**Abstract.**

Vertical profiles of black carbon (BC) play a critical role in modifying the meteorological conditions such as temperature, planetary boundary layer height (PBLH), and regional circulation, which influence surface-layer concentrations of PM<sub>2.5</sub> (particulate matter with a diameter of 2.5  $\mu\text{m}$  or less; surface-layer covers from 0 to 79.5 m). However, BC vertical profiles in current models usually have large uncertainties. In this study, by using measurements of BC vertical profiles in Beijing collected by King-Air350 aircraft and the Weather Research and Forecasting with Chemistry model (WRF-Chem) coupled with an improved integrated process (IPR) analysis scheme, we investigated the direct radiative effect (DRE) of BC with different vertical profiles on meteorology and PM<sub>2.5</sub> concentrations in Beijing during two severe haze events (11-12 December 2016 and 16-19 December 2016). Compared with measurements in Beijing, the model overestimated BC concentrations by 87.4% at the surface and underestimated BC mass by 14.9% at altitudes of 300-900 m as averaged over the two pollution events. The BC DRE with the default vertical profiles from the model heated the air around 300 m altitude but the warming would be stronger when BC vertical profiles were modified for each day using the observed data during the two severe haze events. Accordingly, compared to the simulation with the default vertical profiles of BC, PBLH was reduced further by 24.7 m (6.7%) and 6.4 m (3.8%) in Beijing in the first and second haze events, respectively, with the modified vertical profiles, and hence the surface-layer PM<sub>2.5</sub> concentrations were higher by 9.3  $\mu\text{g m}^{-3}$  (4.1%) and 5.5  $\mu\text{g m}^{-3}$  (3.0%) over central Beijing, owing to increased positive

contributions of vertical mixing and chemical processes. Furthermore, we quantified by sensitivity experiments the roles of BC vertical profiles with six exponential decline functions ( $C(h)=C_0 \times e^{-h/h_s}$  and  $h_s=0.35, 0.48, 0.53, 0.79, 0.82$  and  $0.96$ ) parameterized on the basis of the observations. A larger  $h_s$  means less BC at the surface and more BC in the upper atmosphere, resulting in less solar radiation reaching the ground and consequently a stronger cooling at the surface (+0.21 with  $h_s$  of 0.35 vs. -0.13°C with  $h_s$  of 0.96). Our results indicate that it is very important to have accurate vertical profiles of BC in simulations of meteorology and PM<sub>2.5</sub> concentrations during haze events.

## 1. Introduction

With the rapid economic development and large increases in fossil energy consumption, haze pollution has become one of the most serious challenges in China, especially in the Beijing-Tianjin-Hebei (BTH) region (Wang et al., 2015; Zhang et al., 2019). In 2014 and 2015, the numbers of extremely serious PM<sub>2.5</sub> (particulate matter with an aerodynamic equivalent diameter of 2.5  $\mu\text{m}$  or less) pollution days (with daily mean PM<sub>2.5</sub> > 150  $\mu\text{g m}^{-3}$ ) in Beijing reached 45 and 54, respectively (He et al., 2017). The real-time hourly average concentration of PM<sub>2.5</sub> in Beijing even reached 1000  $\mu\text{g m}^{-3}$  during the severe haze events in January 2013, far exceeding the Chinese Ambient Air Quality Grade I Standards (35  $\mu\text{g m}^{-3}$  for daily mean PM<sub>2.5</sub>) (Liu et al., 2017). With the implementation of the toughest-ever clean air policy since 2013, the observed annual mean PM<sub>2.5</sub> concentrations averaged over 74 cities in China fell from 61.8  $\mu\text{g m}^{-3}$  in 2013 to 42.0  $\mu\text{g m}^{-3}$  in 2017 (Zhang et al., 2016; Wang et al., 2017a; Li et al., 2019; Zhang et al., 2019). However, severe haze events still occurred in Beijing during the COVID-19 lockdown period (January-February 2020) (Huang et al., 2020; Zhu et al., 2020). Therefore, understanding the mechanisms responsible for the occurrence of severe haze is important for air quality management planning.

BC, an important component of PM<sub>2.5</sub>, is emitted mainly from the incomplete combustion of fossil fuel, biofuel, and biomass burning. BC particles can strongly absorb solar radiation in the atmosphere, which alters the Earth's radiation balance (Bond et al., 2013; Huang et al., 2015; Hu et al., 2020). In recent years, researchers have found that the radiative effect of BC significantly affects the structure of planetary

boundary layer (PBL) during severe haze pollution events (Ding et al., 2016; Huang et al., 2018; Wang et al., 2018; Liu et al., 2019). Ding et al. (2016) illustrated by using the Weather Research and Forecasting model coupled with Chemistry (WRF-Chem) that BC suppressed the development of PBL by heating the air in the upper PBL and reducing the solar radiation at the surface in Beijing in December 2013. This process was defined as the “dome effect” of BC by Ding et al. (2016). This “dome effect” was also found over the Indian Ocean (Wilcox et al., 2016). BC can also change the land-sea thermal contrast and induce circulation anomalies during severe haze events (Gao et al., 2016b; Qiu et al., 2017; Ding et al., 2019a; Chen et al., 2021). Ding et al. (2019a) showed by using the WRF-Chem model that, during a haze event in December 2013, the direct radiative effect (DRE) of BC enhanced advection between land and sea by causing a cooling ( $-1.0^{\circ}\text{C}$ ) in air temperature over land and a warming ( $+0.8^{\circ}\text{C}$ ) in air temperature over sea, which transported moist air from the sea to the Yangtze River Delta region. Qiu et al. (2017) and Chen et al. (2021) also reported by using the WRF-Chem model that the radiative effect of BC induced strong anomalous northeasterly winds from the sea during a haze event in North China Plain (NCP) in February 2014.

BC can influence concentrations of  $\text{PM}_{2.5}$  during haze events because of its impact on PBL and other meteorological fields (Gao et al., 2016b; Wilcox et al., 2016; Miao et al., 2017; Qiu et al., 2017; Gao et al., 2018; Wang et al., 2019; Chen et al., 2021). Gao et al. (2016b) used the WRF-Chem model to simulate the haze event that occurred in the NCP in January 2010 and found a maximum increase in  $\text{PM}_{2.5}$  of  $14.4\ \mu\text{g m}^{-3}$  (5.1%) due to the DRE of BC. Qiu et al. (2017) also analyzed the impact of BC on surface-

layer PM<sub>2.5</sub> during a haze pollution in NCP in February of 2014 by using the WRF-Chem model and found that the average PM<sub>2.5</sub> concentration increased by 2.1  $\mu\text{g m}^{-3}$  (1.0%) owing to the DRE of BC. Chen et al. (2021) analyzed, by using the WRF-Chem model, the DRE from the aging of BC and its impact on PM<sub>2.5</sub> concentration over the BTH region during a haze event in February 2014. They found that the near-surface PM<sub>2.5</sub> concentration average over BTH increased by 9.6  $\mu\text{g m}^{-3}$  (7.0%) due to the aging of BC.

So far few studies examined the impacts of vertical distributions of BC aerosol on meteorology and PM<sub>2.5</sub> concentrations. Wang et al. (2018) examined the role of BC at different altitudes in influencing PBL height (PBLH) by considering a single column using the WRF-Chem version 3.6.1. They divided the height from 150 to 2250 m evenly into 7 layers and increased BC concentrations from 0 to 30  $\mu\text{g m}^{-3}$  with an increment of 2  $\mu\text{g m}^{-3}$  at one of the layers with the BC concentrations at the other layers fixed to 0  $\mu\text{g m}^{-3}$ . Model results showed that the near-surface BC could increase PBLH by 0% - 4%, while BC aloft would decrease PBLH by 2% - 16% due to the warming of atmosphere by BC. Current chemistry-climate models were reported not to be able to represent the BC vertical profiles accurately, so sensitivity studies were carried out to adjust vertical profiles of BC in the model by changing the vertical resolution, aerosol microphysical scheme and emission height (Wang et al., 2019; Yang et al., 2019; Watson-Parris et al., 2019).

In recent years, measurements of BC vertical distribution have been conducted by aircraft during the severe haze events in Beijing, using a single particle soot photometer

(SP2) (Zhao et al., 2018; Tian et al., 2019; Zhao et al., 2019; Tian et al., 2020; Liu et al., 2020). During the period of severe pollution from 11 to 19 December 2016, Zhao et al. (2019) collected BC vertical profiles over Beijing by Air350 aircraft and found that the vertical profiles can be classified into two types. The first type was characterized by decreases in BC concentration with altitude, which was the case mainly controlled by local emissions. The second type had maximum BC concentration around 900 hPa, which was mainly affected by regional transport from the polluted south/southwest region. Generally, the first type occurred more frequently than the second type during haze events in Beijing. Observations of vertical profiles of BC in severe haze events over Beijing in 2018 by a King-Air350 aircraft by Ding et al. (2019b) also obtained the same types of profiles.

In this work, we use the BC vertical profiles observed during two severe haze events (11-12 December 2016 and 16-19 December 2016) over Beijing and the online-coupled WRF-Chem model to investigate the DRE of BC vertical profiles on meteorology and PM<sub>2.5</sub> concentrations. Compared with previous studies that examined the impact of BC on meteorology and PM<sub>2.5</sub>, our study is the first to pay attention to the role of BC vertical profile as well as the underlying mechanism. The description of the model, observational datasets and numerical experiments are presented in Section 2. Section 3 evaluates simulated meteorological and chemical variables by comparing with observations. Section 4 compares of the DRE of BC with original and modified vertical profiles, and Section 5 discusses the role of BC vertical profiles in influencing meteorological parameters and PM<sub>2.5</sub> concentrations. The conclusions of this study are

given in Section 6.

## 2. Method

### 2.1 Model configuration

A fully coupled online Weather Research and Forecasting with Chemistry model (WRF-Chem version 3.7.1) (Grell et al., 2005; Skamarock et al., 2008) was employed to simulate the two severe haze events in Beijing from 7 to 20 December 2016 and the initial 4 days are spin-up. This model adopts Lambert projection and two nested domains with grid resolutions of 30 km (domain 01) and 10 km (domain 02). Figure 1 shows that the outer domain covers the most of China with 100 (west-east)  $\times$  100 (south-north) grid cells and the second domain covers the BTH region with 58 (west-east)  $\times$  76 (south-north) grid cells. The number of vertical layers is 29 with the first 15 layers below 2 km for finer resolution in the PBL. Meteorological initial and boundary conditions in this model were derived from National Center for Environmental Prediction (NCEP) Final (FNL) Operational Model Global Tropospheric Analyses (ds083.2) with a spatial resolution of  $1^\circ \times 1^\circ$ . MOZART-4 (Model for Ozone And Related chemical Tracers-4) simulation results provided the initial and lateral boundary conditions for the concentrations of chemical species in our model (Emmons et al., 2010).

Anthropogenic emission data in year 2016 were obtained from the MEIC inventory with a spatial resolution of  $0.25^\circ \times 0.25^\circ$  (Zheng et al., 2018). This inventory includes sulfur dioxide (SO<sub>2</sub>), nitrogen oxides (NO<sub>x</sub>), carbon monoxide (CO), non-methane

volatile organic compounds (NMVOC), ammonia (NH<sub>3</sub>), BC, organic carbon (OC), PM<sub>2.5</sub>, PM<sub>10</sub> and carbon dioxide (CO<sub>2</sub>), which were categorized into agriculture, industry, residence, transport and power generation sectors (Li et al., 2015). The biogenic emissions were calculated online using the MEGAN (Model of Emissions of Gases and Aerosol from Nature), including isoprene, terpene and other substances emitted by plants (Guenther et al., 2006). Biomass burning emissions were taken from the Fire INventory from NCAR (FINNv1.5) which provides daily emissions at a horizontal resolution of ~1 km<sup>2</sup> (Wiedinmyer et al., 2011).

The parameterization schemes of physical and chemical processes of WRF/Chem model adopted in the study are summarized in Table 1. The Carbon-Bond Mechanism version Z (CBMZ) is chosen to simulate the gas-phase chemistry. The aerosols scheme is the Model for Simulating Aerosol Interactions and Chemistry (MOSAIC) which includes sulfate, nitrate, ammonium, chloride, sodium, BC, OC and other inorganic aerosol, and the aerosol particles are divided into 8 particle size segments. However, the formation of secondary organic aerosol is not considered in this scheme (Zhang et al., 2012; Gao et al., 2016a). In MOSAIC, the aerosol particles are assumed to be internal mixture and aerosol optical properties are calculated by the volume averaging mixing method (Barnard et al., 2010; Stelson, 1990). The choice for photolysis schemes is Fast-J photolysis scheme.

