10

11 **Abstract.** Dust particles, serving as ice nucleating particles (INPs), may impact the Arctic
12 surface energy budget and regional climate by modulating the mixed-phase cloud properties and
13 lifetime. In addition to long-range transport from low latitude deserts, dust particles in the Arctic
14 can originate from local sources. However, the importance of high latitude dust (HLD) as a
15 source of Arctic INPs (compared to low latitude dust (LLD)) and its effects on Arctic mixed-
16 phase clouds are overlooked. In this study, we evaluate the contribution to Arctic dust loading
17 and INP population from HLD and six LLD source regions by implementing a source-tagging
18 technique for dust aerosols in version 1 of the US Department of Energy’s Energy Exascale
19 Earth System Model (E3SMv1). Our results show that HLD is responsible for 30.7% of the total
20 dust burden in the Arctic, whereas LLD from Asia and North Africa contribute 44.2% and
21 24.2%, respectively. Due to its limited vertical transport as a result of stable boundary layers,
22 HLD contributes more in the lower troposphere, especially in boreal summer and autumn when
23 the HLD emissions are stronger. LLD from North Africa and East Asia dominates the dust
24 loading in the upper troposphere with peak contributions in boreal spring and winter. The
25 modeled INP concentrations show a better agreement with both ground and aircraft INP
26 measurements in the Arctic when including HLD INPs. The HLD INPs are found to induce a net
27 cooling effect (-0.24 W m^{-2} above 60°N) on the Arctic surface downwelling radiative flux by
28 changing the cloud phase of the Arctic mixed-phase clouds. The magnitude of this cooling is
29 larger than those induced by North African and East Asian dust (0.08 and -0.06 W m^{-2} ,
30 respectively), mainly due to different seasonalities of HLD and LLD. Uncertainties of this study
31 are discussed, which highlights the importance of further constraining the HLD emissions.

32

33 **1 Introduction**

34 The Arctic has experienced long-term climate changes, including rapid warming and shrinking
35 in sea ice extent. Arctic mixed-phase clouds (AMPCs), which occur frequently throughout the
36 year, strongly impact the surface and atmospheric energy budget and are one of the main
37 components driving the Arctic climate (Morrison et al., 2012; Shupe and Intrieri, 2004; Tan and
38 Storelvmo, 2019). The AMPCs lifetime, properties, and radiative effects are closely connected to
39 the primary ice formation process, as the formed ice crystals grow at the expense of cloud liquid
40 droplets due to the lower saturation vapor pressure with respect to ice than that to liquid water
41 (so-called Wegener-Bergeron-Findeisen process or, in short, WBF process; Liu et al., 2011; M.
42 Zhang et al., 2019). Large ice crystals with higher fall speeds than liquid droplets can readily
43 initiate precipitation and further deplete cloud liquid through the riming process. All these
44 processes can also interact with each other nonlinearly and impact the phase partitioning of
45 mixed-phase clouds (Tan and Storelvmo, 2016).

46 Primary ice formation in mixed-phase clouds only occurs heterogeneously with the aid of ice
47 nucleating particles (INPs). According to Vali et al. (1985), the heterogeneous ice nucleation is
48 classified into four different modes: through the collision of an INP particle with supercool liquid
49 droplet (contact freezing), by an INP particle immersed in a liquid droplet (immersion freezing),
50 when the INP particle also serves as a cloud condensation nucleus (condensation freezing), or by
51 the direct deposition of water vapor to a dry INP particle (deposition nucleation). The immersion
52 freezing is usually treated together with condensation freezing in models, as instruments cannot
53 distinguish between them (Vali et al., 2015). This immersion/condensation freezing is generally
54 thought to be the most important ice nucleation mode in the mixed-phase clouds (de Boer et al.,
55 2011; Prenni et al., 2009; Westbrook and Illingworth, 2013). It remains a significant challenge to

56 characterize the INP types and concentrations, partially because only a very small fraction of
57 aerosols can serve as INPs (DeMott et al., 2010). This is especially the case for the clean
58 environment in the Arctic. Therefore, the potential sources and amounts of Arctic INPs are still
59 largely unknown.

60 Mineral dust aerosols are identified as one of the most important types of INPs in the
61 atmosphere due to their high ice nucleation efficiency (DeMott et al., 2003; Hoose and Möhler,
62 2012; Murray et al., 2012; Atkinson et al., 2013) and their abundance in the atmosphere (Kinne
63 et al., 2006). They are mainly emitted from arid and semi-arid regions located at low- to mid-
64 latitudes, such as North Africa, the Middle East, and Asia. Observational studies found that LLD
65 can be transported to the Arctic (Bory et al., 2003; VanCuren et al., 2012; Huang et al., 2015)
66 and act as a key contributor to the Arctic INP population (Si et al., 2019). A modelling study also
67 suggested that low latitude dust (LLD) has a large contribution to dust concentrations in the
68 upper troposphere of the Arctic (Groot Zwaaftink et al., 2016), since LLD is usually lifted by
69 convection and topography and then transported poleward following slantwise isentropes. This
70 finding confirms the potential of LLD to serve as INPs in AMPCs. The impact of LLD INPs on
71 clouds was further investigated by Shi and Liu (2019), who found that LLD INPs induce a net
72 cooling cloud radiative effect in the Arctic, due to their impacts on cloud water path and cloud
73 fraction.

74 Although LLD has attracted much of the attention in the past, it is recognized that 2–3% of the
75 global dust emission is produced by local Arctic sources above 50°N (Bullard et al., 2016),
76 which include Iceland (Arnalds et al., 2016; Dagsson-Waldhauserova et al., 2014; Prospero et al.,
77 2012), Svalbard (Dörnbrack et al., 2010), Alaska (Crusius et al., 2011), and Greenland (Bullard
78 and Austin, 2011). Groot Zwaaftink et al. (2016) found that high latitude dust (HLD) contributes

79 27% of the total dust burden in the Arctic. Different from LLD, most of the emitted HLD is
80 restricted at the lower altitudes in the Arctic, because of the stratified atmosphere in the cold
81 environment (Bullard, 2017; Groot Zwaafink et al., 2016).

82 It is also noted that HLD is likely an important source to the observed INPs in the Arctic,
83 especially during the warm seasons. For example, Irish et al. (2019) suggested that mineral dust
84 from Arctic bare lands (likely eastern Greenland or north-western continental Canada) is an
85 important contributor to the INP population in the Canadian Arctic marine boundary layer during
86 summer 2014. Attempts have been made to quantify the ice nucleating ability of HLD.
87 Paramonov et al. (2018) found that the Icelandic glaciogenic silt had a similar ice nucleating
88 ability as LLD at temperatures below -30 °C. Similarly, Sanchez-Marroquin et al. (2020)
89 suggested that the ice nucleating ability of aircraft-collected Icelandic dust samples is slightly
90 lower but comparable with that of the LLD. Some other studies also noticed that HLD can act as
91 efficient INPs at warm temperatures. As early as the 1950s, the airborne dry dust particles from
92 permafrost ground at Thule, Greenland, were found to nucleate ice at temperatures as warm as -5
93 °C (Fenn and Weickmann, 1959). This is corroborated by a more recent study which investigated
94 the glacial outwash sediments in Svalbard and ascribed the remarkably high ice nucleating
95 ability to the presence of soil organic matter (Tobo et al., 2019).

96 Despite their potential importance, HLD sources are largely underestimated or even omitted in
97 global models (Zender et al., 2003). Fan (2013) noticed that the autumn peak in measured
98 surface dust concentrations at Alert was underestimated by the model, likely due to a lack of
99 local dust emission. Similarly, Shi and Liu (2019) also mentioned that the distinction of
100 simulated and satellite retrieved dust vertical extinction in the Arctic became larger near the
101 surface.

102 In this study, we account for the HLD dust emission by replacing the default dust emission
103 scheme (Zender et al., 2003) with the Kok et al. (2014a, b) scheme in the Energy Exascale Earth
104 System Model version 1 (E3SMv1). We further track explicitly the dust aerosols emitted from
105 the Arctic (HLD) and six major LLD sources using a newly developed source-tagging technique
106 in E3SMv1. The objectives of this study are to (1) examine the source attribution of the Arctic
107 dust aerosols in the planetary boundary layer and in the free troposphere; (2) examine the
108 contribution of dust from various sources to the Arctic dust INPs; and (3) quantify the
109 subsequent influence of dust INPs from various sources on the Arctic mixed-phase cloud
110 radiative effects. We are particularly interested in the relative importance of local HLD versus
111 long-range transported LLD.

