Abstract. After the Fukushima nuclear accident, atmospheric ¹³⁴Cs and ¹³⁷Cs measurements were taken in Fukushima city for eight years, from March 2011 to March 2019. The <u>airborne</u> surface air concentrations and deposition of radio-Cs were high in winter and low in summer; these trends are the opposite of those observed in a contaminated forest area. The <u>effective</u> half-

- 5 lives of ¹³⁷Cs in the concentrations and deposition before 2015 (275-d0.754 and 1.11-30 yr, respectively) were significantly shorter than those after 2015 (756-d2.07 and 4.69 yr, respectively). The half-lives of ¹³⁷Cs in the concentrations and deposition were shorter before 2015, probably because the dissolved radio-Cs was discharged from the local terrestrial ecosystems more rapidly than the particulate radio-Cs. In fact, The-the dissolved fractions of precipitation were larger than the particulate fractions were larger after 2016. The half-lives of ¹³⁷Cs in the concentrations and the particulate fractions were larger after 2016. The half-lives of ¹³⁷Cs in the concentrations and the particulate fractions were larger after 2016. The half-lives of ¹³⁷Cs in the concentrations and the particulate fractions were larger after 2016. The half-lives of ¹³⁷Cs in the concentrations and the particulate fractions were larger after 2016. The half-lives of ¹³⁷Cs in the concentrations and the particulate fractions were larger after 2016. The half-lives of ¹³⁷Cs in the concentrations and the particulate fractions were larger after 2016. The half-lives of ¹³⁷Cs in the concentrations and the particulate fractions were larger after 2016. The half-lives of ¹³⁷Cs in the concentrations and the particulate fractions were larger after 2016. The half-lives of ¹³⁷Cs in the concentrations and the particulate fractions were larger after 2016.
- 10 deposition were shorter before 2015, probably because the dissolved radio-Cs was discharged from the local terrestrial ecosystems more rapidly than the particulate radio-Cs.-X-ray fluorescence analysis suggested that biotite may have played a key role in the environmental behavior of particulate forms of radio-Cs after 2014. However, the causal relationship between the seasonal variations in particle size distributions and the possible sources of particles is not yet fully understood. The current study also proposes an evaluation method of evaluating-the consistency of a numerical model for radio-Cs resuspension and
- 15 suggests that improvements to the model are necessary.

Keywords: Fukushima nuclear accident, long-term observation, radiocesium, atmospheric radioactivity, precipitation radioactivity

1 Introduction

We conducted eight-year measurements of atmospheric ¹³⁴Cs and ¹³⁷Cs in Fukushima city after the Fukushima Daiichi Nuclear Power Plant (FDNPP) accident that occurred in March 2011 to understand the time variations in and emission sources of ¹³⁴Cs and ¹³⁷Cs and to propose effective ways to reduce atmospheric radioactivity. Among the various radionuclides released to the

- 5 environment, radio-Cs is particularly important due to its abundance in terrestrial ecosystems (the impacts of other nuclides were negligibly small 100 days after the accident; Yoshimura et al., 2020), long half-lives (2.06 yr for ¹³⁴Cs and 30.17 yr for ¹³⁷Cs), and bioaccumulation (accumulation in muscle tissues, with biological half-lives of 30-150 d; WHO, 2011). Radio-Cs forms aerosols in the air and is therefore efficiently deposited onto the ground surface via-by precipitation (wet deposition) or during dry weather conditions (in addition to via dry deposition). Approximately 30 % of the radio-Cs released in March 2011
- 10 was deposited onto the ground surface in Japan (the aircraft-measured deposition on the ground was 2.7 PBq for ¹³⁷Cs; (NRA, 2012), and the most updated estimate of ¹³⁷Cs emissions by the Japan Atomic Energy Agency is 10 PBq; (Terada et al., 2020). (The activity of ¹³⁴Cs in the environment was equivalent to that of ¹³⁷Cs in March 2011). Once radio-Cs is deposited onto the ground surface, it circulates within local terrestrial ecosystems, so the discharge from the local environment to downstream or downwind regions may not be substantialis not expected to be significant (0.02 0.3 % yr⁻¹ to river; Iwagami et al., 2017,
- 15 approximately 1 % yr⁻¹ to atmosphere¹). Thus, long-term monitoring of atmospheric radio-Cs at even one station may allow us to understand the mechanisms of its circulation in the local terrestrial ecosystems, to estimate the external and inhalation exposure risks to the local residents, to propose efficient ways to reduce health risks to the residents, and to assess the effectiveness of decontamination efforts.
- To date, a great number of studies have focused on the circulation of radio-Cs in terrestrial ecosystems (Onda et al., 2020). In terms of the long-term monitoring of atmospheric radio-Cs with a focus on resuspension from the ground surface to the atmosphere, several papers have been published as follows. Based on atmospheric measurements taken in the contaminated forest area of the Abukuma Highlands (30 km northwest of the FDNPP) from October 2012 to December 2014, Ochiai et al. (2016) reported that the airborne surface activity concentrations of ¹³⁷Cs were higher in summer and lower in winter and that the time variations of the fine-mode (< 1.1 µm in diameter using an impactor) and coarse mode (> 1.1 µm) behaved differently.
 The coarse-mode fractions were larger in summer, and the fine-mode fractions were larger in winter. Kinase et al. (2018) conducted surface concentration measurements at four locations in the forest area of the Abukuma Highlands from July 2011 to March 2014 and found that the concentrations of ¹³⁴Cs and ¹³⁷Cs were lower in winter and early spring and higher from late spring to autumn. Their size-resolved measurements with a six-stage cascade impactor showed that the backup filter (< 0.39 µm) activity concentrations were high in winter, consistent with Ochiai et al. (2016). However, Kinase et al. (2018) found through scanning electron microscopy (SEM) that there were significant amounts of soil dust particles in the backup filter;

¹ The annual resuspension rate to the atmosphere was estimated as 0.047 % yr⁻¹ by Kajino et al. (2016). However, the current study found that the resuspension rate was likely substantially underestimated (see Sect. 3.5 and Fig. 9). A value of approximately 1 % yr⁻¹ was obtained from improved simulations, but that manuscript is still in preparation.

these particles were larger but bounced off the upper impactor stages. Therefore, they concluded that the sizes of radioactive particles were not small but were actually large (coarse-mode particles). In late spring, the surface-concentrations were positively correlated with the wind speed, so they concluded that the wind-blown soil particles carried radio-Cs in this season. In the summer and autumn, the concentrations were positively correlated with temperature but negatively correlated with wind

- 5 speed, so they concluded that the resuspension mechanisms were different in the winter and summer. The SEM analysis revealed that there were more abundant bioaerosols in summer than in winter. Based on simulations, Kaijno et al. (2016) indicated that the summer peaks in surface concentrations in the Abukuma Highlands could be accounted for by the bioaerosol emissions from forest ecosystems, even though the emission mechanism remains unknown. Igarashi et al. (2019a) further investigated the mechanisms of bioaerosol emissions in forests in summer by using fluorescent optical microscopic observation
- and high-throughput DNA sequencing techniques. They suggested that the fungal spores that accumulate radio-Cs may be significantly involved in resuspension in the forest in summer. Kita et al. (2020) suggested that rain induced the emission of radio-Cs associated with fungal spores in the forest in summer. Minami et al. (2020) combined aerosol flux measurements and a multilayer atmosphere-soil-vegetation model and estimated that the bioaerosol emission flux was on the order of $10^{-2} \,\mu g \, m^{-2} \, s^{-1}$, which could account for the surface concentrations of 137 Cs in the forests in summer (Kajino et al., 2016; Kinase et al.,
- 15 2018; Igarashi et al., 2019a). Kinase et al. (2018) also showed that there was no enhancement in the ¹³⁷Cs concentration associated with forest fire events in the region. The surface concentration of ¹³⁷Cs was not correlated with that of levoglucosan, which is often used as a marker of biomass burning. Certainly, it is not indicated that the forest fire did not reemit radio-Cs, because in fact These results are distinct from those from Chernobyl, where wildfire playeds a key role in the migration of radio-Cs associated with the event in the Chernobyl case (Ager et al., 2019; Igarashi et al., 2020). The contributions of
- 20 additional ¹³⁷Cs emissions from the nuclear reactor buildings of FDNPP to the surface concentrations in Japan were negligibly small compared to the resuspensions from the ground surface (Kajino et al., 2016). On the other hand, unintentional emissions in the premises of FDNPP such as debris removal operations contributed to some observed sporadic peaks (Steinhouse Steinhauser et al., 2015; Kajino et al., 2016), although the impacts of such events might be small in terms of long-term averages and trends.