## **2.2 Integrated process rate (IPR) analysis**

The IPR analysis has been widely applied to illustrate the impacts of each physical/chemical process on the variations in O<sub>3</sub> concentrations (Zhang and Rao, 1999;

Jiang et al., 2012; Gao et al., 2017; Gao et al., 2018). The improved IPR analysis method developed by Chen et al. (2019) in WRF-Chem model is used in this work to quantitatively analyze the contributions of physical/chemical processes to PM<sub>2.5</sub> concentrations, including the contributions from the sub-grid convection (CONV), vertical mixing (VMIX), chemistry (CHEM), regional transport (TRA), wet scavenging (WET), emission source (EMI) and other processes (OTHER). CONV refers to the transport within the sub-grid wet convective updrafts, downdrafts, and precipitation (Chen et al., 2019) and VMIX is affected by atmospheric turbulence and vertical distribution of PM<sub>2.5</sub> concentrations (Zhang and Rao, 1999; Gao et al., 2018). CHEM represents PM<sub>2.5</sub> production and loss including gas-phase, cloud and aerosol chemistry. TRA is caused by advection, which is highly related to wind and horizontal distribution of PM<sub>2.5</sub> concentrations (Gao et al., 2018; Chen et al., 2019). WET represents the wet removal processes of aerosols by in-cloud scavenging and below-cloud washout. EMI is controlled by emission source. OTHER represents the processes other than the above 6 processes in the model. The NET is the sum of all physical and chemical processes, which matches the variations in PM<sub>2.5</sub> concentrations. It is worth noting that each IPR variable is an accumulated value which is the sum of each time step.

## **2.3 Observational data**

To evaluate the model performance in simulating near-surface meteorological fields, the observed hourly temperature at 2 m (T2), relative humidity at 2 m (RH2), wind speed at 10 m (WS10) and wind direction at 10 m (WD10) at Beijing-Capital International Airport station (40.08°N, 116.58°E) are collected from NOAA's National

Climatic Data Center (<http://gis.ncdc.noaa.gov/maps/ncei/cdo/hourly>). Due to the limited observations of planetary boundary layer heights (PBLH), shortwave downward radiation flux (SWDOWN) and total cloud cover in Beijing, the reanalysis data of 3-hourly PBLH, SWDOWN and total cloud cover for Beijing from the Global Data Assimilation System (GDAS) with a spatial resolution of  $1^{\circ} \times 1^{\circ}$  (<http://ready.arl.noaa.gov/READYamet.php>) were used for model evaluation. More details about the GDAS dataset can be found in Rolph (2013) and Kong et al. (2015). The radiosonde data (temperature and relative humidity profiles) in Beijing were obtained from the University of Wyoming, Department of Atmospheric Science (<http://weather.uwyo.edu/upperair/sounding.html>). Hourly concentrations of PM<sub>2.5</sub>, CO, NO<sub>2</sub>, SO<sub>2</sub> and O<sub>3</sub> at Beijing Station were obtained from the China National Environmental Monitoring Center (CNEMC, <http://www.cnemc.cn/>), which were used to evaluate the model performance in simulating pollutants at the surface. Aerosol optical depth (AOD) at 550 nm over China retrieved from MODIS (Moderate Resolution Imaging Spectroradiometer) satellite was used to evaluate the horizontal distribution of simulated optical properties of aerosols in this study (<https://ladsweb.modaps.eosdis.nasa.gov/>). The MYD03 (Level-1A) product with 1 km spatial resolution from Aqua platform and the MOD03 (Level-1A) product with 1 km spatial resolution from Terra platform were used in this study. The values of daily aerosol optical depth (AOD) at 500 nm and 675 nm in Beijing were obtained from the AERONET data set (<https://aeronet.gsfc.nasa.gov/>).

The vertical profiles of BC mass concentrations in Beijing were collected by King-

Air350 aircraft using SP2 during 11-12 and 16-19 December 2016. The aircraft departed from Shahe (~20 km to the central Beijing) (Fig. 1) at 12:00-13:00 local time (LT) and returned during 15:00-16:00 LT, which avoided the possible diurnal variation of the PBL among flights. Most flights could reach 2.5 km. Zhao et al. (2019) reported that these vertical profiles of BC could be expressed as an exponential decline function  $C(h) = C_0 e^{-\frac{h}{hs}}$  except 11 December 2016, where  $C(h)$  ( $\mu\text{g m}^{-3}$ ) is BC concentration at altitude  $h$  (km),  $C_0$  ( $\mu\text{g m}^{-3}$ ) is BC concentration at the surface, and each  $hs$  value is calculated for each flight of BC vertical profile using nonlinear regression (Table S1). Tian et al. (2019) observed a regional transport of pollution in Beijing from 10 to 12 December 2016 using SP2 and they found a different vertical structure of BC from that of Zhao et al. (2019), with the BC concentration at the altitudes of 400-900 m being 1.5 times higher than the near-surface BC concentration on 11 December 2016. More detailed information about King-Air350 aircraft dataset can be found in Zhao et al. (2019), Ding et al. (2019b) and Tian et al. (2019).

## 2.4 Numerical experiments

To compare the DRE of BC with original and corrected vertical profiles and quantify the role of BC vertical profiles in influencing meteorological conditions and air pollutants, we performed the following numerical experiments as summarized in Table 2.

1. CTRL: The control simulation with the direct and indirect radiative effects of all aerosols (BC, OC, sulfate, nitrate, ammonium,  $\text{Na}^+$ ,  $\text{Cl}^-$  and OIN) included for the time period of 11-20 December 2016. The vertical profiles of BC were the default ones

simulated by the model.

2. NoBCrad: The same as the CTRL simulation, except that the DRE of BC was turned off.

3. VerBC\_obs: The same as the CTRL simulation, except that the BC vertical profiles in the model were modified according to the observed ones. The specific method will be discussed below.

4. VerBC\_hs1-6: The same as the CTRL simulation, except that the vertical profiles of BC in the model were modified according to the exponential decline function ( $C(h)=C_0 \times e^{-h/hs}$ ). The values of  $hs$  in VerBC\_hs1 to VerBC\_hs6 were 0.35 to 0.96 (from small to large), respectively.

5. VerBC\_RT: The same as the VerBC\_hs1-6 simulations, except that the BC vertical profiles in the model were modified according to the observed transport BC vertical profile on 11 December 2016 which was affected by regional transport.

In the case of NoBCrad, the BC DRE was turned off by setting the BC mass concentration equal to zero when calculating the optical properties of BC, following the studies of Qiu et al. (2017) and Chen et al. (2021). In VerBC\_obs experiment, we modified the simulated BC vertical profile online using the observed BC vertical profile on the corresponding day. Firstly, we interpolated the observed BC concentrations to the height of each layer in the model as  $C_{obs\_int(i)}$ . Each layer in the model has a top height and a bottom height and we selected the middle height of this layer for interpolation. Secondly, we used  $C_{obs\_int(i)}$  to calculate the BC mass column burden in each layer ( $M_{obs\_int(i)}$ ) in the model, and  $P_{obs\_int(i)}$  is the percentage of BC mass column

burden in each layer to the total BC mass column burden (Fig. S1) calculated by

$$M_{obs\_int(i)} = C_{obs\_int(i)} * (H_{sim\_top(i)} - H_{sim\_bot(i)}) \quad (1)$$

where  $H_{sim\_top(i)}$  is the top height of layer  $i$  and  $H_{sim\_bot(i)}$  is the bottom height of layer  $i$ .

$$P_{obs\_int(i)} = \frac{M_{obs\_int(i)}}{\sum_{i=1}^{16} M_{obs\_int(i)}} * 100\% \quad (2)$$

In the VerBC\_obs simulation, the simulated BC mass column burden was redistributed to each layer below 2.5 km according to the calculated  $P_{obs\_int(i)}$ . These procedures ensure that the modification of BC vertical profile for each day in the model by using the observed data does not change the total BC mass column burden. Since the aircraft measured only BC concentrations below 2.5 km, we modify BC profile up to the 16th model layer (about 2.5 km in Beijing).

In the experiment of VerBC\_hs1~6, we also used the above method to modify the BC vertical profile by an exponential decline function which is  $C(h)=C_0 \times e^{-h/h_s}$ . However, in cases of VerBC\_hs1~6, we modified for the dates of 12 and 16-19 December. On December 11, BC did not show an exponential decline with height due to the regional transport. In simulation of VerBC\_RT, the method and setting were the same as VerBC\_hs1~6, except that the BC vertical profile in the model was modified according to the observed one on 11 December 2016. In VerBC\_obs, VerBC\_hs1~6 and VerBC\_RT cases, the modifications of BC vertical profiles were performed only when the direct radiative forcing of BC was calculated. All other physical and chemical processes in these experiments still used the original BC vertical profiles simulated by the model. The BC vertical profiles were only modified in the blue square shown in Fig.

1a.

### 3 Model evaluation

#### 3.1 Near-surface air pollutants and BC vertical profiles

Figures 2a-2i show the horizontal distributions of simulated surface-layer PM<sub>2.5</sub> concentrations at 2 pm LT from 11 to 19 December 2016. In Beijing, high PM<sub>2.5</sub> concentrations of 234.1 and 165.9  $\mu\text{g m}^{-3}$  occurred on December 11 and 12, respectively. The severe pollution in Beijing on December 11 was caused by regional transport from the southern heavily polluted area under a prevailing southerly air flow (Tian et al., 2019). From December 16, PM<sub>2.5</sub> started to accumulate in the eastern China and the concentrations of PM<sub>2.5</sub> reached highest value of 217.8  $\mu\text{g m}^{-3}$  on 19 December in Beijing. The daily PM<sub>2.5</sub> concentrations (Fig. 2j) in Beijing had low values during 13-15 December 2016. The model results for Beijing in this paper are the averages over the region of blue square shown in Fig. 1a unless stated otherwise. The severe pollution during 16-19 December 2016 was mainly affected by local emissions. We are mainly focused on the two heavy pollution incidents (11-12 and 16-19 December 2016) in the following sections.

Results from the CTRL simulation were compared with the observed hourly surface concentrations of PM<sub>2.5</sub>, NO<sub>2</sub>, O<sub>3</sub>, CO and SO<sub>2</sub> during 11-19 December 2016 in Beijing in Fig. 3. The observed maximum PM<sub>2.5</sub> concentration of 219.5  $\mu\text{g m}^{-3}$  occurred on December 18, far exceeding the national air quality standard for daily PM<sub>2.5</sub> of 75  $\mu\text{g m}^{-3}$  (Wang et al., 2017a). The correlation coefficient (R), mean bias (MB), normalized mean bias (NMB) and mean fraction bias (MFB) are summarized in Table

3. The model can reasonably reproduce the temporal variations of PM<sub>2.5</sub>, NO<sub>2</sub>, O<sub>3</sub> and CO; the correlation coefficients between simulated and observed hourly concentrations are 0.77, 0.78, 0.66 and 0.73, respectively. The correlation coefficient for SO<sub>2</sub> is lower (0.38). Gao et al. (2016b) explained that WRF-Chem model cannot represent well the SO<sub>2</sub> concentration and its change with time due to the uncertainty in SO<sub>2</sub> emissions and missing heterogeneous oxidation. Compared with observations, the model overestimates the concentrations of PM<sub>2.5</sub> and NO<sub>2</sub> in Beijing with the MBs and NMBs of (13.2  $\mu\text{g m}^{-3}$ , 10.0%) and (8.5 ppbv, 21.6%), respectively, and underestimates the concentrations of O<sub>3</sub> (-0.1 ppbv, -1.2%) and CO (-0.1 ppmv, -4.9%). It should be noted that the model performance in simulating PM<sub>2.5</sub>, SO<sub>2</sub>, CO and O<sub>3</sub> is better during the two haze events than on clean days. For hourly PM<sub>2.5</sub>, for example, the MBs (NMBs) are 29.1  $\mu\text{g m}^{-3}$  (82.5%) on clean days and 6.3  $\mu\text{g m}^{-3}$  (3.5%) during the two haze events. The possible reasons for the overall overestimation of PM<sub>2.5</sub> are as follows: (1) the model biases in underestimating WS10 and daytime PBLH; (2) the uncertainties in anthropogenic emission data (e.g. the overestimation in the BC emissions) (Qiu et al., 2017; Chen et al., 2021). Overall, the model can capture fairly good the two severe pollution events in Beijing during 11-19 December 2016.