112 The paper is organized as follows. The E3SMv1 model and experiments setup are introduced
113 in Section 2. Section 3 presents model results and comparisons with observations. The
114 uncertainties are discussed in Section 4, and Section 5 summarizes the results.

115 **2 Methods**

116 **2.1 Model description and experiment setup**

117 Experiments in this study are performed using the atmosphere component (EAMv1) of the U.S.
118 Department of Energy (DOE) E3SMv1 model (Rasch et al., 2019). The model predicts number
119 and mass mixing ratios of seven aerosol species (i.e., mineral dust, black carbon (BC), primary
120 organic aerosol, secondary organic aerosol, sulfate, sea salt, and marine organic aerosol (MOA))
121 through a four-mode version of modal aerosol module (MAM4) (Liu et al., 2016; Wang et al.,
122 2020). The four aerosol modes are Aitken, accumulation, coarse, and primary-carbon modes,
123 while dust aerosols are carried in accumulation and coarse modes. Aerosol optical properties in

124 each mode is parameterized following Ghan and Zaveri (2007). The dust optics used in this study
125 are updated according to Albani et al. (2014).

126 EAMv1 includes a two-moment stratiform cloud microphysics scheme (MG2) (Gettelman and
127 Morrison, 2015). We note the WBF process rate in EAMv1 is tuned down by a factor of 10,
128 which results in more prevalent supercooled liquid water clouds in high latitudes than
129 observations and many other global climate models (Y. Zhang et al., 2019; Zhang et al., 2020).
130 In addition, the Cloud Layers Unified By Binormals (CLUBB) parameterization (Bogenschutz et
131 al., 2013; Golaz and Larson, 2002; Larson et al., 2002) is used to unify the treatments of
132 planetary boundary layer turbulence, shallow convection, and cloud macrophysics. Deep
133 convection is treated by the Zhang and McFarlane (1995) scheme.

134 In EAMv1, the heterogeneous ice nucleation in mixed-phase clouds follows the classical
135 nucleation theory (CNT) (Hoose et al., 2010; Y. Wang et al., 2014). CNT holds the stochastic
136 hypothesis, which treats the ice nucleation process as a function of time.
137 Immersion/condensation, contact, and deposition nucleation on dust and BC are treated in the
138 CNT scheme. More details about CNT parameterization are provided in Text S2.1 in the
139 Supplement.

140 The experiments we conducted for this study are shown in Table 1. For the control experiment
141 (hereafter CTRL), the EAMv1 was integrated from July 2006 to the end of 2011 at 1° horizontal
142 resolution and 72 vertical layers. The first six months of the experiment were treated as model
143 spin-up and the last five-year results were used in analyses. The horizontal wind components
144 were nudged to the MERRA2 meteorology with a relaxation timescale of 6 hours (Zhang et al.,
145 2014). In addition to CTRL, we conducted three sensitivity experiments to investigate the INP
146 effect of dust from major source regions. In these sensitivity experiments, heterogeneous ice

147 nucleation in the mixed-phase clouds by dust from local Arctic sources, North Africa, and East
148 Asia is turned off (i.e., noArc, noNAf, and noEAs, respectively). The other settings of these three
149 experiments are identical to CTRL. Analyses related to the sensitivity experiments are provided
150 in Section 3.4.

151 **2.2 Dust emission parameterization and source-tagging technique**

152 Dust emission in the default EAMv1 is parameterized following Zender et al. (2003) (Z03),
153 which uses semi-empirical dust source functions to address the spatial variability in soil
154 erodibility. The HLD emission is omitted in the Z03 scheme, since it was thought to be dubious
155 (Zender et al., 2003). In this study, we replaced the Z03 scheme with another dust emission
156 parameterization (Kok et al., 2014a, b) (K14) that avoids using a source function (see more
157 details about K14 in Text S1). The K14 scheme is able to produce the HLD emission over
158 Iceland, the Greenland coast, Canada, Svalbard, and North Eurasia (Figure 1a). Furthermore, to
159 address the overestimation in dust emission in clay size ($< 2 \mu\text{m}$ diameter) (Kok et al., 2017), we
160 changed the size distribution of emitted dust particles from Z03 to that based on the brittle
161 fragmentation theory (Kok, 2011). 1.1% of the total dust mass is emitted to the accumulation
162 mode and 98.9% of that is emitted to the coarse mode based on the brittle fragmentation theory,
163 whereas the fractions are 3.2% and 96.8%, respectively in Z03.

164 To quantify the source attribution of dust, we implemented a dust source-tagging technique in
165 EAMv1. This modeling tool was previously applied to BC (H. Wang et al., 2014; Yang et al.,
166 2017b), sulfate (Yang et al., 2017a), and primary organic aerosol (Yang et al., 2018) in the
167 Community Atmosphere Model version 5 (CAM5). In this method, dust emission fluxes from
168 different sources are assigned to separate tracers and transport independently, so that dust
169 originating from different sources can be tracked and tuned separately in a single model

170 experiment. As shown in Figure 1a, dust emissions from 7 source regions are tagged: Arctic (Arc;
171 above 60°N, HLD source), North America (NA_m), North Africa (NA_f), Central Asia (CA_s),
172 Middle East and South Asia (MSA), East Asia (EA_s), and rest of the world (RoW). The Arctic
173 source is further divided into four sub-sources: Alaska (Ala), North Canada (NCa), Greenland
174 and Iceland (GrI), and North Eurasia (NEu) (Figure S1), which are used in the analysis of INP
175 sources in Section 3.3. RoW represents the three major dust sources in the Southern Hemisphere
176 (South America, South Africa, and Australia), along with very low emissions from Europe and
177 the Antarctic.

178 The global dust emission for CTRL is 5640 Tg yr⁻¹, which is tuned so that the global average
179 dust aerosol optical depth (DOD) is 0.031. This is within the range of the observational estimate
180 (0.030±0.005) by Ridley et al. (2016). To maintain the magnitude of the global averaged DOD,
181 our tuned global dust emission exceeds the range of the AeroCom (Aerosol Comparisons
182 between Observations and Models) models (500 to 4400 Tg yr⁻¹; Huneeus et al., 2011), likely
183 due to a short lifetime caused by too strong dust dry deposition at the bottom layer near the dust
184 source regions in EAMv1 (Wu et al., 2020). It is also about 2000 Tg yr⁻¹ higher than the previous
185 EAMv1 studies (Shi and Liu, 2019; Wu et al., 2020), because we distribute less dust mass into
186 the accumulation mode and more dust mass into the coarse mode based on Kok (2011). The
187 HLD emission is further tuned up by 10 times so that it accounts for 2.6% (144 Tg yr⁻¹) of the
188 global dust emission (Figure 1b), which is comparable with the recent estimates of 2-3% above
189 50°N by Bullard et al. (2016) and of 3% above 60°N by Groot Zwaafink et al. (2016). The
190 majority of global dust emission is contributed from North Africa (51.9%, 2929 Tg yr⁻¹) and
191 Asia (37.7%, 2124 Tg yr⁻¹), with Asian emissions composed of MSA (20.2%, 1140 Tg yr⁻¹), EA_s
192 (10.9%, 613 Tg yr⁻¹), and CA_s (6.6%, 371 Tg yr⁻¹). NA_m has a weak dust emission of 33.4 Tg

193 yr⁻¹ that only contributes 0.6% to the global emission, while the RoW has a combined
194 contribution of 7.3% (410 Tg yr⁻¹). In addition, the seasonal variations between HLD and LLD
195 emissions are different - the HLD (Arctic) source is more active in late summer and autumn,
196 while the LLD sources (e.g., Naf, MSA, EAs) peak in spring and early summer (Figure 1c).

197 **3 Result**

198 **3.1 Model validation**

199 To evaluate the model performance in simulating the dust cycle, we compare the model
200 predictions with measured aerosol optical depth (AOD), dust surface concentrations, and dust
201 deposition fluxes from global observation networks (Figure 2). We select and process the level
202 2.0 AOD data (2007-2011) at 40 “dust-dominated” AErosol RObotic NETwork (AERONET;
203 Holben et al., 1998) stations following Kok et al. (2014b). We note that the AERONET AOD
204 measurements are biased towards clear-sky conditions due to the cloud-screening procedure
205 (Smirnov et al., 2000). For dust surface concentrations, we use the same measurements at 22
206 sites, which Huneus et al. (2011) used for the AeroCom comparison, and further extend the
207 dataset with measurements at three high latitude stations: Heimaey (Prospero et al., 2012), Alert
208 (Sirois and Barrie, 1999), and Trapper Creek (Interagency Monitoring of Protected Visual
209 Environments; IMPROVE). It is noted that the measurements at Trapper Creek only include dust
210 particles smaller than 2.5 μm and are only compared with simulated dust concentrations at the
211 same size range. All other concentration measurements capture dust particles below 40 μm and
212 are compared with simulated dust over the whole size range ($< 10 \mu\text{m}$). The dust deposition
213 fluxes dataset, which including 84 stations, is also the same as Huneus et al. (2011). The
214 locations of the observation network are shown in Figure 2d, with the AOD data taken close to

215 source regions and the dust surface concentrations and deposition fluxes measured at relatively
216 remote regions. The Pearson correlation coefficient (r) are provided for each comparison. We
217 note that the comparisons are subject to representative biases caused by comparing an
218 observational station with a global model grid point (with a horizontal resolution of ~ 100 km).
219 The comparisons of dust concentration and deposition flux also have systematic errors because
220 the measurements were for a different time period than that of the model simulation.

