2013).

Emissions were calculated using the EPA's Emission Modeling Platform (v6.3) for the National Emissions Inventory for 2011 (NEI11) (Eyth and Vukovich, 2016) using the default 2017 projected values. Base emissions were calculated first at a 12 km resolution for the full modeling domain using the Sparse Matrix Operator Kernel Emissions (SMOKE) model and our WRF meteorological data. For the higher resolution grids, the spatial surrogates provided with Platform v6.3 were used for all sectors except commercial cooking and on-road traffic for which custom surrogates were developed. The emissions by all sources together with the chemical composition are summarized in Table 1 (for the winter period) and Table 2 (for the summer period)..

In this work, we used normalized restaurant count to distribute the commercial cooking emissions in space in the 1x1 km inner domain. Geographical information was collected for all locations labeled as "restaurant" from the freely accessible Google Places Application Programming Interface (API) for the western Pennsylvania area, eastern Ohio and northern West Virginia. Using this new spatial surrogate, $PM_{2.5}$ emissions from commercial cooking are enhanced primarily in the Pittsburgh urban core with a maximum increase of 1200 kg $g^{-1}$ $km^{-2}$ (Figure 2a).

To accurately capture spatial patterns of on-road traffic, we use the output of a link-level, origin-destination by vehicle class traffic model of Pittsburgh (Ma et al., 2020). This traffic model simulates traffic counts and speed by hour-of-day using observations from

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

Pennsylvania Department of Transportation sites throughout Pittsburgh. As expected, emissions in areas with major highways are high (Figure 2b).

## 4. $PM_{2.5}$ concentrations and sources during winter

### 4.1 Effect of grid resolution

The results of the simulations with the four resolutions for the winter period are shown in Figure 3 and Figure 4. For the area of interest, the simulations at 36 x 36 km resolves concentration fields at the county scale. The urban-rural gradient is resolved in the 12 x 12 km simulations. Increasing the resolution to 4 x 4 km, large stationary sources such as power plants and large industrial installations are resolved. Finally, the resolution increase to 1 x 1 km resolves the intra-urban variations in Pittsburgh and medium-sized industrial installations.

In the winter period, the predicted maximum $PM_{2.5}$ concentration in the inner domain increases from 10.4 μg $m^{-3}$ at 36x36 km, to 11.8 μg $m^{-3}$ at 12x12, to 12.9 μg $m^{-3}$ at 4x4, and finally to 16.4 μg $m^{-3}$ at 1x1 km (Figure 3), a 58% increase. On the other end, the predicted minimum $PM_{2.5}$ concentration changes from 8.2 μg $m^{-3}$ at 36 x 36 km to 7 μg $m^{-3}$ at 12 x 12 and remains practically the same at even higher resolutions. This corresponds to the "background" concentration level for the area during the simulation period, so further resolution enhancements do not change this value. The standard deviation of the predicted concentration can be used as a measure of the concentration variability in the area. This standard deviation changes from 0.9 μg $m^{-3}$ at 36x36, to 1.24 μg $m^{-3}$ at 12x12, to 1.45 μg $m^{-3}$ at 4x4 and to 1.35 μg $m^{-3}$ at 1x1 km. These results indicate an increase of the $PM_{2.5}$ variability by 50% when one moves from the coarse to the finest resolution. However, most of this change in variability (38% out of the 50%) appears when one moves from 36x36 to 12x12 km.

Elemental carbon is a primary aerosol component with sources that are quite variable in space. In winter, the predicted maximum $PM_{2.5}$ EC increased by a factor of 2.9, from 0.6 μg $m^{-3}$ at the 36 x 36 km resolution to 1.6 μg $m^{-3}$ at 1 x 1 km (Figure 3). The predicted maximum EC is, as expected in the Pittsburgh downtown area. On the other hand, the predicted minimum of EC is reduced by only 0.1 μg $m^{-3}$, from 0.34 μg $m^{-3}$ at 36x36 km to 0.24 μg $m^{-3}$ at resolutions lower or equal than 4x4 km. The standard deviation of the

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

predicted EC almost doubles from 0.1 μg $m^{-3}$ at 36 x 36 km to 0.18 μg $m^{-3}$ at 1 x 1 km. Approximately 50% of this increase in variability appears in the transition from the coarse to the intermediate resolution of 12 x 12 km. The fine and the finest resolutions are needed to resolve the other half of the predicted variability.