Because of the lack of measured BC vertical profiles from 13-15 December 2016 in Beijing, Figure 4 compares only the simulated vertical profiles of BC with observations for the two polluted events (11-12 and 16-19 December 2016). Observed mass concentrations of BC decreased exponentially with altitude in all days except for December 11 when regional transport of pollution dominated. On December 11, the

observed maximum mass concentration of BC ( $7.0 \mu\text{g m}^{-3}$ ) occurred at 850 m altitude, which was much higher than the surface-layer concentration of  $4.7 \mu\text{g m}^{-3}$ . Compared with the observed vertical profiles of BC, the model can well represent the decreases of BC mass concentration with height on December 12 and 16-19, but cannot reproduce the vertical profile on December 11. Possible reasons for model's failing to represent BC vertical profile on December 11 are as follows: (1) the model cannot capture the wind at high altitudes and does not reproduce the high-altitude BC concentrations in the surrounding areas of Beijing; (2) the model underestimates the daily maximum PBLH in Beijing which inhibits the upward transport of surface-layer BC. Averaged over the two pollution events, the simulated BC mass concentration was overestimated by 87.4% on the ground and underestimated by 33.1% at altitude of 1000 m compared with the observations in Beijing. The inaccuracy of the vertical distribution of BC would lead to inaccurate representation of the interactions between BC and PBL, especially in heavily polluted events.

## **3.2 Meteorological parameters**

The first haze event started on December 11 when southeasterlies transported polluted air from southern BTH to Beijing (Fig. 2a). Although the southeasterlies turned into northeasterlies in Beijing on December 12,  $\text{PM}_{2.5}$  concentrations were still high because of the high relative humidity (63.2%) that was conducive to the formation of secondary aerosols. With the relatively high wind speed of  $3.6 \text{ m s}^{-1}$  and low relative humidity of 37.2% in Beijing during 13-15 December, the haze pollution gradually disappeared (Fig. 2c-2e). From 16 to 19 December,  $\text{PM}_{2.5}$  began to accumulate again

with unfavorable diffusion conditions (WS10 of  $1.4 \text{ m s}^{-1}$ ) and enhanced formation of secondary aerosols under high relative humidity of 67.1% (Li et al., 2019; Dai et al., 2021). Throughout the simulated period of 11-19 December 2016, Beijing had no precipitation and was partly cloudy (Fig. 5g-5h). Figure 5 shows the hourly simulated and observed T2, RH2, WS10, WD10, PBLH, SWDOWN, precipitation and total cloud cover in Beijing from 11 to 19 December 2016. The statistical metrics are summarized in Table 3. In the two severe haze events, the observed maximum RH2 in each day exceeded 70.0%, which accelerated the formation of secondary aerosols (Sun et al., 2006; Wang et al., 2014). Compared with the observations, the model can well represent the temporal variation of T2 and RH2 with correlation coefficients of 0.77 and 0.75, respectively, but slightly overestimates T2 with a MB of  $0.1 \text{ }^{\circ}\text{C}$  and underestimates RH2 with a MB of 3.4%. For WS10, observations and simulated results both show low wind speed with the mean values of  $1.5$  and  $1.4 \text{ m s}^{-1}$  in Beijing during the two periods of haze events. Such meteorological condition was very beneficial to the accumulation of near-surface pollution. The WRF-Chem model also captures the high values of WS10 from 14 to 15 December. For wind direction at 10 m, the NMB is -9.0% and the R is 0.45, which indicates that the model can simulate the change of wind direction during the period of heavy pollution. For PBL, the reanalysis PBL was 118.7 m during the two severe haze events, compared to 287.5 m during the clean period. The model can represent the change of PBLH in Beijing from 11 to 19 December 2016 with R of 0.72. The model overestimates PBLH by 30.9 m (17.7%) in Beijing as averaged over 11-19 December 2016. The overestimation is mainly in hours of 0:00-8:00 LT and 17:00-

23:00 LT. It is noted that the reanalysis PBLH values provided by GDAS of NOAA were mostly 50-60 m at 0:00-8:00 LT and 17:00-23:00 LT in Beijing, far below the simulated mean value of 154.5 m in these hours. There might be biases in the PBLH from GDAS. Several previous studies showed that the values of observed PBLH from Lidar measurements were about 200 m at night during haze events (Wang et al., 2012; Luan et al., 2018; Chu et al., 2019). The simulated SWDOWN in CTRL experiment agrees well with the observations with R and MB of 0.76 and -14.9 W m<sup>-2</sup>. Due to the limitation of the model outputs, the model provides only information of whether there is cloud in the grid or not. The model can reproduce well the presence of cloud during 11-19 December 2016. Both observations and model results show no precipitation in the studied time period.

The simulated and observed vertical profiles of temperature in Beijing during 11-19 December 2016 are shown in Fig. S2. The observed temperature vertical profiles are available only at 8:00 and 20:00. During the two severe pollution events, strong temperature inversions below 1500 m were observed in Beijing, which inhibited vertical mixing and caused the accumulation of pollutants near the ground. The model captures these temperature inversions well but overestimates the inversion layer height on December 11 and underestimates the inversion layer height from 16 to 19 December. The inaccuracy of the simulated inversion layer height may be due to the fact that the model cannot correctly represent the vertical profiles of BC (Fig. 4).

### **3.3 AOD and AAOD**

AOD (AAOD) is the measure of aerosols (absorbing aerosols) distributed within a

column of air from the surface to the top of the atmosphere (Khor et al., 2014). Figure S3 shows the horizontal spatial distributions of observed and simulated AOD at 550 nm over the NCP averaged over 11-19 December 2016. The model can generally reproduce the horizontal distribution of AOD, with a spatial correlation coefficient of 0.89. However, the model underestimates AOD over the NCP region. Many previous studies have shown that MODIS retrieval tends to overestimate AOD over NCP (Li et al., 2016; Qiu et al., 2017). We also compared the simulated hourly AAOD at 550 nm with AERONET AAOD in Beijing and Xianghe station in Fig. 6. The correlation coefficient between simulations and observations is 0.85. Compared with AERONET AAOD, simulated AAOD values at Beijing and Xianghe are overestimated by 0.02 (33.3%) and 0.02 (39.9%), respectively.

#### **4. A comparison of BC DRE with original and modified vertical profiles**

As shown in Fig. 4, the model does not represent well the vertical distribution of BC concentrations during the two heavily polluted events, especially on December 11. So, in this section, we examine the differences in the BC DRE on meteorology and concentrations of pollutants with the original and modified vertical profiles.

##### **4.1 Direct radiative effect of BC on meteorology**

Figure 7 shows the atmospheric temperature and PBLH simulated from the CTRL simulation and their changes caused by BC DRE with original profiles (CTRL minus NoBCrad) and modified profiles (VerBC\_obs minus NoBCrad), over Beijing from 11 to 19 December 2016. Light-absorbing BC heated the air at around 300 m on December

11 and 16-19, regardless of the original or modified BC vertical profiles (Fig. 7b and 7c). With the original and modified BC profiles, the maximum warming effects in the PBL were 0.8°C and 0.9°C, respectively, at 14:00 LT on December 18. Although BC concentration was the highest at the surface, the largest increase in temperature occurred in the upper layers because of the stronger shortwave absorption efficiency of BC at higher altitude (Ding et al., 2016; Wang et al., 2018). The warming at around 300 m resulted in a more stable stratification, thereby weakening convective motions (Gao et al., 2018). The largest reductions in PBLH were 133.8 m (28.0%) at 14:00 LT on December 12 and 141.2 m (59.0%) at 14:00 LT on December 18 in Beijing with original and modified BC vertical profiles, respectively. On December 11 when regional transport of pollution dominated, relative to the simulation with original BC profile, simulated air temperature with modified profile was lower by about 0.5°C within the PBL (Fig. 7d), which was caused by the observed maximum mass concentration of BC around 850 m altitude (Fig. 4a). Correspondingly, the maximum reduction in PBLH of 74.2 m was also simulated on December 11. On December 16-19 when local emissions dominated, compared the effects of original BC profiles, the air temperatures at around 300 m were all higher with modified BC. The largest difference of +0.1°C was simulated in the PBL on December 18 (Fig. 7d).

Figure 8 shows the spatial distributions of changes in T2, sea-level pressure (SLP) and wind at 10 m caused by BC DRE with original and modified vertical profiles. BC DRE with both original and modified vertical profiles produced anomalous northeasterlies in eastern BTH during the two haze events. The mechanism of such

changes is that BC DRE induced a strong warming over the Bohai Sea in the east of BTH with a maximum warming of about 1.8°C, resulting in an anomalous low-pressure here and consequently anomalous northeasterlies in eastern BTH (Fig. 8c-8d). The similar changes in winds caused by the heating effect of BC were also reported in previous studies (Gao et al., 2016b; Qiu et al., 2017; Chen et al., 2021).

## 4.2 Direct radiative effect of BC on PM<sub>2.5</sub> concentration

By altering the meteorological conditions, BC exerts feedback onto PM<sub>2.5</sub> concentrations. Figure 9 illustrates the impacts of BC DRE with original and modified vertical profiles on surface-layer PM<sub>2.5</sub> as well as the differences in simulated surface-layer PM<sub>2.5</sub> between VerBC\_obs and CTRL (VerBC\_obs minus CTRL) in Beijing during the two haze events. Because of the differences in BC-induced changes in air temperature, wind field, and PBLH, changes in surface-layer PM<sub>2.5</sub> concentrations in the northern and southern Beijing were different. In the first haze event of 11-12 December, although PBLH was reduced in the northern Beijing due to BC DRE, enhanced northerlies brought in relatively clean air to northern Beijing, leading to decreases in surface-layer PM<sub>2.5</sub> concentrations with maximum values of 12.5 µg m<sup>-3</sup> (9.4%) and 10.6 µg m<sup>-3</sup> (8.0%) in this region with the original and modified BC vertical profiles, respectively. Nevertheless, PM<sub>2.5</sub> concentrations increased by up to 17.8 µg m<sup>-3</sup> (6.6%) and 24.0 µg m<sup>-3</sup> (9.3%) in the southern Beijing due to BC effect with original and modified vertical profiles, respectively. In the second haze event of 16-19 December, the surface-layer PM<sub>2.5</sub> concentrations increased in most areas of Beijing with both vertical profiles. Compared to the simulation with the original profiles, the

modified profiles of BC led to larger increases in  $\text{PM}_{2.5}$  concentrations over Beijing, and the maximum differences in  $\text{PM}_{2.5}$  were simulated over central Beijing, which were  $9.3 \mu\text{g m}^{-3}$  (3.6%) and  $5.5 \mu\text{g m}^{-3}$  (3.1%) in the first and second haze events, respectively.

To explain the changes in surface-layer  $\text{PM}_{2.5}$  concentrations in Beijing due to BC effects, we carried out process analysis for  $\text{PM}_{2.5}$  for 12:00-18:00 of each day when the DRE of BC is the largest (Figs. 9a3, 9b3, and 9c3). From 11 to 19 December 2016, VMIX had dominant positive contribution to changes in  $\text{PM}_{2.5}$  concentration, which reached the maximum contributions of  $32.4 \mu\text{g m}^{-3}$  and  $33.9 \mu\text{g m}^{-3}$  on December 18 with original and modified BC vertical profiles, respectively. The vertical mixing was strongly restrained by PBLH, therefore, the decreases in PBLH caused accumulation of  $\text{PM}_{2.5}$  in the lower layers. Meanwhile, CHEM contributed  $4.8 \mu\text{g m}^{-3}$  and  $6.1 \mu\text{g m}^{-3}$  to  $\text{PM}_{2.5}$  changes because more aerosol precursors restrained in the boundary layer led to the formation of secondary particles. TRA was the major process that had negative contribution to the changes in  $\text{PM}_{2.5}$ , which can be explained by the enhanced northerlies in the central part of NCP due to BC effects as shown in Fig 8. Relative to the case with original BC vertical profiles, VMIX and CHEM contributions increased largely with modified profiles, with increases of  $8.6 \mu\text{g m}^{-3}$  (6.5%) and  $7.7 \mu\text{g m}^{-3}$  (26.8%), respectively, as averaged over the two haze events, reflecting the further decreases in PBLH (Fig. 7d).