25

30

The current study is distinct from other studies, as it includes long-term comprehensive measurements (time-resolved and size-resolved measurements of <u>airborne</u> surface-<u>air activity</u> concentrations together with measurements of dissolved and particulate forms of activity in precipitation) at an urban/rural location in the Fukushima Basin in the vicinity of contaminated forests in the Abukuma Highlands. The field observation and the simulation methods are described in Sect. 2. Sect. 3 presents the results for the surface-concentrations (Sect. 3.1), deposition amounts (Sect. 3.2), size distribution (Sect. 3.3), chemical compositions (Sect. 3.4), comparison with simulations (Sect. 3.5), and comparison with measurements taken outside Fukushima Prefecture (Sect. 3.6). The seasonal variations and possible emission sources are discussed in Sect. 4.1, the impacts of decontamination and natural variations on the differences in trends before and after approximately 2015 are discussed in Sect. 4.2, the reasons for the substantial deposition amount in January in Fukushima city are discussed in Sect. 4.3, and major

findings and future issues are summarized in Sect. 5. The observation data used in the study are provided as a Microsoft Excel file in the Supplement.

Figure 1: Map of Fukushima Prefecture and the surrounding prefectures. The locations mentioned in this study and terrestrial elevations are depicted in the map.

2 Methods

2.1 Sampling site

The observation site, Fukushima University, is located in Fukushima city, located in the northernmost basin (Fukushima basin) in the Nakadori Valley, surrounded by the Ou mountains-Mountains to the west and the Abukuma Highlands to the east (Fig. 1). The distance of the observation site from the FDNPP is approximately 60 km. The Nakadori Valley was formed by the Abukuma River, which starts in the mountains in Fukushima Prefecture near the border of Tochigi Prefecture and flows

northeast through the central parts of Fukushima city to the Pacific Ocean in Miyagi Prefecture. The major radioactive plumes arrived twice in Fukushima city, on March 15 and 20 (plume #3 and #8, as identified by Nakajima et al. (2017), respectively). These plumes were transported over the Abukuma Highlands (where the <u>peaks summits</u> are mostly lower than 1,000 m) but were blocked by the higher Ou Mountains (<u>peaks summits</u> are 1,000 - 2,000 m) and thus transported along the Nakadori Valley

5 (Nakajima et al., 2017). The land surface of Fukushima city was contaminated mainly on the afternoon of March 15 with plume #3. The air dose rate in Fukushima city started to increase at 17:00 local time (LT), associated with the weak rain that started at 13:00 LT, and peaked at 19:30 LT at a value of 24.0 μSv h⁻¹.

2.2 Airborne Surface surface air concentrations

2.2.1 High-volume air sampler, cascade impactor, and radioactivity measurement

- 10 The air samples were collected using high-volume air samplers (Kimoto electric Co., Ltd., Model-120SL) placed on the roof of the building at Fukushima University (37.68°N, 140.45°E) at a height of 25 m from above ground level. In this study, we carried out two types of air sampling: time-resolved observations and aerosol size-resolved observations. In the former case, aerosol samples were collected on a quartz fiber filter (Tisch Environmental, Inc., TE-QMA-100). The air suction rate of the sampler was 700 L min⁻¹. The typical duration of each sample collection was 24 hours, from May 8 to September 2, 2011.
- 15 Then, we switched to 72 hours of collection until December 27, 2017; after that, 1 week of continuous collection was performed until March 28, 2019. For the latter observations, a cascade impactor system (Shibata Scientific Technology Ltd., HV-RW) was placed into a high-volume air sampler. The air suction rate was 566 L min⁻¹. The aerosols were collected separately by diameter on six quartz filters (Kimoto, TE-236). The <u>50% cut range</u> of particle sizes <u>ranges</u> in this system was 0.39-0.69, 0.69-1.3, 1.3-2.1, 2.1-4.2, 4.2-10.2, and >10.2 μm. (Note that the sizes in the manuscript indicate the 50 % cutoff aerodynamic
- 20 diameters.) Fine particles with a size of <0.39 µm were captured on a backup filter (Kimoto, TE-230-QZ). The typical sample collection time for the size-resolved observations was three weeks. In types of both observations, activated carbon fiber filters (Toyobo Co., Ltd., KF-1700F 84 mmφ) were also placed at the exit of the high-volume air samplers to collect gas state aerosols-volatile or semi-volatile compounds.</p>
- The collected aerosol samples were sealed into polyethylene bags at Fukushima University. After being shaped into definite shapes, the gamma rays from the samples were measured by high-purity germanium detectors (coaxial with 15, 35 and 40 % relative efficiencies, SEIKO EG&G, ORTEC and coaxial with 40 and 60 % relative efficiencies, CANBERRA) connected to a multichannel analyzer system (MCA7600, SEIKO EG&G) at the Radioisotope Research Center, Osaka University. The radioactivities of ¹³⁴Cs and ¹³⁷Cs were identified at gamma-ray intensities of 605 keV and 662 keV, respectively. The detection efficiencies of the respective detectors for each gamma ray were determined from the same-shape filter samples from standard ¹³⁴Cs and ¹³⁷Cs solutions obtained from the Japan Radioisotope Association. The typical
- measurement time of each sample was 1-3 days. Under these conditions, the detection limits of ¹³⁴Cs and ¹³⁷Cs were

approximately 5×10^{-3} Bq. The errors in the measured values are derived from the systematic error of geometrical configuration and the standard sample itself in addition to statistical error. All radioactivities determined by our measurements were corrected at mid sampling times.

The radioactivities of both ¹³⁴Cs and ¹³⁷Cs were identified for most filter samples. The deviation in concentration 5 between ¹³⁴Cs and ¹³⁷Cs became larger over time due to the relatively short half-life of ¹³⁴Cs. According to the radioactive decay correction performed in March 2011, the activity ratios of ¹³⁴Cs/¹³⁷Cs were approximately 1. These ratios are consistent with those in other reports related to FDNPP accident, so we concluded that the detected radiocesium originated from FDNPP accident. During the measurement period, no radioactivity from ¹³⁴Cs and ¹³⁷Cs was detected from the carbon filters₂; that is, the component of gaseous radioactive cesium was negligibly small.

10 2.2.2 Impactor/cyclone system

Since the filters for the high-volume air samples were quartz fiber filters, they could not be used for elemental analysis with X-ray fluorescence spectrometry (XRF). For the XRF analysis, we used an impactor/cyclone system (Tokyo Dylec Corp., no-number special order, 1100 L min⁻¹) in which the aerosols were separated by size into $< 2.5 \mu m$ and $> 2.5 \mu m$ using an impactor; those $< 2.5 \mu m$ and $> 0.1 \mu m$ were sampled in glass bottles (As One corp., 2-4999-07) using a 0.1 μm cyclone with sampling

15 intervals of one month from September 2014 to January 2018. Aerosols larger than 2.5 μ m were collected on quartz fiber filters in the system and thus only the fine mode particles in the glass bottles were measured by XRF. Aerosol samples in glass bottles (0.1 – 2.5 μ m) were defined as fine-mode PM (PM_f), and those on quartz fiber filters (> 2.5 μ m) were defined as coarsemode PM (PM_c). The radioactivities of ¹³⁴Cs and ¹³⁷Cs in the samples were also measured in the same manner.

2.2.3 Possible artifacts of impactor measurements

- 20 Size separation by an impactor is associated with the artifacts caused by bouncing effects. In fact, in cascade impactor measurements, Kinase et al. (2018) observed abundant coarse-mode particles such as mineral dust and bioaerosol particles in the backup filters due to bouncing effects. In the impactor/cyclone system, the glass fiber filters used as an impaction surface were immersed in silicone oil to prevent particles from bouncing (Okuda et al., 2015). In this study, silicone oil was not used for the cascade impactor but was used in the impactor/cyclone system. However, the long-duration measurements (such as the
- 25 monthlong measurements) could be associated with the larger particles that rebounded at the impactor and were collected in glass bottles (Okuda et al., 2015).

2.3 Deposition (dry plus wet deposition, dissolved and particulate fractions)

The total deposition (dry plus wet deposition or fallout) samples were collected with a precipitation sampler (Miyamoto Riken Ind. Co., Ltd., RS-20) with a funnel diameter of 20 cm. Since a heating device was not installed on the sampler, any snow in

the funnel was manually melted in a water bath in winter. The accumulated snow in the funnel never reached the top of the funnel during the whole observation period. A filtration device was installed in the sampler using membrane filters (Advantec, 4-880-03) with a pore size of $0.45 \,\mu$ m. The radioactivities of ¹³⁴Cs and ¹³⁷Cs in the filtered water stored in the polyethylene bottle and those on the filters were both measured by high-purity germanium detectors at Osaka-Fukushima_University and were defined as the dissolved and particulate fractions of the deposition, respectively. It should be noted here that this separation does not perfectly differentiate water-soluble and insoluble radio-Cs. The clogging of the pores of the membrane filter can occur during filtration. The measured total (dissolved plus particulate) deposition amounts were compared with those measured by the official method of Japan (MEXT, 1976) at the Fukushima Prefecture Nuclear Power Center (Fig. 1), which is located 6.5 km north-northwest of Fukushima University. Our method was found to be consistent with their official method: the correlation coefficient *R* was 0.81, with a slope of 1.1658 (the values from Fukushima University were larger by 16 %). Differences in locations and sampling intervals (daily at the Fukushima Prefecture Nuclear Power Center; monthly at Fukushima University) could also have contributed to the differences in the measured values at the two sites.