During this winter period a significant fraction (79%) of the OA in the Pittsburgh area is primary and therefore the higher resolution results in increases of the predicted maximum concentrations in space from 2.8 μg $m^{-3}$ at the coarse resolution to 3.7 μg $m^{-3}$ at the intermediate to 4.8 μg $m^{-3}$ at the finest resolution (Figure 3). This corresponds to an increase by a factor of 1.7, more than the change for total $PM_{2.5}$, but much less than that for EC. The predicted maximum is located in downtown Pittsburgh, with additional hotspots in neighboring counties that are resolved at the fine and finest resolution. The predicted minimum changes from 2.1 μg $m^{-3}$ at 36x36 to 1.7 μg $m^{-3}$ at 12x12 with small reductions at higher resolutions. The variability (standard deviation) of the OA concentration field of the predicted concentration increases by a factor of approximately 1.6 from 0.35 μg $m^{-3}$ at 36 x 36, to 0.51 μg $m^{-3}$ at 12 x 12 km. The increase is small at even higher resolutions with the standard deviation of OA reaching 0.53 μg $m^{-3}$ at 1 x 1 km (an increase by a factor of 1.7).

The predicted fine nitrate levels are relatively high ranging from 1.78 to 2.24 μg $m^{-3}$ in the coarse-resolution simulation. This is expected in this wintertime period due to the partitioning of nitric acid and ammonium in the particulate phase. This predicted concentration range increases to 1.5-2.24 μg $m^{-3}$ in the finest scale simulation with higher levels in the northeast of the domain. The standard deviation of the predicted concentration does not show any significant trend changing from 0.19 μg $m^{-3}$ at 36 x 36 to 0.15 μg $m^{-3}$ at 1 x 1 km.

For $PM_{2.5}$ ammonium, changes with increasing resolution are modest with the predicted minimum being reduced from 1.07 μg $m^{-3}$ at 36x36 to approximately 0.95 μg $m^{-3}$ at all other higher resolutions. The predicted maximum stays relatively constant between 1.25 μg $m^{-3}$ and 1.27 μg $m^{-3}$ at all resolutions. As with nitrate, the standard deviation does not show any significant trend changing from 0.08 μg $m^{-3}$ at 36 x 36, to 0.09 μg $m^{-3}$ at 12 x 12, to 0.07 μg $m^{-3}$ at 4 x 4 and 1 x 1 km resolutions.

Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

## 4.2 Source Apportionment

We performed zero-out simulations in the 1x1 km Pittsburgh grid to determine the local contributions of eight source categories to the total $PM_{2.5}$. The local sources quantified included: commercial cooking, industrial, biomass burning, on-road traffic, power generation, and miscellaneous area sources. The miscellaneous area sources sector includes a large variety of emission sources that are not classified in any of the sources in Table 2. These include chemical manufacturing, solvent utilization for surface coatings, degreasing and dry cleaning, storage and transport of petroleum products, waste disposal and incineration, and cremation. The emissions from agricultural dust, river barges, off-road equipment, oil-gas activities, and rail were grouped on the "others" source. All emissions (particulate and gas-phase) from each source were set to zero, and the results of the zero-out simulation were subtracted from those of the baseline simulation to estimate the corresponding source contribution. The contribution of long-range transport from outside the inner domain was also estimated by setting all local sources to zero.

Biomass burning is used during the winter for residential heating and recreation. This source contributes a maximum of 3.31 μg $m^{-3}$ in Cranberry, a northern suburb of Pittsburgh located in the neighboring Butler county. In the downtown Pittsburgh area, the contribution from biomass burning accounts for 7% of the $PM_{2.5}$. This source shows the highest variability with a standard deviation of 0.5 μg $m^{-3}$.

The maximum contribution of 8.05 μg $m^{-3}$ from industry is predicted near a cluster of industrial facilities in the town of Butler, 37 km northwest of Pittsburgh. The maximum $PM_{2.5}$ concentration of the modeling domain is located here. In this location long-range transport contributes 37% of the $PM_{2.5}$ followed by industrial sources with 49% and biomass burning with 7%. On average, the contribution from industrial sources is low with 3.7%. In downtown Pittsburgh, the contribution is lower still with 2%.