Figure 10 shows the vertical profiles of the contributions of physical/chemical processes to changes in  $\text{PM}_{2.5}$  over Beijing due to BC DRE with original (CTRL minus NoBCrad; Figs. 10a1 and 10b1) and modified vertical profiles (VerBC\_obs minus

NoBCrad; Figs. 10a2 and 10b2) in the two haze events. In the first haze event of 11-12 December when regional transport of pollution dominated, the NET contribution to  $PM_{2.5}$  was positive below 256 m, because of the positive contribution of VMIX was larger than the negative contribution of TRA. However, in the upper layers (from 256 to 1555 m), the contributions of VMIX and CHEM became negative with both original and modified vertical profiles, which can be explained by the decreases in PBLH inhibiting the transport of low-layer pollutants to the upper layer. Compared to the original BC vertical profiles, the modified BC vertical profiles increased  $PM_{2.5}$  in the entire vertical layers below 2080 m, in which the positive contribution between 256-757 m was caused by TRA. These results agree with the observed high concentrations of BC at altitudes of 600-1500 m on December 11 (Fig. 4a). In the second haze event, the NET contribution to  $PM_{2.5}$  was positive below 127 m and negative at 127-504 m. However, the effects of BC on  $PM_{2.5}$  were small above 504 m because BC concentrations decreased rapidly with altitude.

### **4.3 Model performance in simulating meteorology and $PM_{2.5}$ with the original and modified BC vertical profiles**

It is of interest to compare the performance of CTRL (with original BC vertical profiles) with that of VerBC\_obs (with modified BC vertical profiles) in simulating meteorological parameters and  $PM_{2.5}$  during the two haze events. Figure S4 shows the comparisons between observed T2, RH2, WS10, WD10, PBLH and the simulated values from the CTRL and VerBC\_obs simulations in Beijing in the two haze events (11-12 December and 16-19 December 2016). Relative to CTRL simulation with

original BC vertical profiles, VerBC\_obs simulation with modified BC vertical profiles has better performance in simulating T2, WS10 and PBLH except for WD10 and RH2 in the first pollution event. While the MBs of T2, RH2, WS10, WD10 and PBLH are 0.2°C, 0.0%, -0.4 m s<sup>-1</sup>, 3.8°, and 45.0 m in CTRL, they are 0.0°C, 2.2%, -0.1 m s<sup>-1</sup>, 10.9°, 29.0 m in VerBC\_obs, respectively (Table S3). In the second pollution event, the positive bias in PBLH (MB=43.7 m, NMB=42.9%) in CTRL is reduced to 33.9 m and 33.3% in VerBC\_obs.

Table S4 shows the statistical comparison between observed hourly surface-layer PM<sub>2.5</sub> and the model results from CTRL and VerBC\_obs in Beijing for each day during the two haze events. The model with modified BC vertical profiles can enhance the capability in simulating the temporal variation of PM<sub>2.5</sub> for each day; the correlation coefficient between simulated hourly concentrations and hourly observations in each day of the studied period increased from 0.04-0.84 in CTRL to 0.24-0.93 in VerBC\_obs.

## **5. Roles of BC vertical profiles**

BC has higher light-absorbing efficiency at higher altitudes (Ding et al., 2016; Wang et al., 2018). As described in Section 2.3, the observed vertical profiles of BC on heavily polluted days (12 and 16-19 December) can be parameterized as exponential decline functions using nonlinear regression ( $C(h)=C_0 \times e^{-h/h_s}$ ) with  $h_s$  values of 0.35, 0.48, 0.53, 0.79, 0.82 and 0.96, and the profiles affected by regional transport had high concentrations of BC at high altitudes. We conducted seven sensitivity experiments which applied six exponential functions and one observed transport-dominated vertical profile, as described in Section 2.4, to examine the roles of BC vertical profiles in

influencing meteorological conditions and PM<sub>2.5</sub> during severe haze events. In these sensitivity experiments, we only modify the BC vertical profiles for the dates of 12 and 16-19 December. In the function of  $C(h)=C_0\times e^{-h/h_s}$ , a larger  $h_s$  means less BC at the surface and more BC in the upper atmosphere, as shown in Fig. 11.

## 5.1 Impacts of BC vertical profiles on meteorology

Figure 12 shows the simulated changes in atmospheric temperature induced by BC DRE with exponential functions (VerBC\_hs1-6 minus NoBCrad) and with the transport-dominated vertical profile (VerBC\_RT minus NoBCrad). BC had a significant warming effect at altitudes of 256-421 m from 12:00 to 18:00 (Fig. 7). Generally, with the value of  $h_s$  gradually increasing, the BC-induced warming in the afternoon around 300 m became smaller, which can be explained by the highest mass fraction of BC at the altitudes of 256-421 m to total BC column burden in VerBC\_hs1 case (31.7%) and the lowest percentage in VerBC\_hs6 case (21.7%) among the six sensitivity experiments (Fig. S1). The maximum warming around 300 m was 0.42°C in VerBC\_hs1 case and 0.19°C in VerBC\_hs6 case. It should be noted that BC led to a significant cooling effect at the surface (below 80 m) when  $h_s$  values were 0.79, 0.82 and 0.96, with the changes in temperature by -0.08, -0.09 and -0.13°C, respectively. Because more BC mass was assigned into high altitudes (above 1000 m) with higher  $h_s$ , less solar radiation could reach the ground (Fig. S5). These results are consistent with those found in previous modeling and observational studies (Cappa et al., 2012; Ferrero et al., 2014; Ding et al., 2016; Wang et al., 2018). Meanwhile, in the case of VerBC\_RT, BC also had a cooling effect of -0.30°C at the surface (Fig. 12g). In current regional air

quality models, the uncertainties in BC profiles could influence the capability of a model to simulate a cooling effect of BC on surface-air temperature (Wang et al., 2019).

We further use the difference in temperature between the upper PBL ( $T_H$ ; 256-421 m) and the ground ( $T_L$ ; 0-127 m) ( $\Delta T_{BC} = T_H - T_L$ ) averaged over 12:00-18:00 LT of 12 and 16-19 December to quantify temperature inversion caused by BC DRE. BC aerosol leads to cooling at the surface and warming in the upper PBL, both of which weaken the convection in the boundary layer and consequently reduce the PBLH (Ding et al., 2016; Wang et al., 2018; Chen et al., 2021). In our study, with  $h_s$  values increasing from 0.35 to 0.96,  $\Delta T_{BC}$  increased from 0.17 to 0.42°C, and the  $\Delta T_{BC}$  value was 0.51°C in VerBC\_RT case (Fig. 13a). The larger  $\Delta T_{BC}$  indicates stronger cooling at the surface, such temperature inversion at 12:00-18:00 LT resulted in more stable stratification and further inhibited the development of PBL. The cooling at the surface also reduced sensible heat flux from the surface (Fig. S5), suppressing vertical turbulence and hence reducing PBLH (Wilcox et al., 2016). As a result, the reductions in PBLH were larger with higher  $h_s$  (Fig. 13b). The minimum decrease in PBLH was -31.9 m (-14.3%) with  $h_s$  value of 0.35 and the maximum decrease was 48.9 m (22.0%) with  $h_s$  value of 0.96, as averaged the period of 12:00-18:00 of 12, 16-19 December. In the case of VerBC\_RT, the mean PBLH was reduced by 56.9 m (25.6%) during the period of 12:00–18:00.

## 5.2 Impacts of BC vertical profiles on PM<sub>2.5</sub> concentration

Figure 14a shows the changes in surface-layer PM<sub>2.5</sub> concentration caused by BC DRE with six exponential functions (VerBC\_hs1-6 minus NoBCrad) and the transport-dominated vertical profile (VerBC\_RT minus NoBCrad) averaged over 12 December

578 and 16-19 December 2016. From 0:00 to 11:00, the surface-layer PM<sub>2.5</sub> exhibited larger  
 579 BC-induced decreases with a higher value of  $h_s$ . This can be explained by the negative  
 580 contribution of TRA process that increased during the period of 0:00-5:00 (Figs. 14b  
 581 and 14c) when  $h_s$  value changed from 0.35 to 0.96. The surface-layer PM<sub>2.5</sub>  
 582 concentration was reduced by up to 9.1  $\mu\text{g m}^{-3}$  (6.2%) and 12.6  $\mu\text{g m}^{-3}$  (8.6%) at 5:00  
 583 with  $h_s$  values of 0.35 and 0.96, respectively. Compared to the NoBCrad case, the  
 584 surface-layer PM<sub>2.5</sub> concentrations were reduced by up to 13.8  $\mu\text{g m}^{-3}$  (9.4%) at 5:00  
 585 due to BC DRE in VerBC\_RT case. From 12:00 to 18:00, the BC-induced increase in  
 586 surface-layer PM<sub>2.5</sub> concentrations was larger as  $h_s$  values were higher; relative to  
 587 NoBCrad simulation, the mean PM<sub>2.5</sub> concentrations were increased by 5.5  $\mu\text{g m}^{-3}$   
 588 (3.4%) and 7.9  $\mu\text{g m}^{-3}$  (4.9%) with the  $h_s$  values of 0.35 and 0.96, respectively. Because  
 589 the PBL was suppressed by BC DRE from 12:00 to 15:00, the contributions of VMIX  
 590 and CHEM to surface-layer PM<sub>2.5</sub> were positive and larger in magnitude than the  
 591 negative contribution of TRA. The NET of all processes was negative from 16:00 to  
 592 18:00 due to the continuous growth of negative contribution of TRA. The negative  
 593 contribution of TRA process from 12:00 to 18:00 can be explained by the enhanced  
 594 northerlies in the central part of BTH caused by BC DRE, which transported cleaner  
 595 air mass into Beijing (Fig S6). From 19:00 to 23:00, the surface-layer PM<sub>2.5</sub>  
 596 concentrations were decreased by BC DRE, which can be explained by the dominant  
 597 negative contribution of TRA from 19:00 to 21:00. At 22:00, the reduction in surface-  
 598 layer PM<sub>2.5</sub> was 7.5  $\mu\text{g m}^{-3}$  (4.0%) when  $h_s$  value was 0.35 and 6.6  $\mu\text{g m}^{-3}$  (3.5%) when  
 599  $h_s$  was 0.96.

## 6. Conclusions

In this study, a fully coupled online WRF-Chem model with an improved integrated process rate (IPR) analysis scheme is employed to investigate the direct radiative effects (DRE) of BC vertical profiles on meteorology and PM<sub>2.5</sub> concentrations during two severe haze events (11-12 December 2016 and 16-19 December 2016). Sensitivity experiments are conducted to compare the DRE of BC with original and corrected vertical profiles and to quantify the role of BC vertical profiles in influencing meteorological conditions and air pollutants.

Compared to the measured vertical profiles of BC in Beijing, the default vertical profiles of BC from the WRF-Chem model can capture the decreases of BC mass concentration with altitude on December 12 and 16-19 when local emissions dominated, but cannot reproduce the observed maximum mass concentration of BC around 850-m altitude on December 11 when regional transport of pollutants dominated. Averaged over the two severe pollution events, the model overestimated BC mass concentration by 87.4% at the surface but underestimated BC by 33.1% at 1000-m altitude compared with the observations in Beijing.

We carried out simulations with both the default original BC vertical profiles and the modified vertical profiles using the observations (keep the column burden of BC from the WRF-Chem but distribute BC mass vertically according to the observed fractions of BC in individual model layers for each day). Compared with the simulation with original BC profiles, the warming by BC DRE around 300-m altitude was stronger with the modified profiles. Accordingly, the BC-induced reductions in PBLH in Beijing

averaged over the two severe haze events were 43.4 m (18.4%) and 55.4 m (23.5%), respectively, with the original and modified profiles. As a result, relative to the simulation with the original profiles, the modified profiles of BC led to larger increases in PM<sub>2.5</sub> concentrations by BC DRE, because VMIX and CHEM had the dominant positive contributions to the changes in surface-layer PM<sub>2.5</sub> due to the reductions in PBLH.

Seven sensitivity experiments were further carried out to understand the roles of BC vertical profiles. In six assumed exponential functions ( $C(h)=C_0\times e^{-h/hs}$ ) with  $hs$  values of 0.35, 0.48, 0.53, 0.79, 0.82 and 0.96, a larger  $hs$  means less BC at the surface and more BC in the upper atmosphere. As a result, with higher  $hs$ , temperatures were less warming or even cooling occurred at the surface, leading to stronger temperature inversion as well as larger BC-induced increases in PM<sub>2.5</sub>.