221 In general, the three comparisons indicate that our CTRL simulation is capable of capturing
222 the global dust cycle in both near the source and remote regions. As shown in Figure 2a, the
223 modeled AOD is within a factor of two of the observations over most of the stations. The
224 correlation of the AOD comparison is 0.73, which is comparable to the best performing
225 simulation ($r = 0.72$) in Kok et al. (2014b). Our model also does a fairly good job in simulating
226 the dust surface concentrations (Figure 2b) and produces a correlation coefficient of 0.84. For the
227 three high latitude sites, the model shows moderate underestimation at Heimaey and Trapper
228 Creek and large positive bias at Alert (see discussion below). The correlation coefficient for
229 simulated dust deposition fluxes ($r = 0.48$) is also within the range of the AeroCom comparisons
230 (0.08 to 0.84) in Huneeus et al. (2011). The model results over most of the sites are within one
231 order of magnitude difference, except at the polar regions. In particular, the model overestimates
232 the dust deposition flux in Greenland (red triangles in Figure 2c and 2d) by around two orders of
233 magnitude, likely due to too strong local emissions simulated near the coast of Greenland (Figure
234 1a).

235 The seasonal cycle of dust surface concentrations at the three Arctic stations (Heimaey, Alert,
236 and Trapper Creek) are shown in Figure 3, along with the contribution from seven tagged
237 sources. The simulated dust concentrations at Heimaey are dominated by HLD and agree well

238 with the observation in late summer and autumn (Figure 3a). Its annual-averaged low bias shown
239 in Figure 2b mainly comes from the springtime, when Prospero et al. (2012) found the observed
240 dust are related to dust storms in Iceland, indicating a possible underestimation in the simulated
241 Icelandic dust during this time. The HLD also dominates the surface dust concentrations at Alert
242 (Figure 3b), leading to a large overestimation from June to August in our simulation, which
243 possibly implies a high bias and wrong seasonal cycle of HLD emission over Greenland and
244 North Canada. The Trapper Creek station is instead dominated by LLD from East Asia and
245 shows an underestimation for most of the year. It is noted that we only include fine dust
246 (diameter < 2.5 μm) for the comparison at Trapper Creek. Larger size range is likely to be more
247 influenced by HLD sources. The low bias here, especially that during the autumn, can be related
248 to the missing of local emissions from the coast of Southern Alaska (Figure 1a) that occurs most
249 frequently in autumn (Crusius et al., 2011). An underestimation of the transport from Saharan
250 dust may also contribute slightly, as the influence from Saharan dust is found during mid-May at
251 Trapper Creek (Breider et al., 2014).

252 The simulated Arctic dust vertical profiles are also compared with the measured dust
253 concentrations during the Arctic Research of the Composition of the Troposphere from Aircraft
254 and Satellites (ARCTAS) flight campaign (Figure 4) (Jacob et al., 2010). The ARCTAS
255 campaign was conducted over the North American Arctic in April and July 2008. The simulated
256 profiles are averaged over the regions where the aircraft flew, in accordance with Groot
257 Zwaafink et al. (2016). In April, the model does a good job in capturing the Arctic dust vertical
258 profiles (Figure 4a). However, in July, the model underestimates dust by a factor of 2 to 5
259 between 3 and 10 km (Figure 4b). It also shows an overestimation near the surface in July, which
260 agrees with the surface concentrations comparison at Alert station (Figure 3b). The

261 underestimation in the upper troposphere and overestimation near the surface likely imply a too
262 weak vertical transport of HLD in the North American Arctic in summertime. The high bias in
263 the upper troposphere may also be related to an underrepresentation of LLD transport.

264 Finally, we evaluate the simulated dust extinction against the Cloud-Aerosol Lidar and
265 Infrared Pathfinder Satellite Observation (CALIPSO) retrieval (Luo et al., 2015a, b; Yang et al.,
266 2022), which includes nighttime dust extinction for the period of 2007 to 2009. This data set has
267 improvements in dust separation from other aerosol types and thin dust layer detection in the
268 Arctic compared to the standard Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP)
269 Level 2 product (Winker et al., 2013). To make an apple-to-apple comparison, the modeled dust
270 extinction is sampled along the CALIPSO tracks and screened by cloud fraction (Wu et al.,
271 2020). For this comparison, we only use the first three years (2007 to 2009) of the CTRL
272 simulation to be consistent with the observation period. Overall, the model does a good job in
273 capturing the Arctic dust extinction vertical profiles (Figure 5). We notice that the simulated dust
274 extinction is lower than CALIPSO retrievals at the upper troposphere in summer, which agrees
275 with the ARCTAS comparisons. The simulated dust extinction also shows a consistent
276 underestimation in springtime (MAM) and a near surface underestimation in wintertime (MAM).
277 Since the Arctic is mostly covered by ice and snow in these two seasons, the impacts of HLD are
278 expected to be limited and the low biases are most likely due to the underprediction of LLD
279 transport. The near surface underestimation in DJF may indicate a too weak LLD transport in the
280 lower troposphere (e.g., the transport of dust emitted from Central Asia; see Figure 7 and the
281 corresponding discussions in Section 3.2). Moreover, the HLD has a large contribution in the
282 lower troposphere in boreal summer and autumn, which is consistent with its strong emission at
283 that time. In contrast, LLD plays a more dominant role in the upper troposphere, where African

284 dust contributes the most in the springtime and East Asian dust has a larger contribution in the
285 other seasons.

286 **3.2 Arctic dust mass source attribution**

287 Table 2 summarizes the relative contributions from individual sources to the total Arctic dust
288 burden. The transport pathways can be identified from the dust burden spatial distribution for
289 each source in Figure 6, while the relative contribution of each source to the total dust burden is
290 shown in Figure S2. We also calculate the regional burden efficiency for each source (Table S1),
291 which is defined as the mean contribution to the Arctic dust column burden divided by the
292 corresponding dust emission (H. Wang et al., 2014). This metric represents the sensitivity of
293 Arctic dust loading to per unit change of dust emission from each source (i.e., the poleward
294 transport efficiency of each source).

295 Our model results suggest that the HLD (Arc) is the largest contributor (30.7%) to the annual
296 mean Arctic dust burden among all the tagged sources. As shown in Figure 6a and Figure S2a,
297 the local dust is confined within the high latitudes, with the higher amounts and higher
298 contributions to the total dust burden near the sources in North Canada, coast of Greenland, and
299 Iceland. The interior of the Greenland ice sheet, with its higher elevations, is more influenced by
300 LLD from North Africa and East Asia than HLD (Figure S2c and S2f). This is due to the weak
301 vertical transport of local emissions in the Arctic (see more discussions below).

302 On the other hand, all LLD sources are responsible for 69.3% of the dust loading in the Arctic,
303 with considerable contributions from North Africa (24.2%) and Asia (in total 44.2%; EAs:
304 19.9%, MSA: 11.5%, CAs: 12.8%), and minor contributions from NAm (0.1%) and RoW (nearly
305 0). The North African dust is primarily transported westward to the Atlantic and southward to
306 Sahel, with a smaller fraction transported directly northward or northeastward across the Eurasia

307 to the Arctic (Figure 6c; Shao et al., 2011). The westward trajectory can also bring dust to the
308 Arctic through the Azores high (e.g., VauCuren et al., 2012), but this pathway is not clearly seen
309 on Figure 6c likely due to the strong wet removal process over the North Atlantic. As evident by
310 the low transport efficiency in Table S1, the significant contribution of the North African dust to
311 the Arctic dust burden is mainly due to its massive emission. However, this is not the case for
312 EAs. The East Asian dust is first lifted vertically by topography and convection (Shao et al.,
313 2011) and is widely spread over the Northern Hemisphere mid- and high-latitude regions through
314 the westerly flow in the upper troposphere (Figure 6f). The high elevation of East Asian dust
315 plumes results in weaker removal processes and thus an efficient poleward transport. As shown
316 in Table S1, the annual transport efficiency of the East Asian dust is relatively high among the
317 LLD sources, which is nearly three times larger than that of the North African dust. The
318 poleward transport of dust from CAs and MSA both takes the pathway across Siberia (Figure 6d
319 and 6e). The transport efficiency of the CAs dust is two times higher than that of the MSA dust
320 (Table S1). This is attributed to CAs being closer to the Arctic and having less southward dust
321 transport than MSA. Overall, the LLD from North Africa and Asia contributes more to the
322 Eurasia and Pacific sector of the Arctic (Figures S2c to S2f). The impact of NAM dust is limited
323 by its weak emission (Figure 6b), while dust emitted in the Southern Hemisphere (RoW) can
324 hardly pass the equator (Figure 6g).