2.4 X-ray fluorescence analysis (aerosols, deposition, and river sediments)

X-ray fluorescence (XRF) analysis was carried out by using a RIX1000 (Rigaku Corp.) at Fukushima University. The measurement setup recommended by the manufacturer was used for the XRF. The major and trace element contents were analyzed by the fundamental parameter method and calibration curve method, respectively (Takase and Nagahashi, 2007). Measurements were conducted for PM_f (see Sect. 2.2.2), the particulate fractions of precipitation (see Sect. 2.3), and the river sediments. <u>River sediments that characterize the surface soils of the Nakadori valley were also measured to assess the composition correlations with the airborne and deposition samples.</u> River sediments were collected at 15 sites upstream and downstream of Fukushima city in the Abukuma River and its tributaries in 2010. Samples were taken from the gravel layer of

the lower terrace at 5 sites, from alluvial fan deposits at 1 site, and from current riverbed sediments at 9 sites. The dried sediment samples were sieved and divided into two grain size groups: particles smaller than 180 μm (defined as fine sediment particles) and particles 180 μm - 2 mm (coarse sediment particles).

2.5 Numerical simulation and validation data

5

- 25 Kajino et al. (2016) used a Lagrangian model (LM) to simulate the atmospheric dispersion and deposition of ¹³⁷Cs resuspended from bare soil and forest ecosystems from January to December 2013. Since the resuspension fluxes and size distributions were unknown, they adjusted the flux from bare soil (forest ecosystems) so that the simulated <u>airborne</u> surface concentrations matched those measured in Namie (Tsushima) (Namie High School Tsushima Campus, 37.56°N, 140.77°E, 30 km northwest of the FDNPP) (Fig. 1) in the winter (summer) of 2013, and they adjusted the dry and wet deposition parameters (reflecting
- 30 the size distributions and hygroscopicity) so that the simulated total (dry plus wet) deposition over land in March 2011 matched those measured by the aircraft measurements (NRA, 2012). Thus, note that the size distribution of the simulation was assumed to have submicron size ranges that were consistent with those of the primary emissions (the direct emissions associated with

the FDNPP accident in March 2011) but that may not be applicable for resuspension events; the carrier aerosols are presumed to be soil dust or bioaerosols, which are usually larger thanin the superbmicron size range. Kajino et al. (2016) concluded that their simulations are likely reliable because the simulated differences between the surface concentrations in the contaminated area (or emission source area) (i.e., Tsushima) and those in the downwind area (Meteorological Research Institute (MRI),

5 Tsukuba city, 36.06°N, 140.13°E, 170 km southwest of the FDNPP) (Fig. 1) were consistent with the observed differences at the two locations.

However, Kajino et al. (2016) used only surface concentration measurements to validate the simulations. The current study also used concentration and deposition measurements from Fukushima University for model validation. The previous study compared only the two locations in the contaminated forest areas and in the downwind urban/rural regions; the current study includes an additional location in the urban/rural region near the contaminated forest of the Abukuma Highlands (60 km northwest of the FDNPP).

3 Results

10

3.1 Airborne Surface surface air-concentrations

Figure 2 shows the time variations in the atmospheric radioactivityairborne surface concentrations of ¹³⁷Cs from May 2011 to 15 March 2019. Just after the accident, the ¹³⁷Cs concentrations were higher than 0.01 Bq/m³, and the maximum concentration of 0.0169 Bq/m³ was detected on May 23, 2011. The concentration quickly decreased to a level of 10^{-4} Bq/m³, and the minimum concentration of 4.05×10^{-6} Bq/m³ was obtained on December 5, 2018. By taking the annual averaged value, the decreasing tendency in the atmospheric concentration could be expressed as $Y = 0.0418X^{-0.476}$, where Y indicates the annual mean ⁴³⁷Cs concentration and X means the number of years elapsed. The coefficient of determination, R^2 , is 0.993. This demonstrates that the surface concentration decreased exponentially and halved in approximately 4 years; thus, the decrease rate was higher than

the rate of radioactive decay of ¹³⁷Cs.

It is remarkable that the decreasing <u>trends_tendencies</u> in the earlier stage and the later stage were different. The regression lines of the raw data time intervals for the whole period (red; May 2011 - March 2019), the earlier stage (blue; May 2011 - December 2014), and the later stage (greenlime; January 2015 - March 2019) are shown in Fig. 2, with the half-life (T_h) in days and the decrease rate (R_d) in % yr⁻¹. The decreasing <u>trend-tendency</u> ($T_h = 275-0.753$ dy, $R_d = 92.0$ % yr⁻¹) of the earlier stage is approximately three times faster than that of the later stage ($T_h = 756-2.07$ dy, $R_d = 33.5$ % yr⁻¹). It is shown later in Fig. 3 in Sect. 3.2 and discussed in Sect. 4.2, but this could be related to the relative abundance of particulate and dissolved fractions of radio-Cs in the environment. The dissolved fractions of radio-Cs may discharge faster than the particulate fractions from contaminated environments, such as soils and plants. The relative abundance of the dissolved fractions was larger in the earlier in the later stage than in the later stage such that the decreasing <u>tendencytrend</u> in the <u>surface air</u> concentration was faster than that

in the later stage. In addition to the natural variability, decontamination work, which was completed by March 2018 in Fukushima city and the surrounding municipalities, may also have contributed to the difference in the decrease rates; this possibility is also discussed in Sect. 4.2.

The regression analysis is also performed over different time periods, but the results are not substantially different. 5 The T_h and R_d before December 2013, 2014, and 2015 are 0.670, 0.753, and 0.900 yr, and 103, 92.0, and 77.0 % yr⁻¹, respectively. The T_h and R_d after January 2014, 2015, and 2016 are 2.05, 20.7, and 2.56 yr, and 33.8, 33.5, and 27.1 % yr⁻¹, respectively.

10 Figure 2: Time series of <u>airborne</u> surface <u>air activity</u> concentrations of ¹³⁷Cs on the left axis. The red, blue, and <u>green-lime</u> lines indicate the regression lines of the whole period, before 2015, and after 2015, respectively. The half-lives (T_h) and decay

rates (R_d) are also depicted. The gray line indicates the ratio of the running mean of 20 data points (an approximately monthly cycle) to the running mean of 160 data points (an approximately annual cycle) on the right axis to show its seasonal variation.

It is also interesting that our data show different seasonal variations from those measured in Tsushima by Ochiai et al. (2016) and Kinase et al. (2018). The levels in their studies were high in summer and low in winter, but as depicted in the

- 5 gray line in Fig. 2, the concentration rose starting in October, with maxima in the spring season around March and minima in the summer. The maxima in the spring are approximately one order of magnitude larger than the minima in the summer. The measurements of their studies were conducted in high-dose areas in the mountain forest (approximately 400 m above sea level (a.s.l.)), and the high-volume samplers were set near the ground surface. In contrast, the current air sampling was conducted in a relatively low-dose area (10 times lower than that in Tsushima) located in an urban/rural region on a hill (approximately
- 10 200 m a.s.l.) at the southern end of the Fukushima Basin. The heights of the samples were 25 m from the ground surface. Such geographical and altitude differences could have caused these differences.

3.2 Deposition amounts

Figure 3 shows the monthly cumulative deposition of ¹³⁷Cs from March 2011 to March 2019. The monthly deposition amount peaked in March 2011 as $202.2 \times 10^3 \times 200$ Bq m⁻², decreased to 1 % of the initial amount after one year, and decreased to an order of 1 Bq m⁻² after eight years. It also showed seasonal variation and was high from winter to spring. Nevertheless, the current level is from two to three orders of magnitude larger than that before the Fukushima nuclear accident. The monthly trend is expressed as $Y = 48232X^{-1.944}$, where Y indicates the monthly cumulative.¹²⁷Cs deposition and X means the number of months elapsed. R^2 is 0.697.