Results from our study highlight the importance of accurate representation of BC vertical profiles in models, which alter the radiation balance, BC-PBL interaction, and hence the simulated PM<sub>2.5</sub> concentrations. Due to the limitation of observational data, this study was focused on the DRE of BC vertical profiles on meteorology and PM<sub>2.5</sub> concentration in Beijing during severe haze events. However, the results from this study should be generally important for understanding severe haze for urban areas.

There are channels for further improvement in near-future research. We distribute BC mass vertically according to the observed fractions of BC in individual model layers for each day without considering the hourly variations of BC vertical profiles due to the lack of data. Such assumed distribution of BC based on observation may not be

644 consistent with the dynamical (winds, temperature, etc.) and chemical processes of the  
645 atmosphere. Further efforts are needed to examine the roles of BC vertical profiles in  
646 coupled chemistry-weather models.

957 **Table1.** Physical and chemical options for WRF/Chem.

WRF/Chem Model Configuration	Description
Microphysics scheme	Lin microphysics scheme (Wiedinmyer et al., 2011)
Longwave radiation scheme	RRTMG scheme (Zhao et al., 2011)
Shortwave radiation scheme	RRTMG scheme (Zhao et al., 2011)
Gas phase chemistry scheme	CBMZ (Zaveri and Peters, 1999)
Aerosol module	MOSAIC (Zaveri et al., 2008)
Photolysis scheme	Fast-J (Wild et al., 2000)
Boundary layer scheme	Yonsei University Scheme(YSU) (Hong et al., 2006)
Pavement parameterization scheme	Noah Land Surface Model scheme
Cumulus option	Grell 3-D ensemble scheme

**Table 2.** Numerical experiments. Y indicates “on”, and N indicates “off”.

Simulations	BC direct radiative effect (DRE)		
	DRE Turn on/off	BC vertical profiles for calculation of DRE	
		Types description	Modified dates
CTRL	Y	Simulated by model	No modification
NoBCrad	N	Simulated by model	No modification
VerBC_obs	Y	Modified according to intraday observations	11-12 and 16-19 December
VerBC_hs1-6	Y	Modified according to $C(h)=C_0 \times e^{-h/hs}$ function <sup>a</sup>	12 and 16-19 December
VerBC_RT	Y	Modified according to observations on 11 December 2016	12 and 16-19 December

<sup>a</sup> The values of  $hs$  in VerBC\_hs1, VerBC\_hs2, VerBC\_hs3, VerBC\_hs4, VerBC\_hs5 and VerBC\_hs6 are 0.35, 0.48, 0.53, 0.79, 0.82 and 0.96, respectively.

**Table 3.** Statistical metrics for temperature at 2 m (T2; °C), relative humidity at 2 m (RH2; %), wind speed at 10 m (WS10; m s<sup>-1</sup>), wind direction at 10 m (WD10, °), PBLH (m), SWDOWN (W m<sup>-2</sup>), PM<sub>2.5</sub> (μg m<sup>-3</sup>), SO<sub>2</sub> (ppbv), NO<sub>2</sub> (ppbv), CO (ppmv) and O<sub>3</sub> (ppbv).

Variables	SIM <sup>a</sup>	OBS <sup>b</sup>	R <sup>c</sup>	MB <sup>d</sup>	NMB <sup>e</sup>	MFB <sup>f</sup>
T2 (°C)	-0.5	-0.6	0.77	0.1	-17.8%	-13.1%
RH2 (%)	52.5	55.8	0.75	-3.4	-6.0%	-0.3%
WS10 (m s <sup>-1</sup> )	1.8	2.3	0.52	-0.5	-20.6%	-11.5%
WD10 (°)	165.6	182.0	0.45	-16.4	-9.0%	0.7%
PBLH (m)	205.8	174.9	0.72	30.9	17.7%	72.9%
SWDOWN (W m <sup>-2</sup> )	86.0	100.8	0.76	-14.9	-14.8%	-17.4%
PM <sub>2.5</sub> (μg m <sup>-3</sup> )	145.6	132.3	0.77	13.2	10.0%	15.7%
SO <sub>2</sub> (ppbv)	7.9	7.8	0.38	0.1	1.4%	-2.9%
NO <sub>2</sub> (ppbv)	47.7	39.2	0.78	8.5	21.6%	20.2%
CO (ppmv)	1.8	1.9	0.73	-0.1	-4.9%	6.4%
O <sub>3</sub> (ppbv)	6.7	6.8	0.66	-0.1	-1.2%	-36.0%

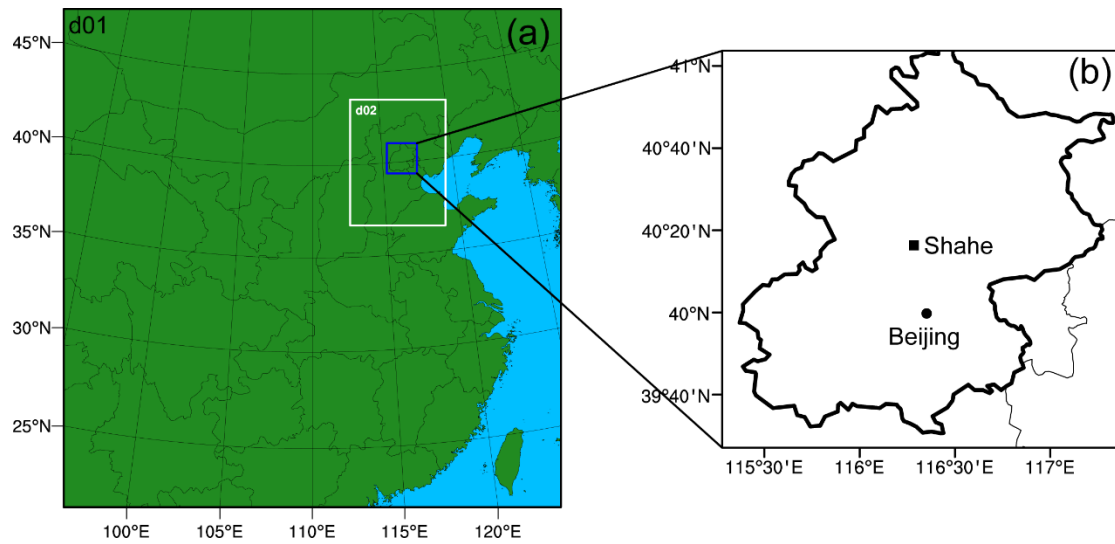

<sup>a,b</sup> SIM and OBS represent the averaged model results and observations in Beijing from 11 to 19 December 2016.

<sup>c</sup> R is the correlation coefficient which is calculated between hourly observations and simulations in Beijing from 11 to 19 December 2016,  $R = \frac{\sum_{i=1}^n |(OBS_i - OBS) * (SIM_i - SIM)|}{\sqrt{\sum_{i=1}^n (OBS_i - OBS)^2 + \sum_{i=1}^n (SIM_i - SIM)^2}}$ , where OBS<sub>i</sub> and SIM<sub>i</sub> are the hourly observed and simulated data in Beijing and n is the total number of hours.

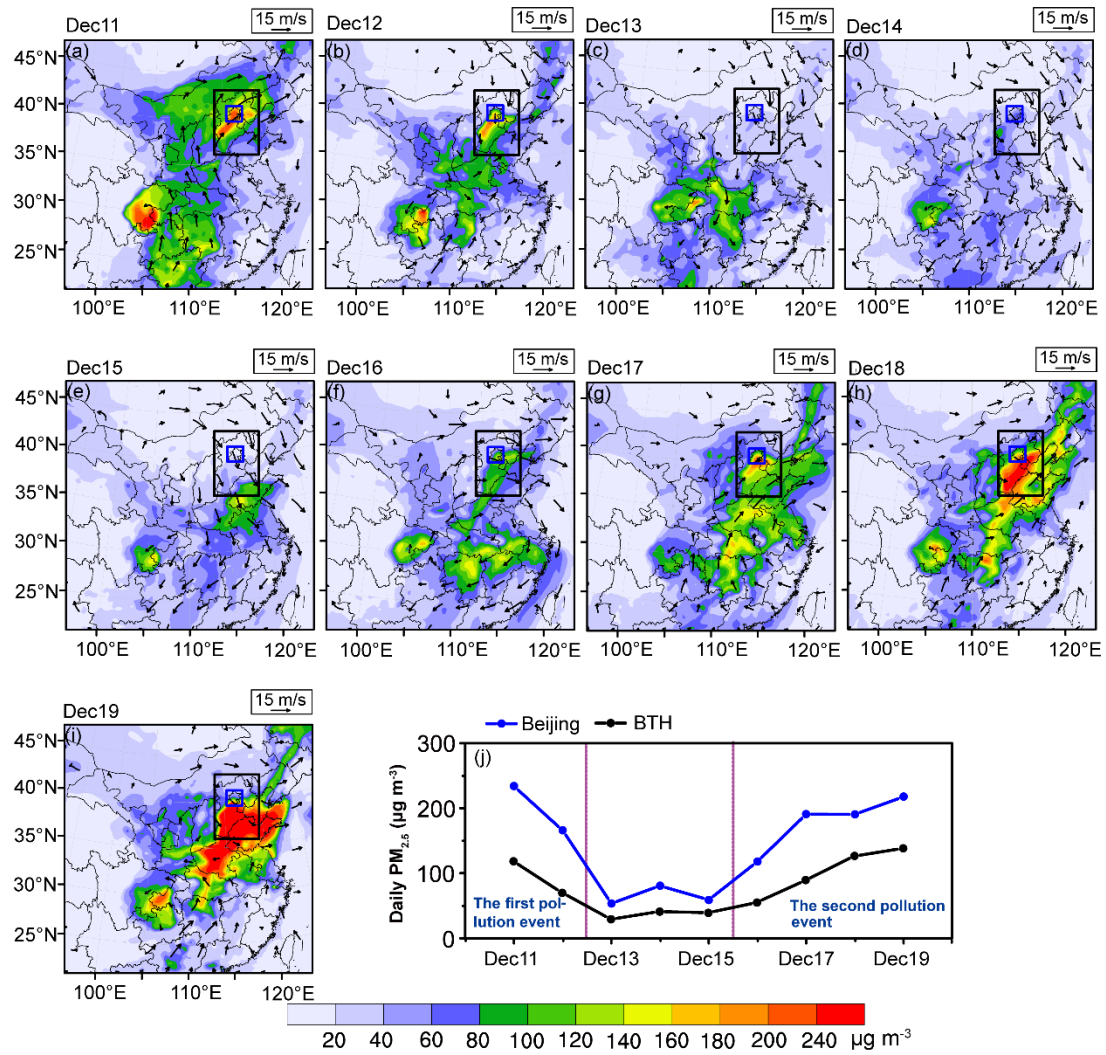

<sup>d</sup> MB is the mean bias,  $MB = \frac{1}{n} * \sum_{i=1}^n SIM_i - OBS_i$ .

<sup>e</sup> NMB is the normalized mean bias,  $NMB = \frac{1}{n} * \sum_{i=1}^n \frac{SIM_i - OBS_i}{OBS_i} * 100\%$ .