325 Earlier modeling studies (Breider et al., 2014; Groot Zwaafink et al., 2016; Luo et al., 2003;
326 Tanaka and Chiba, 2006) also quantify the relative contributions of dust from various regions to
327 the Arctic dust loading. Among these studies, only Groot Zwaafink et al. (2016) includes HLD.
328 Our estimate about the HLD percent contribution is close to that from their study (27%). For
329 LLD, our conclusion about the dominant role of African and Asian dust to the Arctic dust burden

330 is also corroborated by these previous studies. However, the relative importance of African and
331 Asian dust is uncertain. Based on our results, the Asian dust is responsible for 65% of the LLD
332 transport to the Arctic, while the African dust only contributes 35%. Other studies find that 50%
333 (Groot Zwaafink et al., 2016; Luo et al., 2003; Tanaka and Chiba, 2006) to as much as 65%
334 (Breider et al., 2014) of the LLD in the Arctic is attributed to North Africa. These discrepancies
335 may be explained by the different dust emission and scavenging, dust size distribution,
336 meteorological fields, and/or time periods for the model simulation. For example, the wet
337 removal process is expected to have large discrepancies among different models, because of the
338 large uncertainties in the model representation of clouds and precipitation. The different spatial
339 distributions of dust emission due to the use of different emission parameterizations may also
340 contribute to the discrepancies (e.g., North Africa dust in our study contributes slightly less
341 (51.9%) to the global dust emission than the other studies (from 57% to 67%). Isotopic analysis
342 (Bory et al., 2002, 2003) and case studies (Huang et al., 2015; Stone et al., 2005; VanCuren et al.,
343 2012) have proved that both Asian and African dust can be transported to the Arctic. However, it
344 remains unclear which of them contributes more to the Arctic dust loading due to the limited
345 observational constraints.

346 HLD and LLD source regions also have very distinct vertical distributions in the Arctic.
347 Figures 7a and 7b show the annual mean vertical profiles of Arctic dust concentrations from
348 various sources and their percentage contributions, respectively. The Arctic dust in the lower
349 atmosphere is dominated by the local source. HLD accounts for more than 30% of the Arctic
350 dust concentrations below 800 hPa, with up to 85% contribution near the surface. However, the
351 HLD contribution decreases rapidly with height and is less than 10% above 700 hPa. This is
352 because the lower troposphere of the Arctic is more stratified than the mid- and low latitudes,

353 which suppresses the vertical transport of HLD. The lower tropospheric stability (LTS) from the
354 CTRL simulation and comparison with the MERRA2 reanalysis data are shown in Figure S3.
355 The weak HLD vertical transport in the Arctic is also reported by previous studies (Groot
356 Zwaaftink et al., 2016, Baddock et al., 2017; Bullard, 2017). Moreover, the LTS over the Arctic
357 sea ice is much larger than that over open ocean surface (Schweiger et al., 2008), which may lead
358 to a stronger vertical transport of HLD over open waters. This suggests that the vertical transport
359 of HLD may change with the sea ice reduction in a warming future.

360 In contrast, LLD has a higher contribution in the mid- and upper troposphere than near the
361 surface. Such a vertical distribution of LLD is consistent with Stohl (2006) and Groot Zwaaftink
362 et al. (2016). As Stohl (2006) found, aerosols originating from the warm subtropics are
363 transported poleward following the uplifted isentropes and the Arctic lower atmosphere is
364 dominated by the near-impenetrable cold polar dome. Therefore, there is a slantwise lifting of
365 low latitude aerosols during their poleward transport. NAf and EAs are the two key contributors
366 to the Arctic dust vertical concentrations, each of which contributes up to one third of the total
367 dust concentrations above 700 hPa. Dust emission from MSA also has a moderate contribution
368 (15-20%) that increases gradually with height, while the contribution from CAs peaks at 700 to
369 800 hPa, indicating a lower altitude transport pathway than the EAs and MSA dust.

370 In addition, the Arctic dust undergoes a strong seasonal cycle (Table 2 and Figures 7c-j).
371 Because of the strong local emissions (Figure 1c), about half of the Arctic dust burden in
372 summer and autumn come from HLD, with more than 50% contribution of Arctic dust
373 concentrations below 850 hPa in these two seasons. In contrast, LLD plays a dominant role in
374 spring and winter. The North African dust has the largest contribution in spring, which accounts
375 for about 45% of the total dust concentrations above 700 hPa. The East Asian dust is more

376 important in the other three seasons. Due to its high emission height, the relative contribution
377 from EAs tends to increase with height and reaches 30% to 50% of the total dust concentration
378 above 500 hPa in summer, spring, and winter.

379 **3.3 Immersion freezing on dust in the AMPCs**

380 We are particularly interested in the contribution of various dust sources to the Arctic INP
381 populations. Therefore, we compare the simulated INP concentrations with nine Arctic field
382 measurements, which are summarized in Table 3. The modeled dust INP concentrations are
383 diagnosed from monthly averaged aerosol properties using the default CNT scheme and two
384 empirical ice nucleation parameterizations, DeMott et al. (2015; hereafter as D15) and Sanchez-
385 Marroquin et al. (2020; hereafter as SM20). The D15 parameterization, which is representative
386 of Saharan and Asian desert dust, relates dust INP number concentrations to the number
387 concentration of dust particles larger than 0.5 μm diameter and is found to produce the most
388 reasonable LLD INP concentrations in EAMv1 (Shi and Liu, 2019). CNT and D15 are applied to
389 LLD only and all the dust aerosols (LLD and HLD) in Figures 8a-b and Figures 8d-e,
390 respectively. The SM20 parameterization, which is derived for the HLD Icelandic dust, describes
391 the dust INP number concentrations as a function of surface active site density and total dust
392 surface area. Considering the possibly different ice nucleation ability between HLD and LLD,
393 we only applied the SM20 parameterization to HLD and the CNT and D15 parameterizations are
394 still applied to LLD in Figures 8c and 8f, respectively. To account for the contributions from
395 other aerosol types, we also calculate the INP concentrations from BC (Fig. 8g) and sea spray
396 aerosol (SSA; includes MOA and sea salt) (Fig. 8h) following Schill et al. (2020; hereafter as
397 Sc20) and McCluskey et al. (2018; hereafter as M18), respectively. More details about the ice

398 nucleation parameterizations are provided in Text S2. We discuss the choice of dust ice
399 nucleation schemes in Text S2.6 in the Supplement.

400 Overall, only including LLD as INPs results in up to four orders of magnitude underprediction
401 compared to observations (Figures 8a and 8d), while taking into account the contribution from
402 HLD greatly improves the model performance by increasing the simulated dust INP
403 concentrations (Figures 8b, 8c, 8e, and 8f). The CNT parameterization produces 5 to 10 times
404 more INP concentrations than the other two schemes at moderately cold temperatures (-22 to -
405 28°C), while it has a significant underestimation of observed INP concentrations at warm
406 temperatures ($T > -18^{\circ}\text{C}$) (also see Figure S4). D15 and SM20 agree well with each other in
407 simulating HLD INPs, with SM20 producing slightly higher results than D15. Our modeling
408 results also indicate that BC and SSA have much less contributions to INP than dust in all the
409 nine field campaigns (Figure 8g and 8h).

410 A detailed analysis of sources of the INPs for the nine datasets based on modeling analyses
411 and the corresponding observations in the literature are provided in Table 3. Modeling results
412 indicate that HLD has larger contributions to the INPs for the campaigns conducted in summer
413 and autumn than spring, in agreement with the observations. Also, ground-based measurements
414 are more influenced by the nearby HLD sources, while LLD from EAs and NAF contributes
415 more to the aircraft measurements.