- 20 It should be noted here that the initial stage data (i.e., March and April 2011) are excluded to obtain the decreasing rates to extract only the resuspension period and to exclude the influences of primary emissions. The decrease rates of deposition (*T_h* = 1.41-30-4.69 y) were generally slower than those of the surface concentrations (*T_h* = 275-0.753 756-2.07 dy). It is hard-tricky to identify the reason for this phenomenon. A perfect simulation could answer this question, but high uncertainties in atmospheric deposition modeling and land surface modeling inhibit a perfect understanding of these long-term circulations of radio-Cs in the environment. It is safe to presume here that the decreasing tendenciestrends in deposition and surface concentrations are different because the contributions of major emission sources to deposition site and that for of deposition is far from (near) the site, the faster decrease rate in concentration is due to the faster (slower) reduction rate in the nearby sources of emissions than in the far sources.
- 30 There is also a distinct difference in the decreasing <u>tendenciestrends</u> before and after 2015. In addition to the effect of decontamination work, as previously discussed in Sect. 3.1, the relative abundances of the dissolved and particulate fractions

of ¹³⁷Cs could be a part of the reason. The particulate fraction made up 72.6 % of the deposition of March 2011 (Fig. 3), which is presumed to be largely influenced by primary emissions. Here, it is interesting to note that most primary radio-Cs emissions are thought to be composed of water-soluble submicron aerosol particles (e.g., Kaneyasu et al., 2012 and almost all numerical simulations afterwards, such as Sato et al., 2020), while water-insoluble Cs-bearing microparticles (CsMP; Adachi et al., 2013,

- 5 Igarashi et al., 2019b) may contribute somewhat to primary emissions (Ikehara et al., 2020, Kajino et al., 2021). If the primary radio-Cs in aerosols were 100 % in water-soluble forms, the particulate fraction should have made up 0% of the precipitation in March 2011 (although, some of the water-soluble Cs could have converted to a water-insoluble form through adsorption to soil particles accumulated on the membrane filter during filtration). After April 2011, as the contributions of resuspension were thought to be dominant, the dissolved fractions became larger. The ratio varied, but the dissolved fractions were generally
- 10 higher before 2016, and the particulate fractions became dominant after 2016. There seemed to be a regime change in the physicochemical properties of radio-Cs circulating in the environment in the area in approximatelyaround 2015-and 2016, which could have changed the decreasing tendenciestrends of both the surface-concentrations and deposition before and after 2015. This result is consistent with the finding of Manaka et al. (2016), who reported that the exchangeable proportions of radio-Cs rapidly decreased in forest soils from two to four years after the accident, i.e., from 2013 2015.
- 15 The regression analysis is also applied over different time periods and we found a remarkable change in 2015. The T_h before December 2013, 2014, and 2015 are similar 1.09, 1.30, and 1.56 yr, respectively, but T_h after January 2014, 2015, and 2016 are 3.98, 4.69, and 12.67 yr, respectively. The ratios of half-lives (after to before) of the three periods are 3.64, 3.61, and 8.12, respectively, indicating that there could be a remarkable change in the tendency between January 2015 and January 2016. Time series of changes in the ratio before and after a particular date from 2014 to 2016 are illustrated in Fig. S1. Due to
- 20 the lack of data numbers, the half lives after 2015 varied substantially depending on the start month (it exceeded 100 yr for some cases). However, it is obvious that the ratio is stable before January 2015 around 4.0 and start to increase from the spring to summer of 2015. We may be able to conclude that the regime change in the physicochemical properties of radio-Cs occurred during the year of 2015.

Figure 3: (Top) Time series of ¹³⁷Cs activity deposition. The red, blue, and <u>green-lime</u> lines indicate the regression lines of the whole period, before 2015, and after 2015, respectively. The half-lives (T_h) and decay rates (R_d) are also depicted. As T_h and R_d after 2016 are substantially different from those after 2015, the values are additionally depicted in gray. (Bottom) Time series of particulate and dissolved forms of ¹³⁷Cs deposition on the left axis and the ratio of particulate to dissolved ¹³⁷Cs on the right axis.

The seasonal variations in particulate and dissolved ¹³⁷Cs were slightly different from each other and different from those of the surface concentration. The surface concentration peaked in March in almost all years, and the total deposition peaked in January. The peaks of the total deposition in January coincided with those of the dissolved ¹³⁷Cs before 2016, but

5 the peaks of the dissolved ¹³⁷Cs became unclear afterwards. The peaks of particulate ¹³⁷Cs occurred in March before 2016, which coincided with those of the surface-concentrations. After 2016, there were no clear seasonal variations in particulate ¹³⁷Cs. There are clear and different seasonal variations in the surface-concentration and deposition. However, at the current stage, we have no knowledge of or numerical tools to reveal the hidden mechanisms underlying these variations.

3.3 Size distributions

- 10 Figure 4 shows the time series of the seasonal mean atmospheric radioactivity concentrations of ¹³⁷Cs obtained from the cascade impactor measurements. The sampling interval for the cascade impactor measurements was three weeks. The seasonal means included a sampling period if any part of the sampling period was included in the season. For example, the raw data from the sampling period from February to March contributed to the averages of both DJF (December, January, and February, i.e., winter) and MAM (March, April, and May, i.e., spring). The seasonal mean total (all sizes) concentrations of cascade impactor measurements during the sampling period agreed well with those of the time resolved all size observations as presented in (Fig. 2), with *R*² = 0.93. The same seasonal variation discussed for the time resolvedall size observations (Sect. 3.1) was also observed; the atmospheric ¹³⁷Cs concentration was relatively high in DJF and MAM compared to that in JJA (June, July, and August, i.e., summer) and SON (September, October, and November, i.e., autumn).
- The most dominant size range in activity was the backup filter (< 0.39 μm, or rebounded particles such as soil dust and bioaerosols; Kinase et al., 2018), and its seasonal variation agreed well with that of the total particle concentration (high in DJF and MAM). On the other hand, the second largest contribution was made by the size range of 4.2-10.2 μm, which showed the opposite seasonal variation and was relatively high in JJA and SON. The seasonal variations in the largest particle fraction, larger than 10.2 μm, are interesting:- high in DJF and May (same as the backup filter) but high in JJA in 2016 and 2017. The trend appears to be synchronized with that of the backup filter particles (high in DJF and MAM), but the opposite
- 25 trend was observed in 2016 and 2017 (high in JJA). The contributions of other fractions, i.e., 0.49–4.2 μm, were small in the measured period. Even though the contributions were small, the seasonal trend of 0.39–0.69 μm was similar to that of the backup filter particles, but that of 1.3–2.1 μm was similar to that of 4.2–10.2 μm. The reason for the variations and differences is not yet clear, but The the current measurement indicates that the dominant particles and their sizes may be distinct depending on the season. The decrease rates of each size were different before and after approximately 2015, as discussed in Sects. 3.1
- 30 and 3.2, but the size distribution of the surface activity concentration did not change substantially before and after approximately 2015.

Figure 4: (Top) Time series of seasonal mean size-resolved <u>airborne</u> surface <u>activity</u> concentrations of ¹³⁷Cs and (bottom) their relative fractions.

Figure 5: (Top) Time series of <u>airborne</u> surface <u>activity</u> concentrations of ¹³⁷Cs in PM_f (0.1-2.5 μ m) and PM_c (>2.5 μ m) collected by the impactor/cyclone system and those of the backup filter of the cascade impactor. (Bottom) Correlation coefficients of temporal variations among seasonal mean ¹³⁷Cs activity concentrations of different sizes measured by the impactor/cyclone and the cascade impactor. Correlation coefficients higher than approximately 0.4 and lower than approximately -0.4 are colored blue and orange, respectively.

Cascade impactor sampling is associated with the bouncing effect, whereas filters for the impactor/cyclone system were immersed in silicone oil to prevent the bouncing effect. Thus, compared the cascade impactor and the impactor/cyclone measurement data, as shown are compared in Fig. 5. The top panel of Fig. 5 shows the data with the same measurement time intervals (three weeks for the cascade impactor data and one month for the impactor/cyclone data). The surface activity concentrations of ¹³⁷Cs in the backup filters were well correlated with those of PM_f. No remarkable seasonality was observed in PM_c, but some enhancements were observed in JJA in 2015 and SON in 2016.

5

The bottom panel of Fig. 5 shows the correlation coefficients among the seasonal mean size-resolved data from the cascade impactor and impactor/cyclone measurements. If we assume that the bouncing effect on the impactor/cyclone measurements was negligible, the cascade impactor data and the impactor/cyclone data were consistent. There was a positive 10 correlation between PM_f and the backup filter data. There were also positive correlations between PM_c and the 1.3-2.1 μ m and 4.2-10.2 μ m data. There was a negative correlation between PM_c and PM_f, We can assume which strongly indicates that finemode particles are the dominant carriers of ¹³⁷Cs in winter and spring and that coarse-mode particles are the dominant carriers of ¹³⁷Cs in summer and autumn. However, there was also a contradiction in the data. There were low or negative correlation coefficients between the backup filter data and the cascade impactor data at smaller size ranges, such as 0.39-0.69, 0.69-1.3, and 1.3-2.1 µm, but the backup filter data were positively correlated with the impactor data for > 10.2 µm. It appears that 15 bouncing effect might occurred; particles larger than 10.2 µm bounced in the latter stages and were captured in the backup filter. However, as previously discussed, the behaviors of the >10.2 µm-particle data were not consistent in time, i.e., they were generally high in DJF and MAM and were high in JJA in 2016 and 2017 (Fig. 4). Kinase et al. (2018) and Igarashi et al. (2019a) considered that the dominant carriers of resuspended ¹³⁷Cs were coarse-mode particles such as soil dust and bioaerosols. Ochiai et al. (2016) conducted two-stage impactor sampling and measured the airborne_surface activity concentrations of ¹³⁴Cs 20 and 137 Cs above and below 1.1 µm from 2012 to 2014. They showed that the contributions of coarse-mode particles (> 1.1 µm) were dominant, with maxima in summer. The contributions of the fine-mode particles ($< 1.1 \text{ }\mu\text{m}$) were much smaller, and no significant seasonal variations were found. All of their measurement sites were surrounded by contaminated forests in the Abukuma Highlands (Tsushima and the nearby sites), so the sampling sites were different from those in our study. Such larger 25 particles may have contributed to the backup filter data in the current measurements; however, based on the fact that the backup filter data were positively correlated with PM_f and not with PM_c , fine-mode particles (< 2.5 µm) should also play a key role in determining the surface air concentrations in Fukushima city.