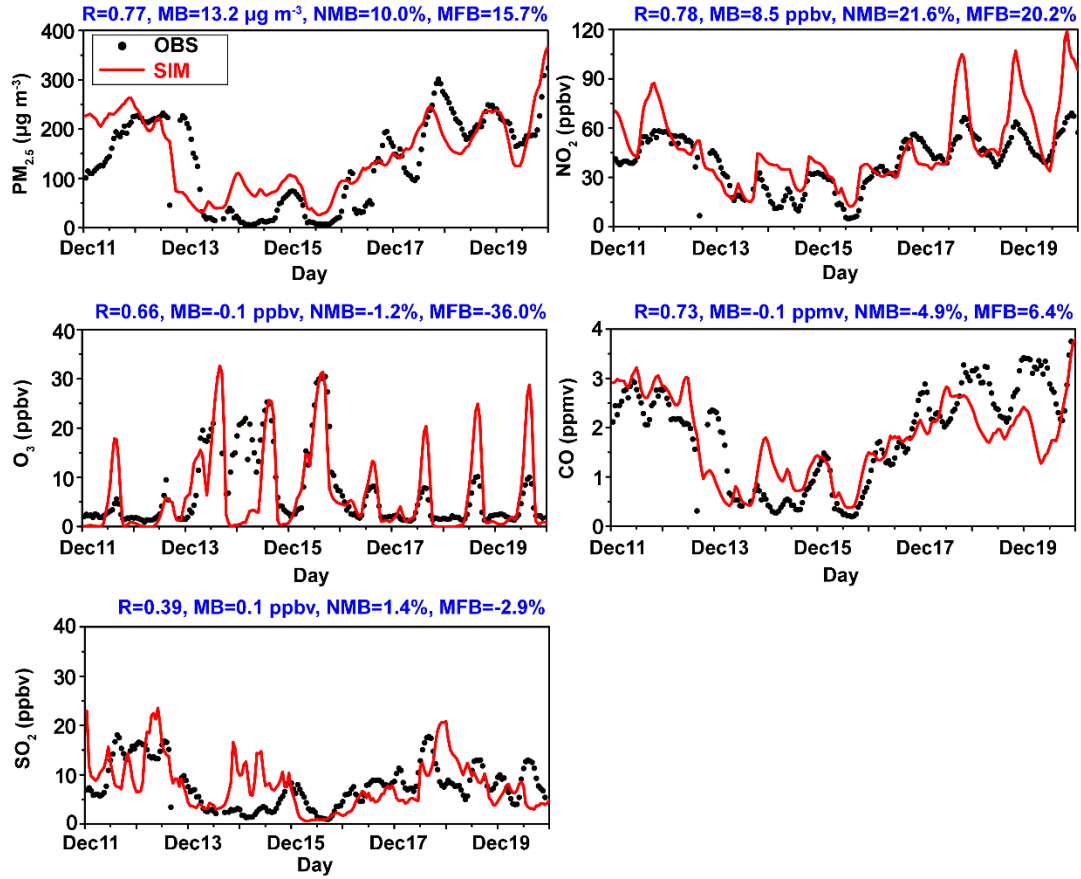

<sup>f</sup> MFB is the mean fraction bias,  $MFB = \frac{2}{n} * \sum_{i=1}^n \frac{SIM_i - OBS_i}{SIM_i + OBS_i} * 100\%$ .

**Figure 1.** (a) Two nested domains with grid resolutions of 30 km (d01) and 10 km (d02).  
 (b) The BC vertical profiles were modified for the blue box which covers the whole of  
 Beijing.

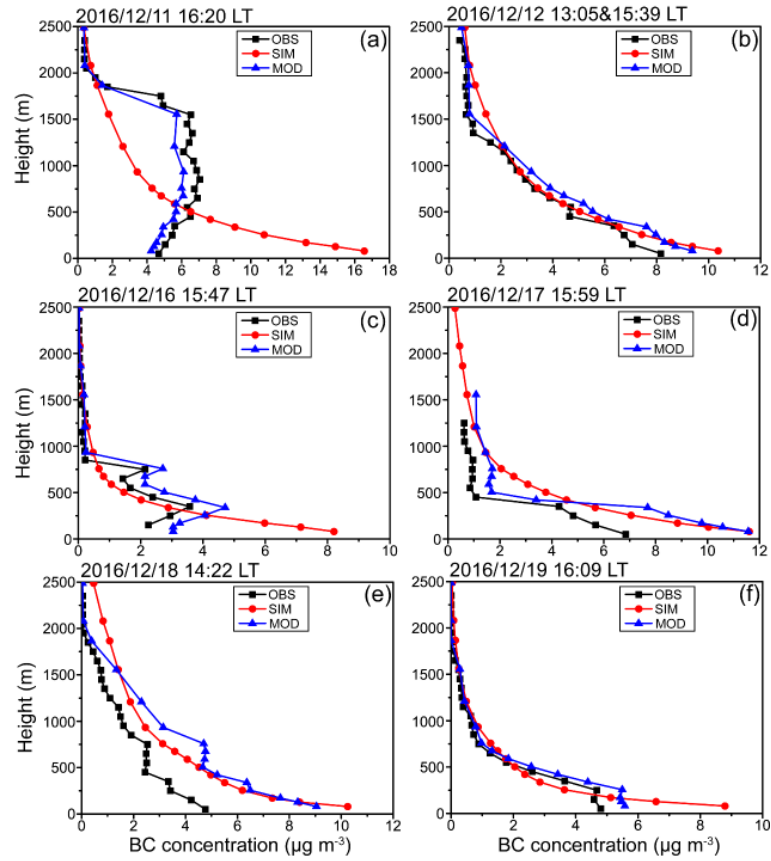

**Figure 2.** (a-i) Simulated spatial distributions of surface-layer PM<sub>2.5</sub> concentrations ( $\mu\text{g m}^{-3}$ ) and winds ( $\text{m s}^{-1}$ ) at 850 hPa at 2 pm local time from 11 to 19 December 2016. Black and blue squares in each panel denote the regions of Beijing-Tianjin-Hebei and Beijing, respectively. (j) Time series of simulated mean daily PM<sub>2.5</sub> concentration from 11 to 19 December 2016 averaged over the Beijing (blue square) and BTH (black square).

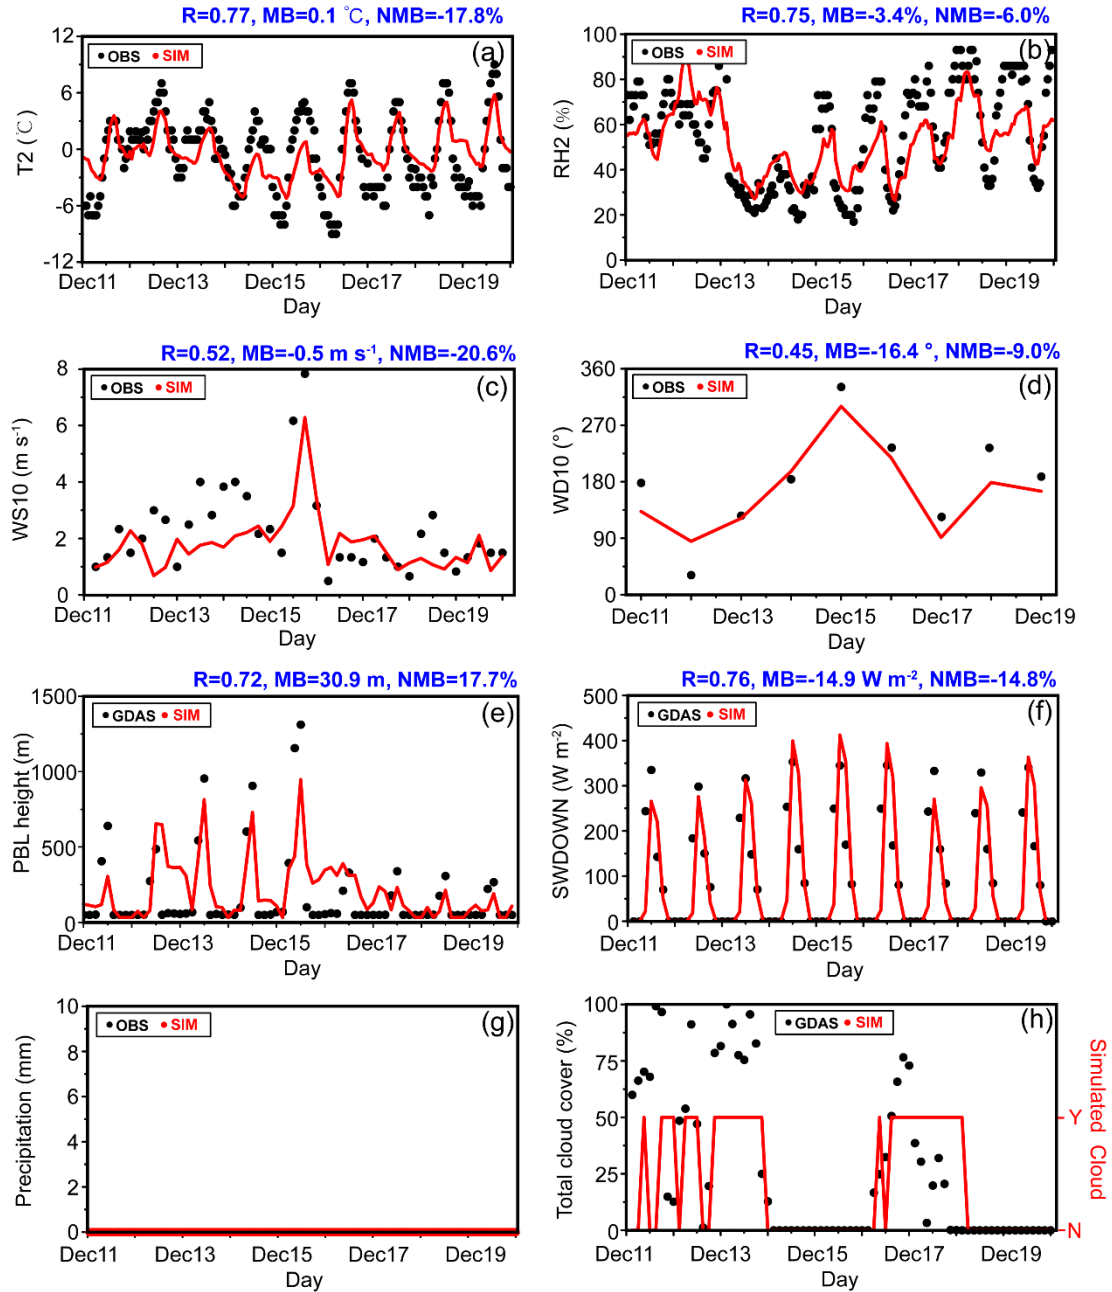

**Figure 3.** Time series of the observed (black dots) and simulated (red lines) hourly concentrations of PM<sub>2.5</sub> (μg m<sup>-3</sup>), NO<sub>2</sub> (ppbv), O<sub>3</sub> (ppbv), CO (ppmv) and SO<sub>2</sub> (ppbv) in Beijing from 11 to 19 December 2016. The observations and simulations in Beijing were averaged over 12 observational sites and corresponding grid points, respectively.