416 Our modeling analyses about the INP sources agree well with the observational studies at
417 Alert in spring 2016 and near Iceland in autumn 2014 (symbol “C” and “I” in Figure 8,
418 respectively), while the model underestimates the observed INP concentrations in both cases.
419 The low bias in dataset C indicates an underprediction in the long-range transport of Asian dust
420 to the Arctic surface in springtime. The underestimation in dataset I is more likely due to the fact

421 that some of the aircraft measurements were taken inside the Icelandic dust plumes (Sanchez-
422 Marroquin et al., 2020), which cannot be resolved by the monthly mean model output and the
423 coarse model horizontal resolution (1°). Such uncertainties exist in all the model-observation
424 comparisons.

425 Some other comparisons in INP sources reveal the lack of marine and carbonaceous INPs in
426 the model. The model results show a dominance of dust INPs in spring 2017 at Zeppelin and
427 Oliktok Point (symbol “D” and “E” in Figure 8) and in Autumn 2004 at Utqiaġvik (symbol “H”
428 in Figure 8), while the observational studies suggested the importance of marine sources at the
429 first two locations and of carbonaceous aerosols at Utqiaġvik. Therefore, it is likely that the
430 model underestimates the contribution of MOA (Wilson et al., 2015; Zhao et al., 2021a) and
431 does not account for terrestrial biogenic INPs (Creamean et al., 2020) due to the lack of
432 treatments in the model. In addition, both D15 and SM20 schemes cannot represent the high ice
433 nucleating ability of HLD at warm temperatures at Zeppelin in summer 2016 (symbol “G” in
434 Figure 8), which is attributed to soil organic matter by Tobo et al. (2019). When these organics
435 are taken into account in the model, model overestimation for site G will get even worse,
436 implying an overestimation of surface dust concentrations and/or HLD dust emission at Svalbard
437 in the summertime. In summary, the model’s INP biases in the Arctic are likely due to biases in
438 the simulated aerosol fields (e.g., dust, MOA, and BC) and uncertainties in current ice nucleation
439 parameterizations or missing representations of other INP sources (e.g., terrestrial biogenic
440 aerosols).

441 In addition, we do not explicitly represent the potential ice nucleation ability differences in
442 freshly emitted HLD and long-range transported LLD caused by the aging and the coatings of
443 pollutants (Kulkarni et al., 2014; Boose et al., 2016). However, D15 and SM20 may already take

444 the aging effect into account implicitly. Because D15 is based on the Saharan and Asian dust
445 data collected over the Pacific Ocean basin and US Virgin Islands, respectively, which are far
446 away from the corresponding LLD sources, while SM20 is derived from the freshly emitted
447 Icelandic HLD, which is subjected to less aging effect.

448 The comparisons above are based on INP concentrations at a given temperature set by the INP
449 instruments, which reflects the potential INP populations under ambient aerosol conditions. Next,
450 we examine the immersion freezing rate of dust originating from the seven tagged sources
451 (Figure 9) to evaluate the influences of HLD and LLD on ice nucleation processes in mixed-
452 phase clouds. It is noted that the immersion freezing rate here is calculated online in the model
453 using the ambient temperature and the default CNT ice nucleation parameterization.

454 Compared with its contribution to the dust burdens, the contribution of the HLD to the annual
455 mean mixed-phase cloud immersion freezing rate is relatively small (~10% below 600 hPa)
456 (Figure 9a). This is because the HLD is mainly located in the lower troposphere and not a lot of
457 HLD can reach the mixed-phase cloud levels (or the freezing level), especially under the case
458 that the HLD tends to be more prevalent in the warm seasons (see more discussion below).
459 Among the LLD sources, North African dust (Figure 9c) and East Asian dust (Figure 9f) are the
460 two major contributors, both of which are responsible for more than 20% of the annual mean
461 immersion freezing rate in the mixed-phase clouds. Consistent with the vertical distribution of
462 dust concentrations, the North African dust has its maximum contribution (30-40%) at around
463 500 hPa, while the East Asian dust plays a more important role at higher altitudes (above 400
464 hPa). Dust from Central Asia also has a moderate contribution (~20%) to the immersion freezing
465 rate in the Arctic (Figure 9d).

466 Considering the different seasonality of HLD and LLD in the Arctic, we next investigate the
467 seasonal variations of the immersion freezing rate in the Arctic mixed-phase clouds from HLD
468 and two dominating LLD sources (NAf and EAs) (Figure 10). HLD has the largest contribution
469 to the Arctic immersion freezing rate in boreal autumn, with more than 30% below 700 hPa and
470 up to 50% near the surface (Figure 10c). It is related to the prevalence of HLD and relatively
471 cold temperatures during this time in the Arctic. This is not the case for the summer, when the
472 freezing level is relatively high. Although it is responsible for 50% of the total Arctic dust
473 burden in the boreal summer, HLD has a limited contribution to the immersion freezing rate in
474 the clouds (Figure 10b), because its weak vertical transport makes it hard to reach the freezing
475 line. The contrast results in summer and autumn suggest that the immersion freezing rate in the
476 Arctic clouds is influenced by air temperature in addition to the aerosols. It also implies that the
477 surface INP measurements may not reflect the complete picture of INP effects and more aircraft
478 INP measurements are needed in the future. The seasonal variations of the immersion freezing
479 rate from NAf and EAs are weaker than that from HLD but are still subjected to the vertical
480 temperature change with season. The North African dust contributes more in spring and winter,
481 while the East Asian dust is more important in summer and autumn.

482 **3.4 Impact on cloud properties and radiative fluxes**

483 Dust INPs can freeze the supercooled liquid droplets, which impacts the cloud microphysical
484 and macrophysical properties and modulates the Earth's radiative balance. To examine such
485 impacts, we conduct three sensitivity experiments that turn off the heterogeneous ice nucleation
486 in the mixed-phase clouds by dust from Arctic local source, North Africa, and East Asia,
487 respectively (i.e., noArc, noNAf, and noEAs in Table 1). The impacts of dust INPs from each
488 source are determined by subtracting the respective sensitivity experiment from CTRL. Due to

489 the feedbacks in dust emission and wet scavenging caused by changing cloud properties, the dust
490 concentrations in the sensitivity experiments are not identical to CTRL, but the absolute
491 differences are mostly within 5% (Figure S5 in the Supplement).

492 The cloud liquid and ice changes caused by dust INPs from each source are shown in Figure
493 11. Due to the strengthening of heterogeneous ice nucleation processes, INPs from all the three
494 sources consistently reduce the total liquid mass mixing ratio (TLIQ) (Figure 11, first column)
495 and cloud liquid droplet number concentration (NUMLIQ) (Figure 11, third column). The
496 influence of HLD is mainly in the lower troposphere (Fig. 11, top row) and the influence of LLD
497 extends to higher altitudes (Fig. 11, bottom two rows). Moreover, the cloud ice number
498 concentration (NUMICE) decreases in the upper troposphere (Figure 11, fourth column), likely
499 due to less cloud droplets available for the homogeneous freezing in cirrus cloud after
500 introducing dust INPs in the mixed-phase clouds. With fewer ice crystals falling from the cirrus
501 clouds to the mixed-phase clouds, the WBF process in the mixed-phase clouds is inhibited
502 (Figure S6). Other ice phase processes such as the accretion of cloud water by snow and the
503 growth of ice crystals by vapor deposition also become less efficient, which decreases the total
504 ice mass mixing ratio (TICE) above 600-700 hPa altitude (Figure 11, second column). TICE in
505 the lower troposphere is increased because of immersion freezing and snow sedimentation from
506 above.

507 Since liquid water path (LWP) is found to play a critical role in the Arctic radiative budget
508 (e.g., Dong et al., 2010; Hofer et al., 2019; Shupe and Intrieri, 2004), we further investigate the
509 seasonal variations of LWP changes caused by dust INPs from the three sources (Figure 12).
510 Corroborated with their large contribution to the immersion freezing rate during this time (Figure
511 10, top row), HLD INPs produce the strongest LWP decrease (-1.3 g m^{-2}) in boreal autumn

512 (Figure 12c), especially over North Canada and Greenland. The influence of LLD INPs on LWP
513 peaks in spring and winter. North African dust tends to have a larger impact on North Eurasia,
514 while East Asian dust impacts the west Arctic more.