On-road traffic emissions are most important in major highway intersections and river crossings surrounding downtown Pittsburgh with a maximum contribution of 3.9 μg $m^{-3}$ accounting for 24% of the $PM_{2.5}$ in this area. On average, on-road traffic contributes 2.5% of the $PM_{2.5}$ mass. The contribution from on-road traffic shows higher variability (standard deviation: 0.36 μg $m^{-3}$) since this sector contributes significantly to areas adjacent to the network of highways that radiates from the Pittsburgh downtown.

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

On average, commercial cooking emissions contribute 0.7% of the $PM_{2.5}$ in the modeling domain with a maximum contribution of 2.44 µg $m^{-3}$ in downtown Pittsburgh, with smaller contributions in the surrounding urban area. Cooking is predicted to account for 16% of the $PM_{2.5}$ mass in downtown Pittsburgh. The contribution from commercial cooking is localized around downtown Pittsburgh and therefore shows little variability throughout the domain with a standard deviation of 0.1 µg $m^{-3}$.

The miscellaneous area source sector contributes 6% of the $PM_{2.5}$ on average. Since this sector encompasses a variety of sources and activities, its contribution shows significant variability with a standard deviation of 0.34 µg $m^{-3}$.The maximum contribution is located in the Pittsburgh urban core with 1.64 µg $m^{-3}$, accounting for 11% of the $PM_{2.5}$.

The power generation sector contributes a maximum of 0.63 µg $m^{-3}$ in the plume of the Bruce Mansfield power plant northwest of Pittsburgh. This sector shows the smallest variability with 0.09 µg $m^{-3}$.

Long-range transport from outside the inner modeling domain is the major source of $PM_{2.5}$ during this period contributing an average of 74%. This contribution varies from 7.1 µg $m^{-3}$ in the southeast corner of the domain decreasing in the direction of the Pittsburgh urban core where the contribution is reduced to 5.9 µg $m^{-3}$. In areas where there are significant local emissions such as the Pittsburgh downtown, the contribution from long-range transport decreases to 38%.

Contributions for all remaining sources are largest in the Pittsburgh downtown with 0.74 µg $m^{-3}$, accounting for 5% of the $PM_{2.5}$. This sector also significantly contributes on the Ohio and Monongahela river valleys, where there is important rail and river traffic. On average, these sources contribute 3% of the $PM_{2.5}$ and show a moderate variability with a standard deviation of 0.1 µg $m^{-3}$.

For all local sources, the minimum contribution is close to zero (less than 0.1 µg $m^{-3}$) and is located at the southwestern corner of the domain, near the Ohio – West Virginia border.

Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

## 5. $PM_{2.5}$ concentrations and sources during summer

### 5.1 Effect of grid resolution

The predicted $PM_{2.5}$ concentrations in the simulated summer period are lower than during the winter period and more uniform, however, the qualitative behavior of the model at the different scales remains the same (Figure 6). The standard deviation of the $PM_{2.5}$ increases from 0.28 µg $m^{-3}$ at 36 x 36, to 0.57 µg $m^{-3}$ at 12 x 12, to 0.72 µg $m^{-3}$ at 4 x 4 and to 0.82 µg $m^{-3}$ at 1 x 1 km. At the finest scale, the predicted variability in the summer is 61% of that in the winter. Similar to the winter period, the predicted maximum $PM_{2.5}$ concentration changes significantly with increasing resolution. The predicted maximum $PM_{2.5}$ increases from 6.4 µg $m^{-3}$ at the coarse to 15.3 µg $m^{-3}$ at the fine resolution. The finest scale better resolves the concentration field in the cluster of industrial installations 37 km northwest of Pittsburgh. The minimum $PM_{2.5}$ drops from 6.5 µg $m^{-3}$ at 36 x 36 to 5.3 µg $m^{-3}$ at 12 x 12, and then to 4.7 µg $m^{-3}$ at 1 x 1 km. As in the winter period, the moderate resolution appears to capture the majority of the concentration change from increasing resolution (67%).