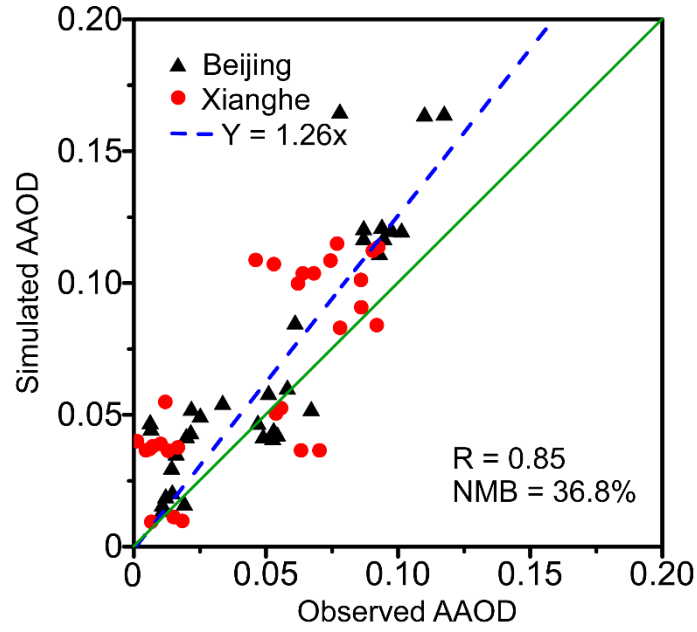

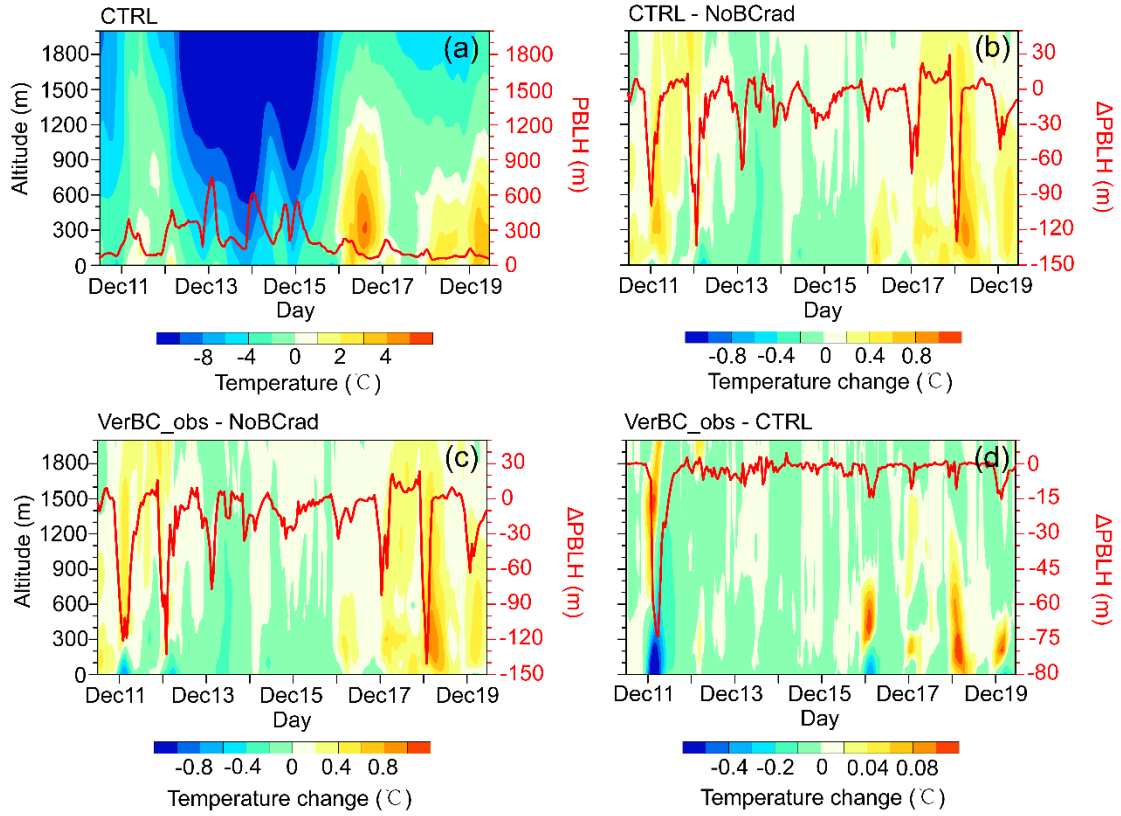

**Figure 4.** Observed (black line), simulated (red line) and modified (blue line) BC vertical profiles in Beijing on 11-12 and 16-19 December 2016. The time of observation is indicated on top of each panel. The model results are two-hour averages around the observation time.

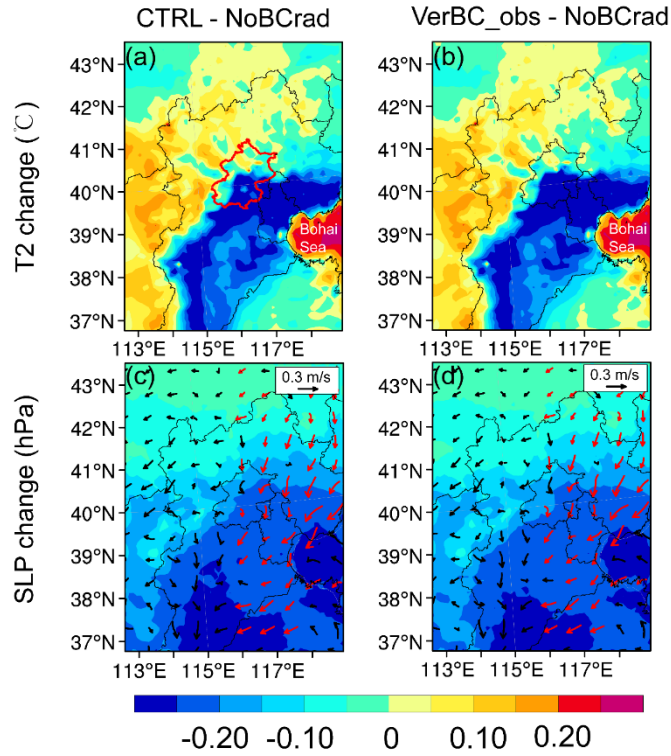

**Figure 5.** Comparisons of simulated meteorological parameters from CTRL simulation with measurements. The black dots and red lines are the observed (reanalysis) and simulated hourly data of T2 (°C), RH2 (%), precipitation (mm), and 3-hourly data of PBL height (m), SWDOWN (W m<sup>-2</sup>), total cloud cover (%), 6-hourly data of WS10 (m s<sup>-1</sup>), and daily data of WD10 (°) in Beijing from 11 December 2016 to 19 December 2016. PBLH, SWDOWN, and total cloud cover are taken from GDAS. The WRF-Chem model output shows only a grid has cloud (Y) or no cloud (N).

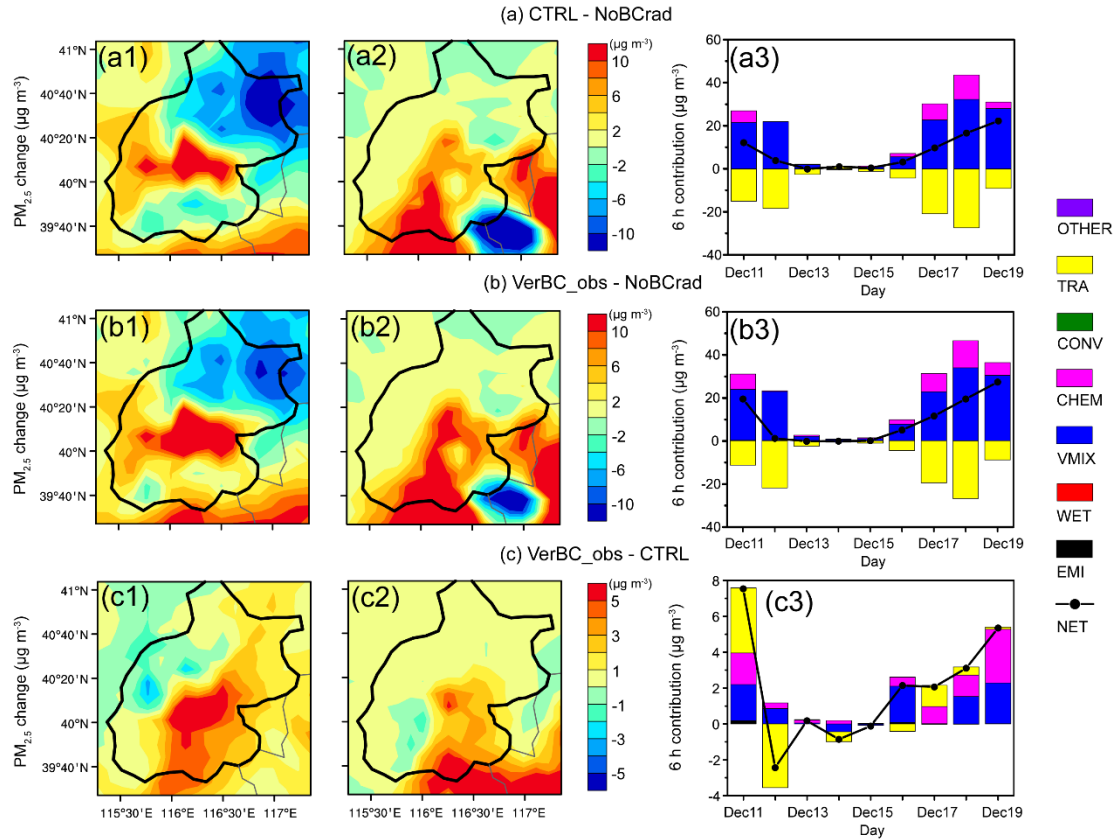

**Figure 6.** Comparison of simulated absorption aerosol optical depth (AAOD) at 550 nm with observations in Beijing (116.38°E, 39.98°N) and Xianghe (116.96°E, 39.75°N) station from 11 to 19 December 2016.

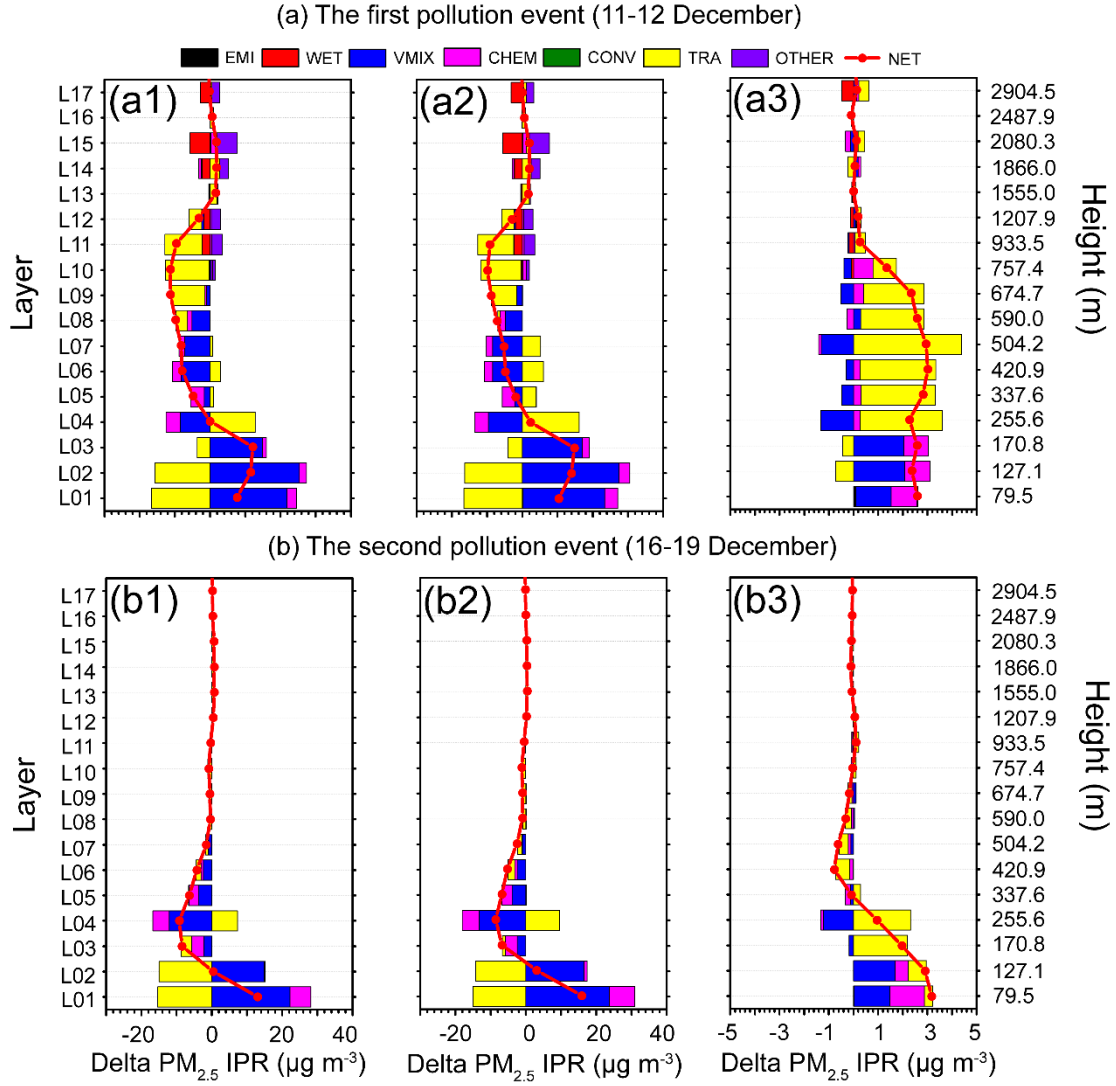

**Figure 7.** (a) Simulated hourly vertical profiles of temperature (contour) and PBLH (red solid line) over Beijing at local time (LT) from 11 December 2016 to 19 December 2016. (b-d) Time series of changes in vertical temperature (contour) and PBLH ( $\Delta$ PBLH; red solid line) induced by BC DRE with original (b; CTRL minus NoBCrad) and modified vertical profiles (c; VerBC\_obs minus NoBCrad), and the difference between the effects of modified and original BC profiles (d; VerBC\_obs minus CTRL) over Beijing region from 11 December 2016 to 19 December 2016.

**Figure 8.** The changes in T2, SLP and wind at 10 m induced by BC DRE with original (a and c; CTRL minus NoBCrad) and modified vertical profiles (b and d; VerBC\_obs minus NoBCrad) averaged over the period of 12:00 – 18:00 LT of the two haze events, respectively. (c-d) The northeasterlies in the east of BTH are denoted in red.