515 Dust INPs from the three sources consistently increase (decrease) the annual mean
516 downwelling shortwave (longwave) radiative flux (FSDS and FLDS) at the surface (Figure 13,
517 left and middle columns). This is mainly due to the LWP decrease, which reduces the cloud
518 albedo and longwave cloud emissivity. For HLD INPs, the FLDS reduction dominates over the
519 FSDS increase and causes a net cooling effect at the Arctic surface (-0.24 W m^{-2}) (Figure 13c).
520 In contrast, FSDS and FLDS changes related to the LLD INPs are comparable, which cancels
521 each other and yields a small net radiative effect (0.08 W m^{-2} for NAF and -0.06 W m^{-2} for EAs)
522 (Figure 13, bottom two rows). These differences in the net radiative effect are associated with
523 different seasonalities of HLD and LLD. The insolation in the Arctic is strong in spring and
524 summer but very limited in autumn and winter. Since the HLD INPs have much stronger
525 influence on LWP in autumn and winter than spring and summer (Figure 12), their contribution
526 to the FSDS warming is weak and the FLDS cooling in autumn and winter dominates the annual
527 mean effect (Table 4, part 1; also seen in Figure S7 to S9). LLD INPs are also important in
528 spring and summer, so their FSDS warming effect is comparable to, and compensates for, the
529 FLDS cooling effect.

530 We also examined the dust INP effect on cloud radiative forcing (CRF) at the top of the
531 atmosphere (TOA) (Table 4, part 2). Dust INPs from the three sources induce a small net cooling
532 (from -0.03 to -0.05 W m^{-2}) in the Arctic, with SW warming and LW cooling effects. The net
533 cooling persists throughout the year, except for the summertime when the sufficient insolation
534 results in a strong SW warming and, consequently, a net warming effect. Shi and Liu (2019) also

535 found LLD can induce a generally net cooling effect above 70°N (0.18 to -1.95 W m⁻²), but in a
536 much higher magnitude than the sum of NAF and EAs dust INP effects (-0.15 W m⁻² above 70°N,
537 not shown in Table 4), which implies the aerosol glaciation effect on mixed-phase clouds is
538 highly non-linear.

539 Finally, we evaluate the model performance in simulating the Arctic LWP and radiative fluxes
540 against the Moderate Resolution Imaging Spectroradiometer (MODIS) LWP and the Cloud and
541 the Earth's Radiant Energy System Energy Balanced and Filled Edition 4.1 (CERES-EBAF
542 Ed4.1) products (Loeb et al., 2018; Kato et al., 2018), respectively (Figure 14). Two MODIS
543 datasets are used, including the standard Collection 6.1 product (Pincus et al., 2012; P12) and
544 Khanal et al. (2020; K20). The P12 product combines MODIS observations from Terra and Aqua
545 and is designed for apples-to-apples comparisons with modelling results from the Cloud
546 Feedback Model Intercomparison Project (CFMIP) Observation Simulator Package (COSP). The
547 standard product has a well-known positive zonal bias near the poles that is strongly correlated
548 with the solar zenith angle (SZA). The K20 product largely reduces this bias by utilizing the
549 SZA and cloud heterogeneity index in their retrieval algorithm. The MODIS simulator is used
550 for to calculate the simulated LWP. According to Fig. 14, the simulated LWP from the four
551 experiments are lower than P12 but higher than K20. All the four experiments also underestimate
552 FSDS with too strong SWCF and overestimate FLDS with too strong LWCF, which likely points
553 to the biases of modeled clouds (e.g., too much LWP as compared to K20). The differences
554 among the model experiments are very small compared to their discrepancies with observations.
555 We notice including dust INPs from the three sources decreases the simulated LWP (i.e., CTRL
556 has less LWP than the other experiments) (Figure 14a), which makes the model performance
557 better if compared to K20. Moreover, it shows noticeable improvements in simulating both

558 surface and TOA radiative fluxes after including dust INPs from each of the three sources (i.e.,
559 the results from CTRL are closer to the CERES results than the other three experiments) (Figure
560 14b-e).

561 Overall, including HLD or LLD INPs do not contribute a lot to the reduction of biases in
562 simulating the LWP and radiative fluxes in the AMPCs. However, the representation of AMPCs
563 in global climate models is associated with multiple cloud macro- and microphysical processes,
564 and large-scale dynamics (Morrison et al., 2012) (see more discussion in Section 4), which
565 interact with one another non-linearly. Therefore, even though including HLD or LLD INPs do
566 not improve the representation of AMPCs significantly in our model, a good representation of
567 dust INPs, especially including HLD INPs, could still be of great importance for parameterizing
568 AMPCs in the model.

569 **4. Discussion**

570 The HLD emission in our CTRL simulation is manually tuned up by 10 times to match the
571 estimate by Bullard et al. (2016), which is derived by compiling field measurements in Iceland
572 and Alaska. Since the instruments were operated under extreme Arctic conditions and the
573 sampling is very scarce, this estimate may have large uncertainties. Therefore, the tuned HLD
574 emission can be biased as well. Considering the overestimation of Greenland dust deposition,
575 summertime surface dust concentrations at Alert station, and surface INP concentrations at
576 Svalbard, our tuning may cause a regional and temporal high bias in HLD dust emissions. We
577 examine this uncertainty by conducting a sensitivity experiment with halving HLD emissions in
578 CTRL (i.e., HLD_half) and analysing the interannual variability of CTRL and HLD_half
579 simulations (Table S2 and Figures S10-S11). The HLD_half simulation indeed has a better

580 performance than CTRL. However, the high bias for Greenland deposition and the summertime
581 overestimation of Alert dust surface concentration still exist, which reflects the limitation of the
582 dust emission parameterization we use. This parameterization may not be able to capture the
583 spatial distribution of dust emissions across the Arctic, considering that the model performance
584 at other sites is much better (e.g., Heimaey, Figure 3a). Also, the HLD emissions and their
585 regional distributions have large interannual variabilities. Therefore, as we mentioned in Section
586 3.1, comparing model simulations with measurements conducted in different years may result in
587 large uncertainties.

588 The overestimation of surface dust and INP concentrations may imply a too weak vertical
589 transport of HLD, considering the low biases of dust in the upper troposphere as compared with
590 ARCTAS measurements and CALIPSO retrievals. The weak vertical transport at the source
591 regions in EAMv1 was also found in Wu et al. (2020), which was related to the too strong dry
592 deposition at the surface layer. If this bias is addressed, HLD would contribute less (more) to the
593 Arctic dust concentrations in the lower (upper) troposphere, which suggests a larger contribution
594 of HLD to the heterogeneous ice nucleation in the mixed-phase clouds in the summertime. As a
595 result, the HLD would induce a more positive net downwelling radiative flux at the surface in
596 summer and a less negative annual mean radiative effect. It is also noted that the underprediction
597 in the upper troposphere dust may come from a weak long-range transport of LLD. If this is the
598 case, the HLD would have a weaker contribution to the upper level dust concentrations and
599 likely less of an impact on mixed-phase cloud heterogeneous ice nucleation in the summertime.

600 In addition, EAMv1 has intrinsic biases in its cloud microphysics parameterizations. As
601 mentioned in Section 2.1, the WBF process rate in EAMv1 is tuned down by a factor of 10,
602 which results in too many supercooled liquid clouds in high latitudes (Y. Zhang et al., 2019; M.

603 Zhang et al., 2020). Shi and Liu (2019) found the sign and magnitude of dust INP cloud radiative
604 effect in the Arctic would change, after removing the tuning factor for the WBF process in
605 EAMv1. Moreover, EAMv1 does not account for several secondary ice production mechanisms,
606 which are suggested to have a large impact on the ice crystal number concentrations and thus
607 cloud phase (Zhao and Liu, 2021; Zhao et al., 2021b). All these uncertainties in the cloud
608 microphysical processes would interact non-linearly and influence our estimate of INP radiative
609 effect and should be addressed in future studies.

610 **5. Conclusions**

611 In this study, we investigate the source attribution of dust aerosols in the Arctic and quantify
612 the relative importance of Arctic local dust versus long-range transported LLD to the Arctic dust
613 loading and INP population. We found that HLD is responsible for 30.7% of the total dust
614 burden in the Arctic, whereas LLD from Asia and North Africa contributes 44.2% and 24.2%,
615 respectively. The vertical transport of HLD is limited due to the stable cold air in the Arctic and
616 thus it contributes more to the dust burden in the lower troposphere. In boreal summer and
617 autumn when the contribution of HLD is at a maximum because of stronger local dust emissions,
618 HLD is responsible for more than 30% of the Arctic dust loading below 800 hPa, but less than 10%
619 above 700 hPa. In contrast, LLD from North African and East Asian dust dominates the dust
620 burden in the free troposphere, since the poleward transport of LLD follows the uplifted
621 isentropes. The North African and East Asian dust accounts for about two thirds of the dust
622 loading above 700 hPa, with the remaining one third from other LLD sources. The North African
623 dust contributes more between 500 and 700 hPa, while the East Asian dust dominates in the
624 upper troposphere (above 400 hPa) because of its high emission heights. In addition, the North

625 Africa source has a larger contribution in springtime, while the other three seasons are more
626 influenced by the East Asian source.