The average EC is lower during the summer with 0.28 µg $m^{-3}$ versus 0.43 µg $m^{-3}$ in the winter. The standard deviation of the predicted average EC increases from 0.06 µg $m^{-3}$ at 36 x 36, to 0.09 µg $m^{-3}$ at 12 x 12, to 0.11 µg $m^{-3}$ at 4 x 4 km, and to 0.13 µg $m^{-3}$ at 1 x 1 km. The peak average EC is located in downtown Pittsburgh and increases by a factor of 3.6 (from 0.35 to 1.27 µg $m^{-3}$) moving from the coarse to the finest resolution. It is noteworthy that the peak is 38% less than that of the winter when the coarse resolution is used, but only 21% when the finest resolution is used. The concentration range (difference between the maximum and the minimum) increases from 0.13 µg $m^{-3}$ to 1.12 µg $m^{-3}$ moving from the coarse to the finest resolution. This increase by a factor of 8.6 shows the importance of the local variations of a primary species like EC in an urban area in both summer and winter.

The OA concentration field is quite uniform at the coarse-scale varying by only 0.17 µg $m^{-3}$ (from 1.72 to 1.89 µg $m^{-3}$) with a standard deviation of 0.07 µg $m^{-3}$ (Figure 6). Variablility increases significantly when one moves to the finest scale, with the range increasing to 2.24 µg $m^{-3}$ (from 1.55 to 3.79 µg $m^{-3}$) and the standard deviation of the OA

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

303 field increases to 0.2 μg $m^{-3}$. The use of the finest scale appears to be needed for the
304 resolution of the OA high concentration areas in the summer more than in the winter.
305 The $PM_{2.5}$ sulfate levels during the summer period are on average 12% higher
306 during the summertime period. At the coarse and intermediate scales, the predicted average
307 concentration fields have relatively little structure (Figure 7). The corresponding
308 concentration ranges are relatively narrow (0.05 μg $m^{-3}$ at 36 x 36 km and 0.42 μg $m^{-3}$ at
309 12x12 km). However, a different picture emerges at the fine and especially the finest scales.
310 The plumes from the major power plants can be clearly seen at these higher resolutions.
311 The maximum increased by 0.5 μg $m^{-3}$ from the coarse scale to the finest scale while the
312 minimum is reduced from 1.78 μg $m^{-3}$ at 36 x 36 to 1.05 μg $m^{-3}$ at 12 x 12, to 0.95 μg $m^{-3}$
313 at 4 x 4 and 1 x 1 km. The standard deviation of the predicted sulfate concentration field
314 at the coarse resolution is low and similar to that in winter, 0.02 μg $m^{-3}$. However, the
315 variability at the finest scale in the summer (0.13 μg $m^{-3}$ at 1x1 km) is twice the predicted
316 variability in the winter.
317 The predicted summertime nitrate concentrations are quite low in the area (average
318 0.5 μg $m^{-3}$ in the coarse and 0.46 μg $m^{-3}$ in the finest resolution). The predicted minimum
319 decreases from 0.42 μg $m^{-3}$ at 36 x 36 to 0.39 μg $m^{-3}$ at 12 x 12, to 0.34 μg $m^{-3}$ at 4 x 4, and
320 to 0.3 μg $m^{-3}$ at 1 x 1 km. The predicted maximum concentration increases from 0.56 μg
321 $m^{-3}$ at the coarse scale to 0.71 μg $m^{-3}$ at the intermediate scale and stays relatively constant
322 at higher resolutions. The concentration field is quite uniform with a standard deviation
323 ranging from 0.06 to 0.09 μg $m^{-3}$ for all scales. However, due to the reduction in the
324 predicted minimum the concentration range increases from 0.14 μg $m^{-3}$ at the coarse
325 resolution to 0.37 μg $m^{-3}$ at the finest resolution.
326 The $PM_{2.5}$ ammonium concentration field is quite uniform at all resolutions (Figure
327 7). The concentration range increases from 0.04 to 0.22 μg $m^{-3}$ moving from the coarse to
328 the finest resolution and the standard deviation increases from 0.02 to 0.04 μg $m^{-3}$.
329
330 **5.2 Source Apportionment**
331 During summer, residential biomass burning is minimal. This source contributes a
332 maximum of 0.04 μg $m^{-3}$ and an average of 0.007 μg $m^{-3}$,accounting for 0.6% of the
333 average total $PM_{2.5}$.