On the other hand, if we assume that the bouncing effect is also significant in the impactor/cyclone system due to the long sampling duration, as suggested by Okuda et al. (2015), the positive correlation between the backup filter particles and PM_f was simply due to the bouncing effects of the larger particles in both systems.

Even though the emission sources of the dominant particles collected by the size-resolved measurements could not be identified in this study, the possible aerosol sources that would explain the differences in size and seasonality of the two locations are discussed later, in Sect. 4.1.

3.4 Chemical characterizations of particles in the air, rainfall, and river sediments

- 5 Figure 6 shows the relative abundance of the XRF-measured atomic number concentrations of elements in the PM_f monthly sample from September 2014 to January 2018. Among the 15 detected species, PM_f was mainly composed of SiO₂, Al₂O₃, and SO₃. The fractions of SiO₂ show clear seasonal variations and were higher around May. The seasonal variations in Al₂O₃ and SO₃ are the opposite of that of SiO₂. A positive temporal correlation was obtained between the ¹³⁷Cs in PM_f and SiO₂ (*R* = 0.30). Negative correlations were obtained for Al₂O₃ and SO₃, with correlation coefficients of -0.36 and -0.35, respectively.
- 10 Note that these results do not prove that the SiO₂-bearing aerosols are the carriers of resuspended 137 Cs, but we can safely conclude that the origins of SiO₂ and 137 Cs may be close to each other (i.e., that both come from the same source or the same area/direction).

Figure 7 shows comparisons of the relative abundance of the periodic mean XRF measured atomic number concentrations in different samples, fine sediment particles, coarse sediment particles, PM_f , and particulate fractions of

- 15 precipitation. The PM_f and precipitation data over the same period, from October 2014 and December 2012, were averaged. The sediment samples were collected in 2010. The 10 species that were common to all samples are shown in Fig. 7. The composition differences are not very remarkable, correlation coefficients for the compositions among samples are above 0.9; showing that the samples have similar origins. The features of the PM_f composition were distinct from the others. PM_f included SO₃ (17.8 %) and Cl (2.65 %), while the others did not.
- Weathered biotite is abundant in the soil in Fukushima and absorbs radio-Cs efficiently (Kogure et al., 2019). The compositional correlation coefficients between the weathered biotite (Takase, 2020) and the four samples were high, at 0.73 to 0.87. However, when the two major components SiO₂ and Al₂O₃ were excluded, the compositional correlation coefficients changed significantly. The eight (the common 10 species shown in Fig. 7 minus SiO₂ and Al₂O₃) compositional correlation coefficients between the fine and coarse sediment particles were 0.98, but those between the sediments and PM_f were 0.01 and 0.19 for the fine and coarse sediment particles, respectively. The eight compositional correlation coefficients for the particulate fractions of precipitation were moderate, at 0.36, 0.44, and 0.45 for fine sediment particles, coarse sediment particles, and PM_f, respectively. The eight compositional correlation coefficients for the particulate fractions of precipitation were moderate, particulate fractions of precipitation were 0.76, 0.71, 0.50, and -0.14 for fine sediment particles, coarse sediment particles, particulate fractions of precipitation.

Figure 6: Temporal variations in the chemical composition of PM_f as measured by XRF.

Figure 7: Periodic mean chemical compositions of fine particles and coarse particles in sediments, PM_f, and the precipitation filter (the particulate fraction of precipitation) measured by XRF.

The findings from the current section are summarized as follows. The mean compositions of both fine and coarse sediment particles are similar to those of biotite, which absorbs radio-Cs efficiently. The similar composition feature was observed for the particulate fractions of precipitation. The composition of PM_f was slightly different from those of the other samples, but the ¹³⁷Cs concentrations in PM_f become larger when the relative fractions of SiO₂, the major component of biotite,

5 increased. Thus, biotite may have played a key role in the environmental behavior of radio-Cs in Fukushima city since September 2014. However, the major carriers of radio-Cs before September 2014 and those in the dissolved fractions in precipitation are still unknown.

3.5 Comparison with the simulation results and climatological deposition velocity analysis

In Fig. 8, the surface concentrations of ¹³⁷Cs in 2013 simulated by Kajino et al. (2016) are compared with the time-resolved

10 observation data (Fig. 2). Kajino et al. (2016) included ¹³⁷Cs resuspended from bare soil, ¹³⁷Cs resuspended from forest ecosystems, and additional ¹³⁷Cs emissions from the FDNPP. The additional ¹³⁷Cs emissions were negligibly small, the concentrations of which in East Japan were two to three orders of magnitude smaller than those from the two sources. Therefore, they are not depicted in the figure. The simulation was successful in explaining the magnitude and seasonal variations in surface concentrations at Tsushima and the MRITsukuba, but the simulation at Fukushima city disagreed with the observations.
15 The simulation showed an enhancement of ¹³⁷Cs from forests in the summer, but that was not detected in the observations. The observed magnitude and seasonal trends are rather similar to those simulated for ¹³⁷Cs from soil dust.

Figure 8: Time series of (black) measured <u>airborne</u> surface <u>activity</u> concentrations of ¹³⁷Cs and those simulated (by Kajino et al., 2016; K16) considering different emission sources, (red) mineral dust from bare soil and (<u>greenlime</u>) aerosols emitted from forest ecosystems.

Kajino et al. (2016) used only the observed surface concentrations to estimate the regional budget of resuspended ¹³⁷Cs in the air, but we used the observed deposition to evaluate the model, as shown in Fig. 9. Suppose there is a simple nonlinear relationship between the deposition (D) and <u>airborne</u> surface concentration (C):

$$D = aC^b, \tag{1}$$

where *a* represents a removal rate and *b* represents nonlinearity, such as spatial and temporal variabilities. If one can take a long-term average of *D* and *C*, Eq. (1) may hold. Eq. (1) is reformulated as

5

$$log(D) = b log(C) + log(a).$$
⁽²⁾

The log-log scatter plot between the monthly mean surface concentrations and monthly cumulative deposition of observed (purple) and simulated (orange) ¹³⁷Cs are depicted in the left panel of Fig. 9. The coefficient of determination of the observation was 0.678, with a risk factor for-< 0.1 %. Eq. (1) holds for the monthly mean resuspended ¹³⁷Cs at Fukushima University. As seen in Eq. (2), the intercept of the Y-axis indicates the removal rate *a*. log(*a*) is dimensionless, but if *b* is close to one, the unit of *a* can be m s⁻¹. From Fig. 9, the value of *b* forof observation is close to one. Therefore, the ratios of the monthly deposition amounts to the monthly mean-surface concentrations are referred to as the climatological deposition velocity (m s⁻¹). Time series of the climatological deposition velocity are presented in the right panel of Fig. 9. Note that the concept of climatological deposition velocity. The dry deposition velocity is defined as the ratio of the mass flux divided by the concentrations, but this climatological deposition velocity is only the ratio of total (dry plus wet) deposition

15 amounts divided by concentrations without the concept of mass flux. To account for the wet deposition flux, both in-cloud and below-cloud concentrations are needed, but such vertical measurement data is not available.

Figure 9: (Left) Scatter diagram of (purple circles) observed <u>airborne</u> surface concentrations and deposition of ¹³⁷Cs and those simulated (by Kajino et al., 2016; K16) considering different emission sources, (orange open squares) mineral dust from bare soil and (orange close squares) aerosols emitted from forest ecosystems. The purple and orange lines indicate the regression
5 lines of the observed data and the simulated (both dust and forest) data. (Right) Time series of (blue) climatological deposition velocity on the left axis and (gray) precipitation amounts on the right axis.