627 Modeled dust INP concentrations are investigated following three ice nucleation
628 parameterizations: CNT, D15 and SM20. Compared with INP measurements, our results show
629 that including HLD as INPs significantly improves the model performance in simulating Arctic
630 INP concentrations, especially for the ground measurements and for the measurements
631 conducted in summer and autumn. We also examine the INP contributions from BC and SSA
632 based on Sc20 and M18, respectively. The model suggests that both of them are only weak
633 sources compared with dust. We note that the model may underestimate SSA INPs and currently
634 misses the representation of terrestrial biological INPs. The model biases of INPs can also be due
635 to bias in simulating Arctic dust concentrations and/or the uncertainties in ice nucleation
636 parameterizations.

637 We examine the contribution of dust from the three sources (Arctic, North Africa, and East
638 Asia) to the ambient immersion freezing rate in the Arctic. The contribution from HLD shows a
639 strong seasonal variation, with the peak contribution in boreal autumn (above 20% below 500
640 hPa). In summer, although HLD has strong contributions to the dust loading and INP
641 concentrations in the lower troposphere, its impact on the ambient immersion freezing rate is
642 limited due to the warm temperatures and weak vertical transport. This finding implies that
643 surface INP measurements may not be sufficient in representing the INP population in the Arctic
644 mixed-phase clouds and more measurements of INP vertical profiles are needed in the future.
645 North African and East Asian dust are the two major LLD contributors to the ambient immersion
646 freezing rate. The annual mean contribution (30-40%) from North African dust peaks at around

647 500 hPa, while the immersion freezing is dominated by East Asian dust (more than 40%) in the
648 upper troposphere (above 400 hPa).

649 The cloud glaciation effects of dust INPs from local Arctic sources, and North African and
650 East Asian sources, are further examined. It is found that INPs from all the three sources
651 consistently result in a reduction in TLIQ and NUMLIQ. TICE and NUMICE at higher altitude
652 also decrease, likely due to the weakening of homogeneous freezing in cirrus clouds. LWP
653 reduction caused by HLD INPs is evident in autumn and winter, while those by dust INPs from
654 the two LLD sources peak in spring. HLD INPs also drive a net cooling effect of -0.24 W m^{-2} in
655 the downwelling radiative flux at the surface in the Arctic, while the net radiative effects of the
656 two LLD INP sources are relatively small (0.08 W m^{-2} for NAF and -0.06 W m^{-2} for EAs). This
657 variation in radiative effect reflects the seasonal difference between HLD and LLD. Our results
658 also suggest that all the three dust sources result in a weak negative net cloud radiative effect ($-$
659 0.03 to -0.05 W m^{-2}) in the Arctic, which is consistent with Shi and Liu (2019).

660 Overall, our study shows that the Arctic local dust, which has been overlooked in previous
661 studies, may have large contributions to the Arctic dust loading and INP population. It can also
662 influence the Arctic mixed-phase cloud properties by acting as INPs. Considering the climate
663 impacts of local Arctic dust emissions will be important given a warming climate, where
664 reduction in snow coverage and more exposure of dryland in the Arctic may lead to increased
665 HLD emissions.

666 *Code availability.* The E3SM code is available on GitHub: <https://github.com/E3SM->
667 [Project/E3SM.git](https://github.com/E3SM-Project/E3SM.git).

668 *Author contribution.* YS and XL conceived the project. YS modified the code, conducted the
669 simulations, and led the analyses with suggestions from XL, MW, XZ, ZK, and HB. XL
670 supervised the study. YS wrote the first draft of the paper. All coauthors were involved in helpful
671 discussions and revised the paper.

672 *Competing interests.* The authors declare that they have no conflict of interest.

673 *Acknowledgements.* The authors would like to thank Kang Yang and Dr. Zhien Wang for
674 providing the CALIPSO dust extinction retrievals and Drs. Meng Zhang and Sarah Brooks for
675 their comments and suggestions. Mingxuan Wu is supported by the US Department of Energy
676 (DOE), Office of Biological and Environmental Research, Earth and Environmental System
677 Modeling program as part of the Energy Exascale Earth System Model (E3SM) project. The
678 Pacific Northwest National Laboratory (PNNL) is operated for DOE by the Battelle Memorial
679 Institute under contract DE-AC05-76RLO1830. This research used resources of the National
680 Energy Research Scientific Computing Center, a DOE Office of Science User Facility supported
681 by the Office of Science of the U.S. Department of Energy under contract DE-AC02-
682 05CH11231.

683 *Financial support.* This research was supported by the DOE Atmospheric System Research
684 (ASR) Program (grants DE-SC0020510 and DE-SC0021211).

1068

1069 **Table 1.** Experiments conducted in this study.

Experiment	Description
CTRL	Control simulation using the CNT parameterization for heterogeneous ice nucleation and Kok et al. (2014a, b) for dust emission parameterization.
noArc	Same as CTRL, but turn off heterogeneous ice nucleation in mixed-phase clouds by HLD.
noNAf	Same as CTRL, but turn off heterogeneous ice nucleation in mixed-phase clouds by North African dust.
noEAs	Same as CTRL, but turn off heterogeneous ice nucleation in mixed-phase clouds by East Asian dust.

1070

1071 **Table 2.** Annual and seasonal mean Arctic (60-90°N) dust burden (mg m⁻²) from different
 1072 sources. The numbers in parentheses are the relative contributions (%) of each source to the total
 1073 Arctic dust burden. The total Arctic dust burden is shown in the last row.

1074

1075 **Table 3.** Summary of the nine Arctic INP measurements used for INP comparisons in Figure 8.

	Location	Time period	Measured platform	Reference	Possible INP source mentioned in literature	INP source attribution from modeling ⁺
A	Utqiagvik	Apr. 2008 (spring)	Aircraft	McFarquhar et al. (2011)	Metallic or composed of dust*	LLD (EAs)
B	Alert	Mar. - May 2014 (spring)	Ground-based	Mason et al. (2016)	Not mentioned	LLD (EAs)
C	Alert	Mar. 2016 (spring)	Ground-based	Si et al. (2019)	LLD from Gobi Desert	LLD (EAs)
D	Zeppelin	Mar. 2017 (spring)	Ground-based	Tobo et al. (2019)	Marine organic aerosols	HLD (NEu)
E	Oliktok Point	Mar. - May 2017 (spring)	Ground-based	Creamean et al. (2018)	Dust and primary marine aerosols	LLD (mainly from EAs and some from Naf)
F	Alert	Jun. - Jul. 2014 (summer)	Ground-based	Mason et al. (2016)	Not mentioned	HLD (NCa)
G	Zeppelin	Jul. 2016 (summer)	Ground-based	Tobo et al. (2019)	HLD from Svalbard or other high latitude sources**	HLD (NEu)
H	Utqiagvik	Oct. 2004 (autumn)	Aircraft	Prenni et al. (2007)	Dust and carbonaceous particles	HLD (NCa) and LLD (EAs)
I	South of Iceland	Oct. 2014 (autumn)	Aircraft	Sanchez-Marroquin et al. (2020)	Icelandic dust	Dominated by HLD (GrI), little from LLD (NAf)

1076 ⁺ The modeling analyses include INP contribution from HLD (using SM20), LLD (using D15),

1077 BC, and SSA. The

1078 * Carbonate, black carbon, and organic may also contribute, according to Hiranuma et al. (2013).