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

Power generation sources have the highest average contribution to total $PM_{2.5}$ of all the local sources of 10%. Industrial sources account for 6% of the average $PM_{2.5}$ but are the most important contributor in the point of the modeling domain with the maximum predicted $PM_{2.5}$ conentration. At this location in Butler County, industrial sources account for 58% of total $PM_{2.5}$

As in the winter period, on-road traffic emissions have the largest contribution to the $PM_{2.5}$ in the downtown Pittsburgh area where four large highways intersect. In this location on-road traffic contributes 26% of the $PM_{2.5}$. On average, local on-road traffic contributes around 3% of the $PM_{2.5}$ mass. During the summer period, the variability of the on-road traffic contribution is slightly lower with 0.33 μg $m^{-3}$ compared with 0.36 μg $m^{-3}$ during winter.

Commercial cooking emissions contribute a maximum of 2.08 μg $m^{-3}$ to the average total $PM_{2.5}$ in downtown Pittsburgh. This source accounts for 17% of the $PM_{2.5}$ in the city but only 1% for the entire modeling domain.

On average, the miscellaneous area sources sector contributes 0.26 μg $m^{-3}$ accounting for 4.3% of the $PM_{2.5}$. In downtown Pittsburgh, where the contribution is highest, this source contributes 7% of the $PM_{2.5}$.

Unlike in the winter period, the plumes from major powerplants in the Ohio river valley are clearly resolved in the summer. The power generation sector contributes a maximum of 2.4 μg $m^{-3}$ in the plume of the Bruce Mansfield power plant northwest of Pittsburgh. On average, the 9.4% contribution from this sector to the $PM_{2.5}$ is much larger than in the winter where it only contributed 2.3%. The plume from the Mitchell power plant in the southwest corner of the modeling domain is clearly resolved and reaches all the way to the city. This increases the contribution from power generation to the $PM_{2.5}$ in the downtown core from 0.22 μg $m^{-3}$ in the winter to 0.61 μg $m^{-3}$ in the summer. The maximum contribution of 8.98 μg $m^{-3}$ from industrial sources is a cluster of industrial facilities in the town of Butler, northwest of Pittsburgh.

Long-range transport from sources outside the region contributes a maximum of 5.2 μg $m^{-3}$ in the southeast corner of the domain decreasing in the direction of the Pittsburgh northern suburbs where the contribution is minimal with 4.1 μg $m^{-3}$. On average, long-

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

range transport accounts for 72% of the $PM_{2.5}$ mass. In downtown Pittsburgh, long-range transport contributes 4.24 μg $m^{-3}$ accounting for 35% of the $PM_{2.5}$.

On average, the contribution from all remaining sources is 3.6% and shows a moderate variability of 0.10 μg $m^{-3}$. The contribution from these sources is maximal in downtown Pittsburgh with 0.78 μg $m^{-3}$ accounting for 6% of the $PM_{2.5}$.

For all local sources, the minimum contribution is close to zero (less than 0.1 μg $m^{-3}$) and is located at the northwestern corner of the domain, near the Ohio – Pennsylvania border.

Relative contributions of all local sources to domain average predicted total $PM_{2.5}$ are shown in Figure 9. The largest differences between February and July are the contributions from biomass burning and power generation. In the winter, biomass burning is the most important local source of $PM_{2.5}$, contributing over 8%. In the summer, this source contributes much less than 1% to total $PM_{2.5}$. This discrepancy can easily be explained by the lack of residential wood combustion in the warmer months of the year. Power generation is a significantly more important source in July than in February. This is likely a result of a lower mixing height in the winter combined with emissions plumes from power plants in the Ohio river vally originating from very tall stacks.

The relative contributions of local sources to average predicted total $PM_{2.5}$ in the maximum concentration cell in Butler County and in downtown Pittsburgh are shown in Figures 10 and 11, respectively. The dominant local source in the Butler County location is industrial emissions, due to the proximity of various industrial installations in this area. Industrial sources here account for around 49% of total $PM_{2.5}$ in February and 58% of total $PM_{2.5}$ in July. A lot of the difference in industrial $PM_{2.5}$ at the Butler County location between months is made up by biomass burning in February, which accounts for 7% more of the total compared to July.