The left panel of Fig. 9 clearly shows that the removal rate (*a*) used in Kajino et al. (2016) can be underestimated by one to two orders of magnitude. The deposition velocities used in Kajino et al. (2016) were estimated from the observation of ¹³⁷Cs in March 2011, which was supposed to be mainly composed of submicron water-soluble particles. However, the current study and the series of previous studies regarding resuspended ¹³⁷Cs indicated that the host particles of ¹³⁷Cs could be substantially larger (e.g., soil and bioaerosols). This may be the reason for the overestimation of simulated ¹³⁷Cs <u>concentration</u> from forests in theduring summer in Fukushima city. If the deposition velocities of the model increased by one to two orders of magnitude, the transport of ¹³⁷Cs from the contaminated forest to Fukushima city in summer may decrease such that the simulated surface-concentration in Fukushima city agrees with the observation. Certainly, their simulated regional budget needs to be reassessed using the realistic deposition velocities indicated in the current study.

The observed climatological deposition velocity varied by more than one order of magnitude over time. There are two main deposition mechanisms: dry deposition and wet deposition. Wet deposition is associated with precipitation. The variations in the climatological deposition rate seem to agree with the observed precipitation, but almost no correlation was

20 observed ($R \sim 0.10$). The mean climatological deposition velocity was 5.3×10^{-1} m s⁻¹, and the peak values occurred in January. The maximum value was 4.9 m s⁻¹ in January 2013, when the monthly precipitation was not very high (81.2 mm). Possible reasons for these peaks in January are discussed later, in Sect. 4.3. The typical order of the dry deposition velocity of supermicron (1–10 µm in diameter) particles is approximately 10^{-3} – 10^{-2} m s⁻¹ (e.g., Petroff and Zhang, 2010), which is substantially lower than the values in our climatological deposition velocity analysis. As mentioned above, Certainly, the magnitudes of the instant deposition velocity and our climatological deposition velocity are not directly comparable, but it seems demonstrates that the efficacy of wet deposition as compared with dry deposition. wet Wet deposition plays an important role in the removal of resuspended ¹³⁷Cs-bearing atmospheric aerosolsparticles from the air.

Figure 10: (Left) Scatter diagram of the observed surface deposition of ¹³⁷Cs at Fukushima University and the MRI from March 2011 to March 2019, with a regression line. (Right) Time series of the ratio of deposition at Fukushima University to deposition at the MRI, with a regression line.

10 3.6 Comparison of deposition amounts at Fukushima University and the MRI

15

Figure 10 compares the deposition amounts of ¹³⁷Cs at Fukushima University (60 km northwest of the FDNPP) and the MRI (170 km southwest of the FDNPP) from March 2011 to March 2019. The deposition data at the MRI are available from Environmental Radioactivity and Radiation in Japan (https://www.kankyo-hoshano.go.jp/data/database/, last accessed: June 14, 2021). There was a significant positive correlation between the deposition amounts of ¹³⁷Cs at the two sites, <u>but the ratios varied substantially over time</u>. The slope of the regression indicates that the ratio of deposition at Fukushima University to that at the MRI did not change significantly from the initial ratio during the eight years, which is approximately 8–9 times (202 Bq m⁻² at Fukushima University and 23100 Bq m⁻² at the MRI). This indicates that deposition was influenced by emissions from nearby sources and was not substantially influenced by long range transport at either site. The right panel of Fig. 10 indicates that the deposition ratios at the two sites were approximately 10, which is almost the same level as the initial amounts (202

20 10³ Bq m⁻² at Fukushima University and 17.6 10³ Bq m⁻² at the MRI), with a variation of more than one order of magnitude

and peaks in winter (especially January) that decreased slightly over time. The right panel of Fig. 9 shows that the January peak is a feature of typical at Fukushima city and was not observed at the MRI. The possible reasons for the January peak in Fukushima City are discussed later, in Sect. 4.3. The slight decreasing tendencytrend was probably due to decontamination, which was ongoing in Fukushima during the period until 2018, as shown later in Table 1. Certainly, natural variations could also have contributed to the decreasing tendencytrend.

4 Discussion

5

10

Even eight years after the FDNPP accident, the airborne surface $\frac{\text{air activity}}{\text{concentration of }^{137}Cs has d not fallen to the level$ before prior to the accident, which was at an order of magnitude of 10⁻⁶ Bg m⁻³. In difficult-to-return zones, the surface concentrations sometimes still exceed 10⁻² Bq m⁻³. Based on long-term measurements, this study tries to understand the characteristics of radio-Cs in the air and its deposition and to reveal its origins in order to identify effective ways to reduce radioactivity in contaminated terrestrial ecosystems.

4.1 Seasonal variation and possible sources

The current study clearly shows that the surface concentrations of ¹³⁷Cs are high from winter to spring, with peaks in March and lows from summer to autumn, in the urban/rural area of Fukushima city (60 km northwest of the FDNPP). It also shows that the deposition amounts of ¹³⁷Cs are high in the winter, especially in January, and low from summer to autumn. This 15 seasonal trend is the opposite of that observed in a forested area in the Abukuma Highlands (Tsushima, 30 km northwest of the FDNPP), which was high in the summer (Ochiai et al., 2016; Kinase et al., 20187). From winter to spring, northwesterly winds prevail over the region associated with migrating disturbances, while southeasterly winds prevail over the region associated with the Pacific high pressure system. The three simulated monthly mean surface wind fields for January to March 20 and June to August are shown in Kajino et al. (2016).

In summer, Fukushima city is downwind of Tsushima. The surface concentrations of ¹³⁷Cs at Tsushima are approximately ten times greater than those at Fukushima city, and Fukushima city is downwind of Tsushima, but there is no enhancement of ¹³⁷Cs in summer. The traveling distances of carrier aerosols depend on their aerodynamic diameters. The distance between the two sites is approximately 30 km. The traveling distances of aerosols below $\leq 10 \mu$ m are not very different

and are larger than 100 km because their gravitational deposition velocities are negligibly small. On the other hand, the 25 traveling distances rapidly decrease proportionally to a square of the diameter above 10 µm, and the traveling distance of an aerosol with a diameter of several 100 μ m is an order of 10 km (Kajino et al., 2021). Aerosols below < 10 μ m can travel longer distances, but their dry deposition amounts increase significantly from 1 um to 10 um (Kajino et al., 2021). Igarashi et al. (2019a) reported that the major proportions of bioaerosols in forests in summer are smaller than 5 µm in diameter and can

30 travel a fairly long distance. Pollen is much larger than 10 μ m, but pollen emission is limited in summer (Igarashi et al., 2019a). Consequently, there was a significant enhancement in surface concentrations in the forests in summer but no enhancement in the downwind urban/rural areas, probably because the carrier aerosols were efficiently deposited onto the ground surface by wet deposition in addition to dry deposition before significant amounts of atmospheric ¹³⁷Cs reached the downwind areas. Consistent with our findings presented in Fig. 5, ¹³⁷Cs in PM_c was more abundant than that in PM_f and the backup filter particles

5 in summer. To obtain a quantitative understanding of the regional cycle of atmospheric ¹³⁷Cs in the northern part of Fukushima Prefecture, accurate simulations are required in the future.

In winter and spring, the surface concentrations of ¹³⁷Cs are probably enhanced due to the local emissions from the nearby sources because the location of the sampling site is upwind of the Abukuma Highlands and the ground surface in the upwind areas of the sampling site in the season (northwest directions) is less contaminated than the site. In winter and spring, ¹³⁷Cs in the backup filter particles and PM_f are pronounced in Fukushima city. These characteristics are somewhat different from those reported in previous studies. Miyamoto et al. (2014) measured the size distributions of radio-Cs with a cascade impactor for two periods, from March 17 to April 1 and May 9 to 13, 2011, at a site 120 km southwest of the FDNPP. They showed that the peak size ranges were 1.2 - 2.1 µm and 0.65 - 1.1 µm in the former and latter periods, respectively. Doi et al. (2013) reported that the peak diameters of the ¹³⁷Cs concentration from April 4 to 11 were 1.0 µm and 1.5 µm at Tsukuba, 170 km southwest of the FDNPP. Kaneyasu et al. (2017) measured the size distributions of ¹³⁷Cs and other chemical components six times at Tsukuba from April to September 2011. The peak diameter ranges were 0.49 - 0.7 µm in the earlier stages (before June 9), but the contributions of coarse-mode particles (> 1 µm) increased after June 9, and the second modes appeared in the ranges of 3.5 - 5.2 µm and 7.8 - 11 µm in July and September, respectively. Judging from their measured mass size distributions of Ca, which is assumed to originate from mineral soil, Kaneyasu et al. (2017) concluded that soil particles could be the major

20 carrier of resuspended radio-Cs in Tsukuba. Our XRF analysis indicated that radio-Cs is carried mainly by soil particles in Fukushima city, but the size distributions are greater in PM_f (<2.5 μm) and in the backup filter particles. If radio-Cs is carried by soil particles, it is natural to presume that the fractions of radio-Cs in PM_c would be large (e.g., Fig. 3 of Kaneyasu et al., 2012 or Fig. 4 of Kaneyasu et al., 2017). One could argue that the bounced coarse mode soil particles are observed in the backup filters, but in fact, the seasonal mean ¹³⁷Cs concentrations in the backup filter are positively correlated with PM_f and negatively correlated with PM_c (Fig. 5). One could further argue that bounced large particles are also collected in PM_f despite the special procedures employed to prevent rebound in the impactor/cyclone system.