**Figure 9.** The spatial distribution of changes in near-surface PM<sub>2.5</sub> concentrations induced by BC DRE with original (CTRL minus NoBCrad; a1 and a2) and modified vertical profiles (VerBC\_obs minus NoBCrad; b1 and b2), and the difference between VerBC\_obs and CTRL (VerBC\_obs minus CTRL; c1 and c2) over Beijing averaged over the period of 12:00 – 18:00 LT of the two haze events. a1-c1 represent the first pollution event of 11-12 December 2016 and a2-c2 represent the second pollution event of 16-19 December 2016. (a3-c3) The daily 6-h contributions of each physical/chemical process (colored bars, each of which is calculated as the concentration at 18:00 minus that at 12:00) to the change in PM<sub>2.5</sub> in Beijing from 11 December 2016 to 19 December 2016. The black dotted line represents the 6-h net contribution to PM<sub>2.5</sub> change by summing over all processes.

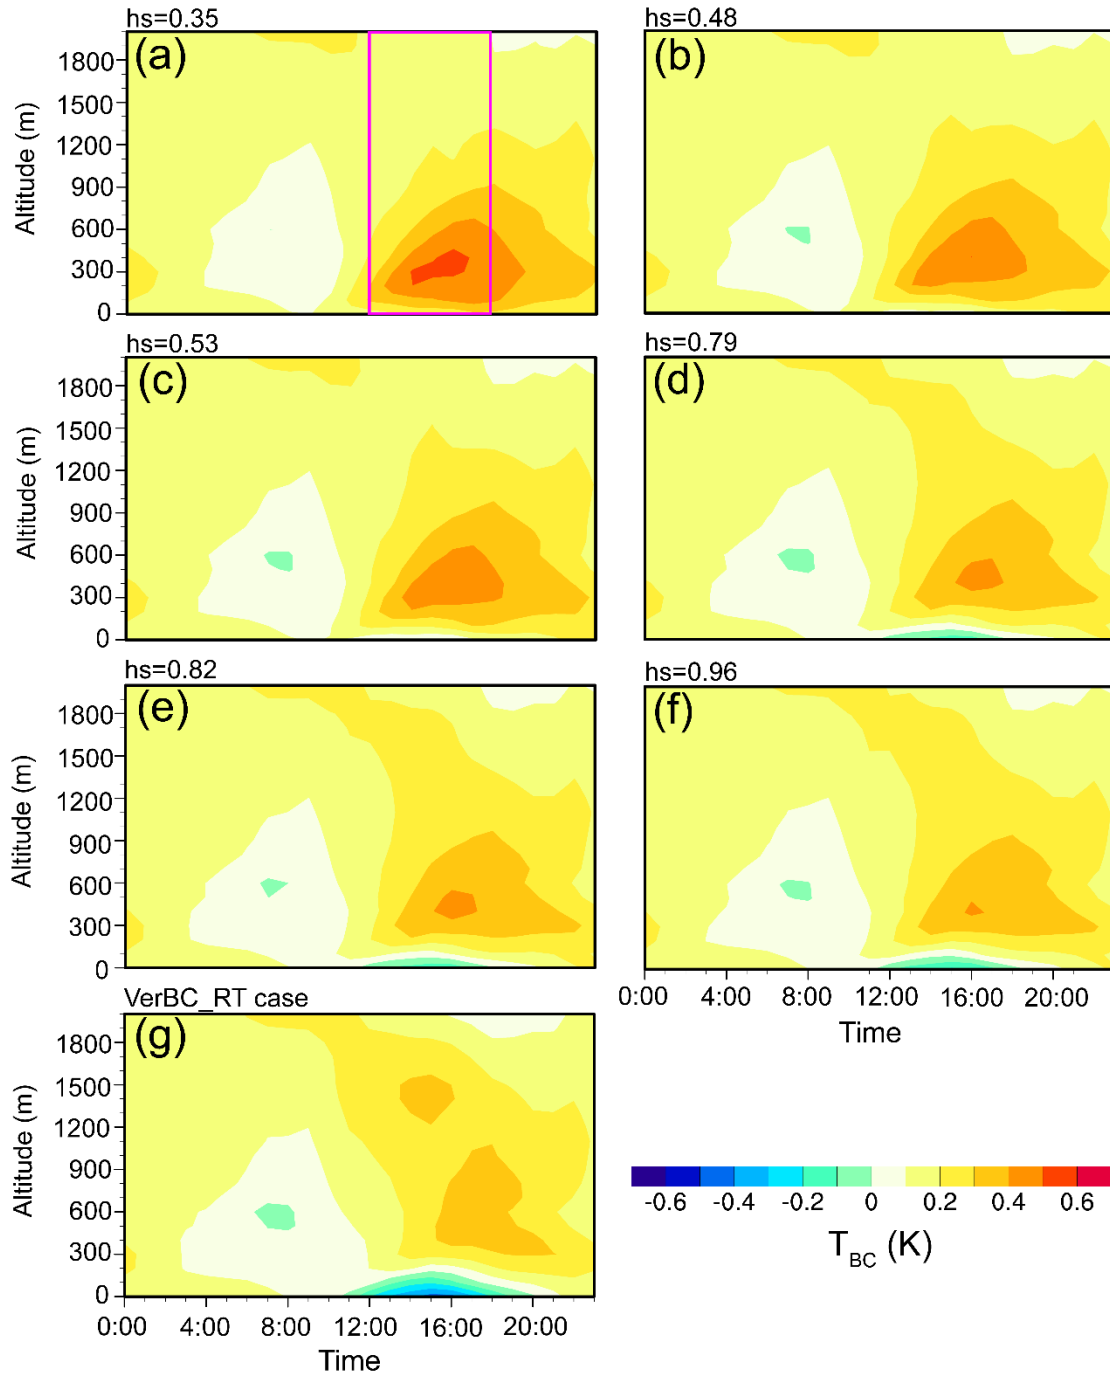

**Figure 10.** Vertical profiles of the 6-h contributions of physical/chemical processes (colored bars; each is calculated as the concentration at 18:00 LT minus that at 12:00 LT) to the changes in PM<sub>2.5</sub> induced by BC DRE with original (CTRL minus NoBCrad; a1 and b1) and modified vertical profiles (VerBC\_obs minus NoBCrad; a2 and b2), and the difference between original and modified BC profiles (VerBC\_obs minus CTRL; a3 and b3) over Beijing. The red dotted lines represent the 6-h net contributions to PM<sub>2.5</sub> changes by summing over all processes.

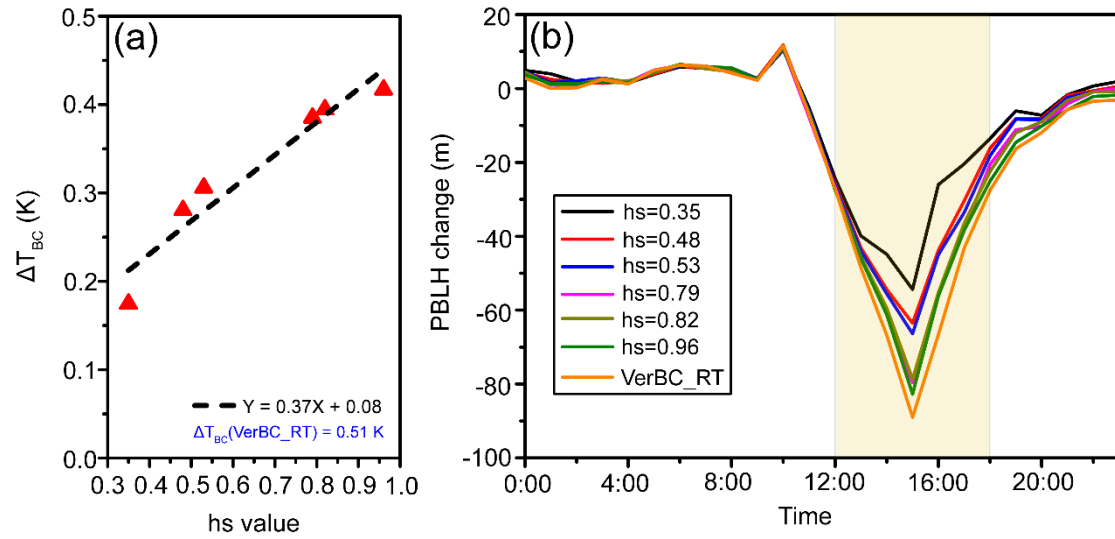

**Figure 11.** Vertical profiles of BC concentrations parameterized as six exponential functions for 12 and 16-19 December 2016.

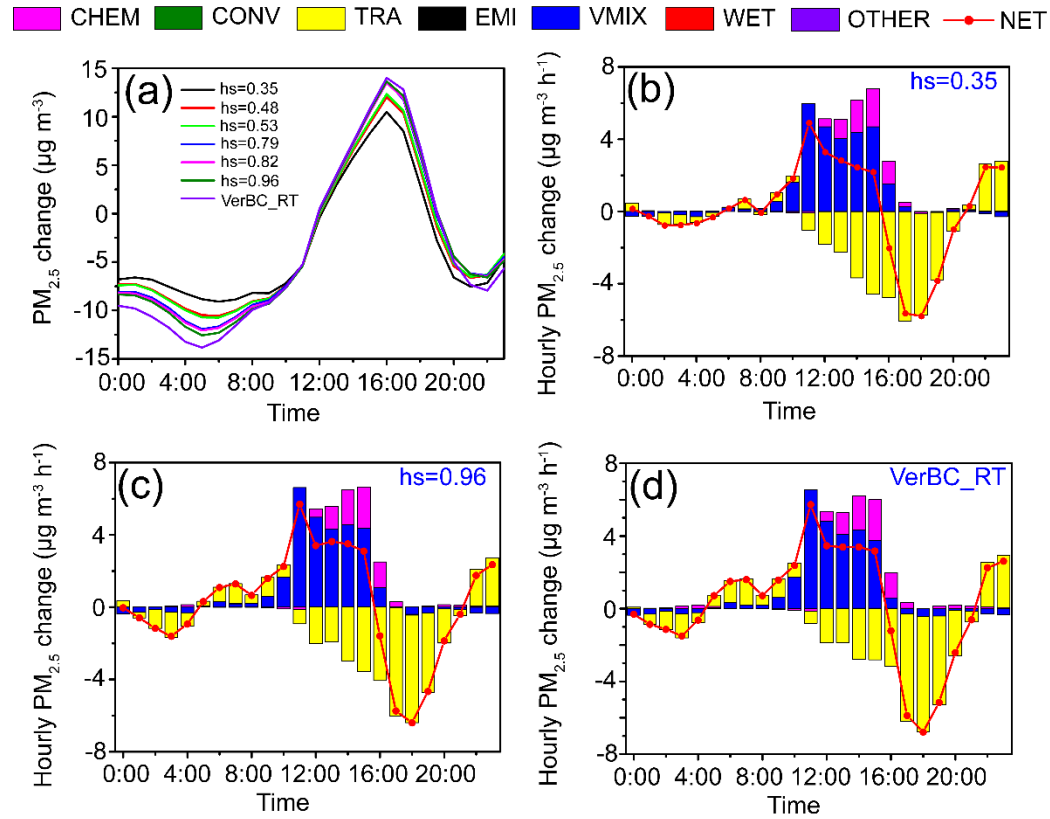

**Figure 12.** Time series of changes in vertical temperature induced by BC DRE with six exponential functions (VerBC\_hs1-6 minus NoBCrad) and one transport-dominated vertical profile (VerBC\_RT minus NoBCrad) averaged over 12 and 16-19 December 2016.

**Figure 13.** (a) Variation of  $\Delta T_{BC}$  caused by BC DRE with increasing  $hs$  values averaged 12 and 16-19 December. The black dash line is the linear fit. (b) Time series of changes in PBLH in Beijing caused by different BC vertical profiles averaged 12 and 16-19 December 2016.

**Figure 14.** (a) Time series of the changes in surface-layer PM<sub>2.5</sub> in Beijing caused by BC with six exponential functions (VerBC\_hs1-6 minus NoBCrad) and one observed transport-dominated vertical profile (VerBC\_RT minus NoBCrad) averaged 12 and 16-19 December 2016. (b-d) The hourly contributions of each physical/chemical process to PM<sub>2.5</sub> changes caused by BC DRE with two exponential functions ( $hs=0.35$  and  $0.96$ ) and one transport-dominated vertical profile.