## 6. Exposure to $PM_{2.5}$

The population data in the inner domain from the 2010 U.S. census was used to estimate the exposure of the population in the Pittsburgh area to model predictions of $PM_{2.5}$ during winter of 2017 at the different grid resolutions. We ranked the average $PM_{2.5}$ concentrations from all the cells in the modeling domain and created bins of 0.2 μg $m^{-3}$. A

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

sum of the population from all the grid cells that fall within each concentration bin was calculated and divided by the total population of the inner grid to construct population exposure histograms.

### 6.1 Winter $PM_{2.5}$ Exposure

Figure 12 shows the population exposure histograms for the Pittsburgh area (inner domain) for each model resolution. At the coarse resolution, there are only four $PM_{2.5}$ values and 46% of the population is exposed to a concentration of 10.4 µg $m^{-3}$ with decreasing exposure with $PM_{2.5}$ concentration. At a 12 km resolution, the low concentration side of the distribution is better resolved but gaps can still be observed at higher levels. At this intermediate resolution, the largest fraction of the population (15%) is exposed to $PM_{2.5}$ concentrations of 11.8 µg $m^{-3}$.

When the resolution is increased to 4 km the biggest improvements on the model ability to resolve the exposure distribution happen at concentrations higher than 9.4 µg $m^{-3}$. At the fine resolution, no gaps appear in the distribution. A maximum of 12% of the population is exposed to $PM_{2.5}$ concentrations of 12 µg $m^{-3}$ while at the highest concentration of 12.8 µg $m^{-3}$ 3% are exposed. At the 1 km resolution, the distribution is much smoother due to the ability of this finest grid to capture local gradients. The largest fraction of the population (6%) is exposed to $PM_{2.5}$ concentrations of 9.2 µg $m^{-3}$. At the highest concentration of 14.4 µg $m^{-3}$ the exposed population is less than 0.1% as this maximum point is located near industrial installations 37 km northwest of Pittsburgh where the population density is very low.

At resolutions of 36 km, 12 km, 4 km, and 1 km the predicted average population weighted total $PM_{2.5}$ concentration during February 2017 is 9.74 µg $m^{-3}$, 9.77 µg $m^{-3}$, 10.28 µg $m^{-3}$, and 10.00 µg $m^{-3}$, respectively. This represents an increase of only 2.6% when moving from lowest to highest resolution. Relative contributions of local sources to average population weighted $PM_{2.5}$ concentration is shown in Figure 14. Compared to the domain average $PM_{2.5}$ concentrations (Figure 9), many local source contributions are enhanced in terms of average population exposure. In February, weighting $PM_{2.5}$ concentrations by population increases the contribution from biomass burning from 8.3% to 11.7%. Other notable increases include onroad traffic (2.5% to 6.5%), and miscellaneous

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

area sources (5.9% to 9.2%). Other local source contributions to population weighted $PM_{2.5}$ were similar to the corresponding non-weighted concentrations.

### 6.2 Summer $PM_{2.5}$ Exposure

Figure 14 shows the population exposure for each simulation grid during the summer period. At the coarse resolution, 88% of the population is exposed to a concentration of 7 to 7.2 µg $m^{-3}$. At 12 x 12 km resolution, the exposure distribution is better resolved but a gap is still present at 7.2 µg $m^{-3}$ and exposure to $PM_{2.5}$ concentrations above 7.6 µg $m^{-3}$ is not resolved at all. At this intermediate resolution, the largest fraction of the population (19%) is exposed to $PM_{2.5}$ concentrations of 7.4 µg $m^{-3}$. Increasing the resolution to 4 x 4 km both shifts the distribution to slightly lower concentrations and resolves exposure to higher $PM_{2.5}$ concentrations than with the 12 x 12 km grid. At this resolution, 14% of the population is exposed to 6.4 µg $m^{-3}$ and smaller portions of the population are exposed to concentrations higher than 8.0 µg $m^{-3}$. Moving to the highest resolution grid further resolves the exposure distribution. Most notably, 1 x 1 km resolution reveals a bimodal distribution of population exposure, with one peak centered around 6.0 µg $m^{-3}$ and another centered around 7.4 µg $m^{-3}$. This likely corresponds to one subset of the population in the urban areas of Pittsburgh who are exposed to higher $PM_{2.5}$ concentrations and another subset representing the surrounding suburban areas.