There are four possible explanations for these results: (1) If the bouncing effect did not occur in either system, the major sources of radio-Cs in Fukushima city are probably related to combustion (a mass peak below 0.39 μm means that the number peak is approximately 100 nm). (2, 3) If the bouncing effect occurred only in the cascade impactor, (2) if the origin of radio Cs is soil particles, (2) the size distributions of soil particles in Fukushima city are smaller, or radio-Cs in the soil exists more within finer particles; or (3) if the origin of radio Cs is soil particles, the coarse-mode fraction deposits to the ground surface faster than the fine-mode fraction, such that the proportion of Cs in PM_f is larger in Fukushima city. (4) The bouncing

effect occurs in both systems, and the origin of radio-Cs is coarse-mode soil particles. (1) is less likely because there is little chance of the artificial combustion of contaminated biomass. In fact, there were no temporal correlations between the ¹³⁷Cs and levoglucosan (a biomass burning marker) surface air concentrations at Tsushima during the forest fire event in the Abukuma Highlands that occurred in March 2013 (Kinase et al., 2018). (3) is also less likely because long-range transport (at

- 5 least 100 km) is required for the major proportions of coarse-mode particles to deposit to the ground surface, whereas Fukushima city is characterized as the emission source region in that season. In terms of (2), the latter sentence, "radio-Cs in the soil exists more with finer particles", contradicts Kaneyasu et al. (2017), suggesting that the radio-Cs is uniformly distributed on the surface of soil particles. (4) is possible, <u>because Okuda et al. (2015) showed that the long-duration</u> impactor/cyclone measurement could be associated with the bouncing effect despite the use of silicone oil. but rebound is
- 10 prevented in the impactor/cyclone system, and there is also no evidence that rebound occurred in the impactor/cyclone system (certainly, there is also no evidence that rebound did not occur). Further experiments are required to determine whether (2) or (4) is more likely and whether some sources are missing. As Kaneyasu et al. (2012) and (2017) reported, comparing the size distributions of ¹³⁷Cs with those of other chemical components in Fukushima city would be an effective way to investigate the origin of resuspended radio-Cs from winter to spring. Alternatively, a PM_{2.5} cyclone or virtual impactor could be used to
- 15 separate the fine-mode and coarse-mode particles, that can completely exclude the bouncing effect.

4.2 Differences in trends before and after approximately 2015 (natural variation and decontamination)

As described in Sects. 3.1 and 3.2, distinct decrease rates were observed before and after approximately 2015 in both the surface concentrations and the deposition. There may be two main reasons for this: natural variation and decontamination. The natural variation (the dissolved fractions of precipitation or the exchangeable proportions of forest soils discharging faster than

20 other forms from the local ecosystems (Manaka et al., 2016)) was previously described, and the effect of decontamination is presented in some detail here.

	March 2014	March 2015	March 2016	March 2017	March 2018
Fukushima City

Table 1: Decontamination achievement ratios in Fukushima City and the surrounding municipalities (Nihonmatsu City, Kawamata Town^a, Date City, and Koori Town)

^aOnly the western part of Kawamata town. The decontamination of areas with an annual cumulative dose exceeding 20 mmSv was assigned to the central government, and that in areas with a dose below 20 mmSv was assigned to municipal governments. The decontamination of the eastern part of Kawamata town was conducted by the central government.

^bRemoval of the litter layer in forests within 20 meters of the forest edge.

5

 Table 1 summarizes the achievement ratios of the scheduled decontamination of different land use types in Fukushima

 city and the surrounding municipalities (available at https://www.pref.fukushima.lg.jp/site/portal/progress.html, last accessed:

- June 14, 2021). The municipalities are in the northern part of Fukushima Prefecture, which comprises 55 % forest area, 15 % farmland area, 6 % residential area, and 23 % other areas (https://www.pref.fukushima.lg.jp/uploaded/attachment/42042.pdf, last accessed: June 14, 2021). More than 94 % decontamination was achieved for the farmland area by March 2014. For the residential and public facility areas, some parts were decontaminated by March 2014, but some others were not fully decontaminated until March 2018. For the road and forest areas, decontamination was not completed in most areas by March
- 15 2014, but extensive decontamination was conducted from 2014 to 2018. Note that only a part of the forest (20 m from the forest edges) was decontaminated, which accounts for approximately 1 % of the whole forest area of the northern part of Fukushima Prefecture. Additionally, only the litter layer of the forest was removed, and the soil layer remained.

Suppose that if contamination occurred independently of the land use type, approximately 30 % (farmland + half of residential and other) of northern Fukushima was decontaminated by 2014, and an additional 15 % (half of residential and

20 other) was continuously decontaminated by 2018. The difference between the decrease rate from May 2011 to December 2014 $(93.1 \% y r^{-1})$ and that after $(30.7 \% y r^{-1})$ was higher than the decontamination rate (30 - 45 % per three to seven years). If the

surface-concentration at Fukushima University was affected mainly by the emissions from nearby sources (i.e., within the northern part of Fukushima Prefecture), decontamination would not be the sole reason for the change in the decrease rates before approximately 2015 and after. Natural variation (i.e., regime changes in the chemical forms of radio-Cs) would likely occur during that period. As previously discussed, biotite may have played a key role in the environmental behaviors of radio-

5 Cs in Fukushima city after approximately 2015, but the current study could not identify the key aerosol particles that carried dissolved (or exchangeable) radio-Cs and were abundant in Fukushima city before approximately 2015.

4.3 Substantial deposition amounts in January in Fukushima city

The climatological deposition velocities (or the ratios of the deposition rate to the mean <u>airborne</u> surface concentration) in Fukushima City were remarkably high in January 2013, 2014, 2015, and 2017 (Fig. 9). They were approximately one order of magnitude larger than those in the other months. The ratio of the deposition in Fukushima and to that at the MRI was approximately 10 on average, but those in January of those years exceeded 100 (Fig. 10). On the other hand, no peaks were observed in January of 2012, 2016, or 2018.

There are two possible explanations for these results: vertical distribution and the existence of superlarge particles. In terms of the former, the substantial proportions of ¹³⁷Cs in the upper air may have caused lower surface concentrations but higher deposition due to the wet removal of ¹³⁷Cs aloft. However, due to the northwesterly winter monsoon, the upper air over Fukushima city is also upwind of the Abukuma Highlands; thus, this possibility is less likely. In terms of the latter, superlarge particles (~100 µm or larger in diameter), have settling velocities that are too high (as high as those of drizzle droplets) to enter the high-volume air sampler but that allow them to settle efficiently in a deposition sampler. A similar feature has been observed in the relationship of the deposition and surface concentration of sodium at observation sites near coastal areas (e.g., particles denoted as large sea salt particles (LSPs) in Kajino et al., 2012). The travel distance of such large particles is

- approximately 1 km (e.g., Kajino et al., 2021), and Fukushima University is surrounded by major roads, such as Route 4 and National Highway E4, within 1 km. January is the month when the highest snow depth occurs in the Fukushima Basin, and the road surface may be wet and muddy due to snow removal work using deicing agents and daytime snow melt on pavements; therefore, road dust emissions from busy transportation activities may be enhanced. The muddy surface conditions may
- 25 produce even larger road dust particles. Although there is no evidence of the existence of such superlarge particles, they may be a possible reason for the substantial deposition amounts in January in Fukushima city. In fact, substantial amounts of road salt from deicing agents could contribute to roadside PM₁₀ samples in winter (Denby et al., 2016), indicating that there could be emissions of particles even larger than 10 μm in diameter. In addition to the direct deposition of ¹³⁷Cs to the rain sampler at Fukushima University, the immediate resuspension of deposited.¹³⁷Cs associated with road dust or road salt from nearby
- 30 roads around the university could contribute additional deposition to the rain sampler. Unfortunately, <u>however</u>, analyses of the surface meteorological observational data for Fukushima City from the JMA, such as temperature, precipitation, snow cover,

and wind speed data, did not reveal the differentiating features between the years with (2013, 2014, 2015, and 2017) and without (2012, 2016, and 2018) high deposition peaks.

5 Conclusions

Eight-year measurements of atmospheric ¹³⁴Cs and ¹³⁷Cs conducted at Fukushima University from March 2011 to March 2019

- 5 are summarized in this study. A high-volume sampler, a cascade impactor, and an impactor/cyclone system were used to collect aerosol samples, and the <u>airborne surface activity</u> concentrations of radio-Cs were detected by high-purity germanium detectors. A precipitation sampler was used to collect deposition samples, and the dissolved and particulate fractions of radio-Cs in the samples were measured. X-ray fluorescence (XRF) analysis was carried out to measure the elemental contents of the aerosol and precipitation samples. The concentration and deposition data measured at Fukushima University were compared with numerical simulation results.
 - The major findings are itemized as follows:

(1) The observed surface concentrations and deposition at Fukushima University (an urban/rural area of Fukushima city, 60 km northwest of the FDNPP) were high in winter and low in summer; these seasonal trends are the same of those observed in the city area (Kitayama et al., 2016) and the opposite of those observed in a contaminated forest area (Ochiai et al., 2016; Kinase et al., 2018) (30 km northwest of the FDNPP, in the Abukuma Highlands). Resuspension due to bioaerosol emissions

15 Kinase et al., 2018) (30 km northwest of the FDNPP, in the Abukuma Highlands). Resuspension due to bioaerosol emissions (Kinase et al., 2018; Igarashi et al., 2019a) may be substantial in forests but may not be in urban/rural areas. The half-life (T_h) and decrease rate (R_d) for the eight years were <u>1.24456 d-yr</u> and 55.6-9 % yr⁻¹ for the concentrations and 2.35-49 yr and 29.527.8 % yr⁻¹ for the deposition, respectively.

(2) The bioavailability of different chemical forms of radio-Cs in soils may be an important factor to determine the tendencies

- 20 of concentrations and deposition at Fukushima University. The decreasing tendenciestrends changed in approximatelyaround 2015 and were associated with changes in the dissolved/particulate fractions of ¹³⁷Cs in precipitation. The T_h and R_d for concentrations before 2015 were 272-0.754 d-yr and 93.12.0 % yr⁻¹, whereas they were 825-2.07 d-yr and 30.733.5 % yr⁻¹ after 2015. The T_h and R_d for deposition before 2015 were 1.10-30 yr and 63.253.4 % yr⁻¹, whereas they were 5.394.69 yr and 12.914.8 % yr⁻¹ after 2015 and 12.7 yr and 5.5 % yr⁻¹ after 2016. The dissolved fractions were higher before 2015, whereas the
- 25 particulate fractions were higher after 2016. This may have been because the dissolved proportion of radio-Cs discharged faster than its particulate forms from the local terrestrial ecosystems. This is consistent with the findings of Manaka et al. (2016). Decontamination likely also contributed to the difference because the decontamination of some land use types, such as agricultural fields, was completed before 2014, and 100 % of the planned decontamination was completed by March 2018. The contribution of decontamination was estimated in this study to be 30 45 % for the three to seven years, which is
- 30 significantly smaller than the differences in the R_d of the concentrations (92.03.1 % yr⁻¹ before 2015 and 30.733.5 (5.5) % yr⁻¹

¹ after 2015 (2016). Therefore, decontamination may play a partial role in explaining the differences in T_h and R_d before and after 2015, but changes in the chemical forms of radio-Cs likely play a major role.

(3) The size-resolved measurements revealed that seasonal variations of ¹³⁷Cs of different sizes are different from each other. Due to the possible bouncing effect of the cascade impactor and long-duration measurement of the impactor/cyclone system,

- 5 it is hard to quantify the values but the current measurement indicates that the dominant particles and their sizes may be distinct depending on the season.showed that the dominant size range in activity in the cascade impactor data was the backup filter (<0.39 µm in diameter, or particles rebounded from larger stages), followed by the 4.2 10.2 µm and >10.2 µm sizes. The backup filter particles were abundant in winter. The seasonal mean ¹³⁷Cs concentrations in the backup filter of the cascade impactor were positively correlated with those in the fine mode aerosols collected by the impactor/cyclone system (PM_f) and
- 10 negatively correlated with those in the coarse-mode aerosols (PM_e). PM_e was high in summer. The impactor/cyclone system prevented the bouncing effect, but bouncing may still have occurred during long duration samplings. The XRF analysis showed that biotite may have played a key role in the environmental circulation of particulate forms of resuspended radio-Cs in Fukushima city after September 2014.

(4) The deposition amounts of ¹³⁷Cs in January were remarkably high compared to the surface concentrations of ¹³⁷Cs and the

15 deposition amounts of ¹³⁷Cs at the MRI. Although we have no observational evidence, we hypothesize that the existence of superlarge particles (~100 μm or larger, with a distance of ~ 1 km or less) associated with snow removal operations on major roads near Fukushima University may be one of the reasons for the remarkable high deposition amounts in January.

Certain issues remained unresolved, and topics for future study are summarized as follows:

(1) The height of our measurement (building roof) is higher than the other measurements referenced in this study (near the

- 20 ground). When the observation site is characterized as an emission source, there should be a clear vertical difference in concentration, and thus the concentration measured at Fukushima University is not equivalently comparable with the other location data. It may be comparable when the site is characterized as a downwind region, because turbulent mixing during transport may reduce the vertical difference. In the future, parallel sampling near the ground and rooftop will need to be installed to characterize the sampling locations and to quantify the vertical differences at the Fukushima University site.
- 25 (2) The rebound issue of the impactor and the cyclone/impactor instruments have not yet been resolved. Parallel sampling is also required for the size-resolved measurements using normal filters and filters with adhesive materials such as vacuum grease. The additional microscopy of the filters is even more useful.

(34) The Abukuma Highlands are upwind of Fukushima city in summer. The enhancement of 137 Cs in PM_c in summer is consistent with the fact that most bioaerosols exist in coarse mode. However, if radiocesium is carried mainly by biotite (i.e.,

30 soil particles) in winter, there should be an enhancement of ¹³⁷Cs in PM_c because major proportions of soil particles exist in

coarse mode (e.g., Kaneyasu et al., 2017). On the other hand, sources of Cs-bearing fine-mode particles such as combustion emissions may be less likely. Thus, the main carrier of radio-Cs may be biotite in winter, but this is still not fully confirmed. XRF measurements were conducted for PM_f from September 2014 to January 2018, when the particulate proportions were dominant in the precipitation. Thus, the carrier aerosols of dissolved radio-Cs in Fukushima city are still unknown. As

5 Kaneyasu et al. (2012) and (2017) reported, comparisons of the size distributions of ¹³⁷Cs with those of other chemical components in Fukushima city would be an effective way to investigate the origin of resuspended radio-Cs from winter to spring. Alternatively, a PM_{2.5} cyclone or virtual impactor could be applied to separate the fine-mode and coarse-mode particles, which can completely exclude the bouncing effect.

(42) The simulation used in this study was made to be consistent with the surface-concentrations in a contaminated forest (Tsushima) and those in a downwind area (the MRI, 170 km southwest of the FDNPP). However, the current study found that the simulated seasonal variation in Fukushima city was totally opposite to the observations. The current study indicated that the deposition velocities applied in the simulation were significantly underestimated. Numerical simulation is a powerful tool for quantitative assessment, but the current simulation requires further improvement. The reasons for the seasonal variations in concentrations and deposition in the different locations need to be investigated with an improved model.

15 (5) The deposition amounts of ¹³⁷Cs in January at Fukushima University were remarkably high compared to the concentrations of ¹³⁷Cs and the deposition amounts of ¹³⁷Cs at the MRI. Although we have no observational evidence, we hypothesize that the existence of superlarge particles (~100 µm or larger, with a distance of ~ 1 km or less) associated with snow removal operations on major roads near Fukushima University may be one of the reasons for the remarkable high deposition amounts in January. The reason needs to be investigated in the future.

Data availability

The observation data used in the study are provided as a Microsoft Excel file in the supplement.

Author contribution

AW conducted the long-term measurements together with KN and AS. YN performed the XRF analysis, and MK performed the numerical simulation. AW, MK, and KN designed the manuscript structure and completed the draft together with all authors.

Competing interests

The authors declare that they have no conflicts of interest.

Acknowledgments

This work was supported by Grants-in-Aid for Scientific Research (KAKENHI), grant numbers JP16H01777 and JP24110009.

- 5 This work was also supported by the Sumitomo Foundation's Environmental Studies Grant and partly supported by the Environment Research and Technology Development Fund (JPMEERF20215003) of the Environmental Restoration and Conservation Agency of Japan. The authors thank Dr. Teruyuki NAKAJIMA of the National Institute for Environmental Studies and Dr. Haruo TSURUTA of the Remote Sensing Technology Center for proving and installing a high-volume sampler and Prof. Naohiro YOSHIDA of Tokyo Institute of Technology for the installation of an impactor observation system. The
- 10 authors thank Dr. Shogo TOGO of the Isotope Research Center of the University of Tokyo for the radioactivity measurements of the initial samples and Dr. Yoshiaki YAMAGUCHI, Dr. Zijian ZHANG, Dr. Makoto INAGAKI, Mr. Shunsuke KAKITANI, Mr. Kazuya FUJIHARA and Mr. Nobufumi FUJITA of Osaka University for their support with the radioactivity measurements of the air samples. The authors also thank Mr. Kakeru KONNAI of the University of Tsukuba for data visualization, Dr. Akane SAYA of the MRI for a useful discussion of aerosol deposition processes, and Prof. Tomoaki OKUDA of Keio University for

15 a useful discussion of the possible artifacts in the impactor measurements.