At resolutions of 36 km, 12 km, 4 km, and 1 km the predicted average population weighted total $PM_{2.5}$ concentration during February 2017 is 7.06 µg $m^{-3}$, 6.78 µg $m^{-3}$, 7.00 µg $m^{-3}$, and 6.99 µg $m^{-3}$, respectively. This represents just a 1% decrease between the lowest and highest resolutions. Similar to the effect seen in February, weighting $PM_{2.5}$ concentrations by population increases the contribution from onroad traffic from 3.3% to 8.9% in July. Contributions from miscellaneous area sources also increased (4.3% to 7.1%) when weighting by population. The population weighted contribution from power generation sources in July decreased from the non-weighted value from 9.4% to 8.3%. All other local source contributions to population weighted $PM_{2.5}$ in July were similar to the non-weighted values.

Atmospheric Chemistry and Physics Discussions

## 7. Conclusions

We applied the PMCAMx chemical transport model over the city of Pittsburgh for the simulation periods of February and July 2017 using a series of telescoping grids at 36 x 36 km, 12 x 12 km, 4 x 4 km and 1 x 1 km. Emissions were calculated using 2017 projections from the 2011 NEI. Emissions were distributed geographically using the spatial surrogates provided with the NEI11 for all grids. For commercial cooking, a new 1 x 1 km spatial surrogate was developed using restaurant count data from the Google Places API. Traffic model data was used to develop a 1 x 1 km spatial surrogate for on-road traffic emissions.

At the coarse resolution, county-level differences can be observed. Increasing the resolution to 12 x 12 km resolves the urban-rural gradient and further increasing to 4 x 4 resolves large stationary sources such as power plants. Only at the finest resolution intra-urban variations and individual roadways are resolved. Low variability, regional pollutants such as nitrate show limited improvement after increasing the resolution to 12 x 12 km while predominantly local pollutants such as elemental carbon and winter organic aerosol have gradients that can only be resolved at the finest resolution.

Biomass burning shows the largest variability during the winter period with many local maxima and significant emissions within the city and in the suburbs. During the summer contributions from this source are negligible. In contrast with the winter period, during the summer the plumes from large power plants in the Ohio river valley can be resolved. These plumes are rich in sulfates and start being resolved at 4 x 4 km with significant detail added at 1 x 1 km. During both periods the largest contributing source to the average $PM_{2.5}$ is particles from outside the modeling domain.

The ability of the model to resolve the exposure distribution increases at different rates according to the concentration. A significant improvement in resolving exposure to concentrations below 9.4 μg $m^{-3}$ in the winter and below 7.0 μg $m^{-3}$ in the summer is achieved by increasing the resolution to 12 x 12 km. Only at the finest resolution is the exposure to concentrations above 9.6 μg $m^{-3}$ in the winter and above 8.6 μg $m^{-3}$ in the summer fully resolved as well as the impact of high concentration spots.

The average exposure in terms of average contribution to population weighted $PM_{2.5}$ concentrations of some local sources is enhanced compared to the non-weighted

https://doi.org/10.5194/acp-2021-568
Preprint. Discussion started: 2 August 2021

Atmospheric Chemistry and Physics Discussions

487 average $PM_{2.5}$ concentrations. In February, weighting by population enhanced the
488 contributions from biomass burning, onroad traffic, and miscellaneous area sources by 3-
489 4%. In July, the contributions from onroad traffic and miscellaneous area sources also
490 increased by 3-5% from this procedure.
491 It was determined that increasing simulation grid resolution from 36 x 36 km to 1
492 x 1 km had minimal effect on the predicted domain average population weighted $PM_{2.5}$
493 concentration. Moving from the lowest to highest grid resolution increased the predicted
494 average population weighted $PM_{2.5}$ by less than 3%. In July, the average decreased by 1%.
495 This negligible change in the predicted average exposure to $PM_{2.5}$ suggests that extremely
496 high resolution predictions of urban $PM_{2.5}$ pollution may not be necessary for accurate
497 epidemiological analysis, however the increased neighborhood scale resolution could be
498 vital for topics related to environmental justice