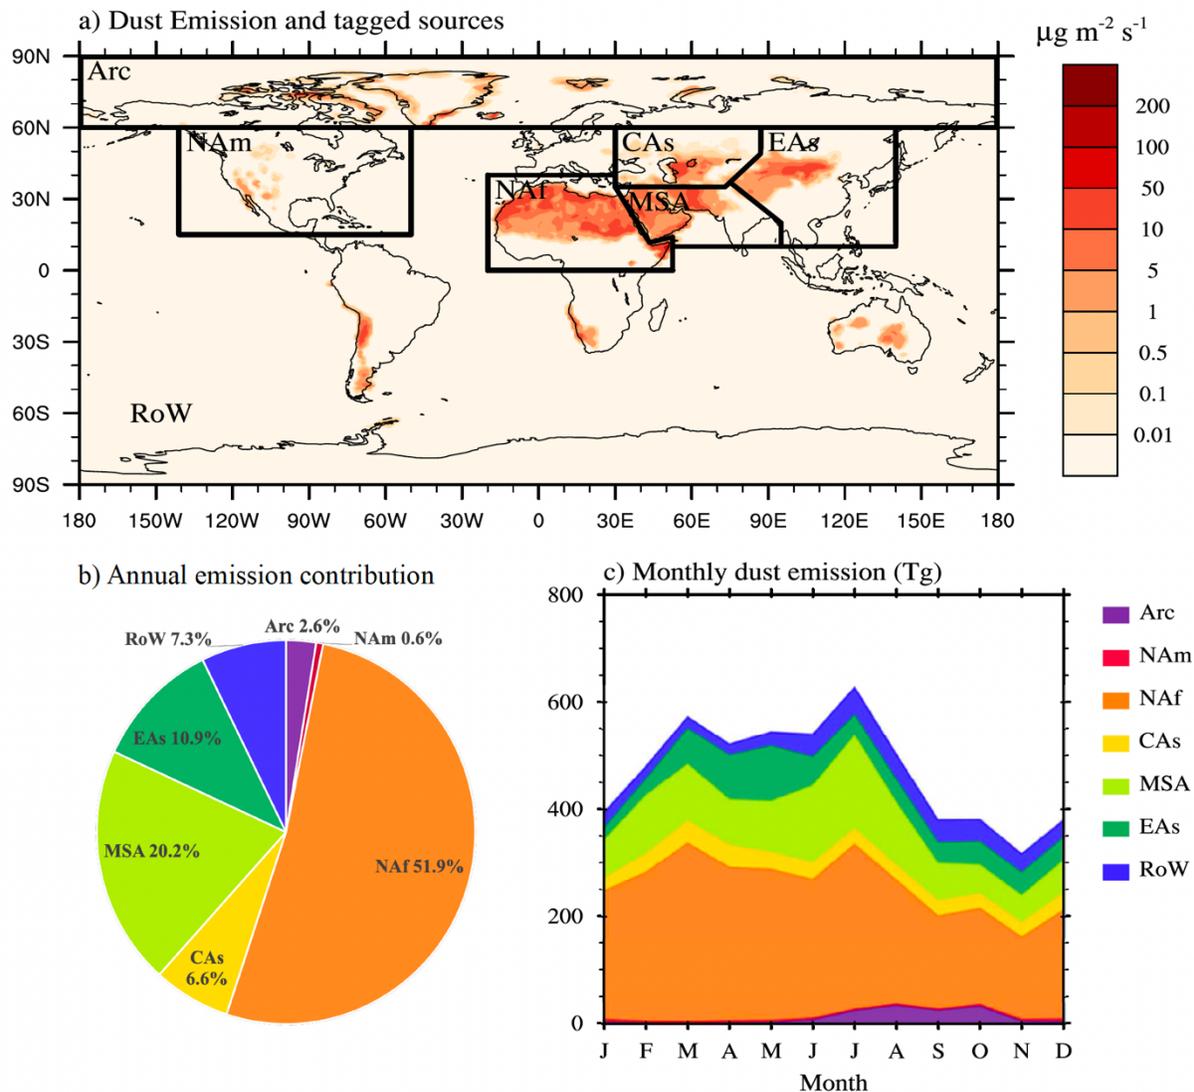

1079 ** The HLD in this campaign is reported to have remarkably high ice nucleating ability, which
 1080 may be related to the presence of organic matter.

1081

1082 **Table 4.** Arctic (60-90°N) averaged surface downwelling radiative fluxes and TOA cloud
 1083 radiative forcing changes caused by dust INPs originated from local Arctic sources (Arc), North
 1084 Africa (NAf), and East Asia (EAs). Units are W m⁻².

1087 **Figure 1.** a) Simulated global annual mean dust emission with 7 tagged source regions (Arc:
 1088 Arctic; NAm: North America; NAf: North Africa; CAS: Central Asia; MSA: Middle East and
 1089 South Asia; EAs: East Asia; RoW: Rest of the World). b) The respective percentage
 1090 contributions to the global annual mean dust emission from the individual source regions. c)
 1091 Seasonal cycle of global dust emission.

1092

1093 **Figure 2.** Comparison of observed and simulated a) averaged AOD at 40 dust-dominated
 1094 stations (stars), b) dust surface concentration at 25 sites (circles), and c) dust deposition flux at
 1095 84 sites (triangles). Solid lines represent 1:1 comparison. Dashed lines mark 2 factor of
 1096 magnitude bias in panel a) and 1 order of magnitude differences in panel b) and c). For each
 1097 comparison, the correlation coefficient (r) is noted. The AOD data is conducted by AERONET.
 1098 The dust surface concentration measurements include 20 stations managed by Rosenstiel School
 1099 of Marine and Atmospheric Science at the University of Miami (Prospero et al., 1989; Prospero,
 1100 1996; Arimoto et al., 1995), two Australia stations (Maenhaut et al., 2000a, b), and three Arctic
 1101 stations (Heimaey (Prospero et al., 2012), Alert (Sirois and Barrie, 1999), and Trapper Creek
 1102 (IMPROVE)). The deposition fluxes data is a compilation of measurements from Ginoux et al.
 1103 (2001), Mahowald et al. (2009), and the Dust Indicators and Records in Terrestrial and Marine
 1104 Paleoenvironments (DIRTMAP) database (Tegen et al., 2002; Kohfeld and Harrison, 2001).
 1105 Stations are grouped regionally and classified by different colors. The locations of the
 1106 measurements are shown in panel d).

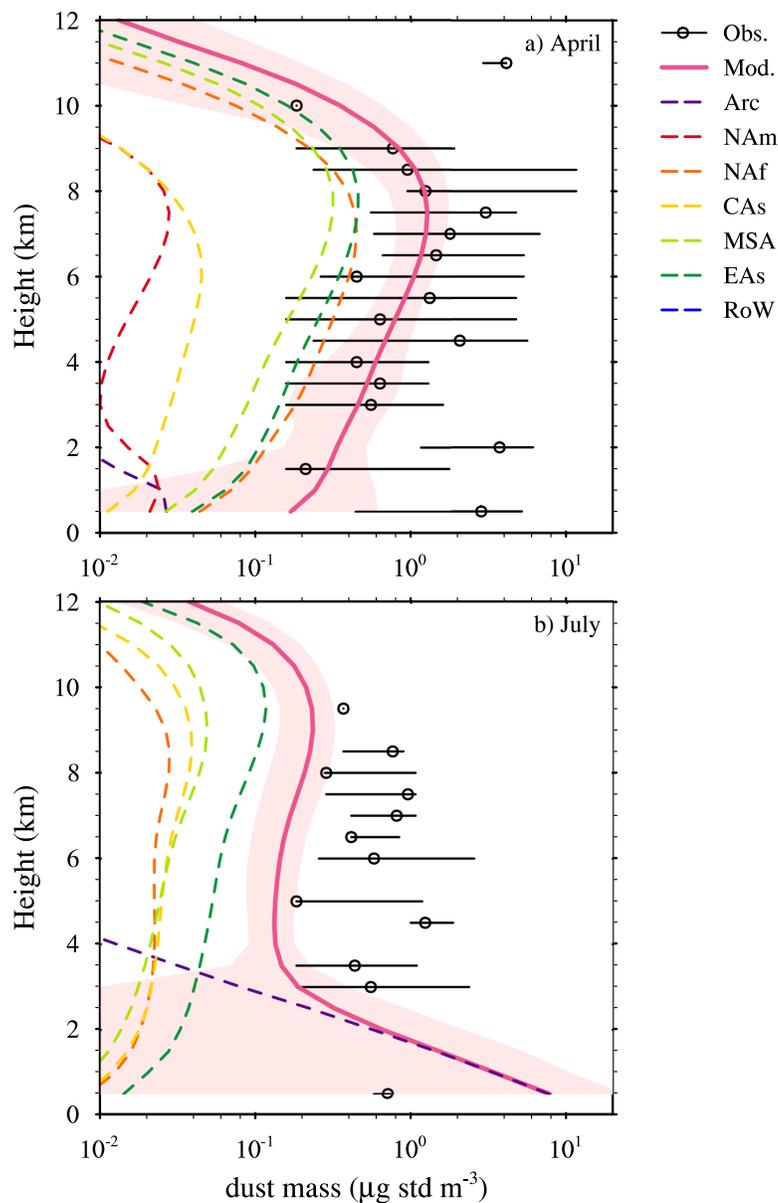

1107

1108

1109 **Figure 3.** Comparison of measured (black solid line, with gray shade representing standard
 1110 deviation) and simulated (pink solid line, with pink shade representing year-to-year variability)
 1111 monthly mean dust surface concentration at three high latitude stations – a) Heimaey, b) Alert,
 1112 and c) Trapper Creek. The model results are averaged from year 2007 to 2011. Contributions
 1113 from seven tagged sources are shown by colored dashed lines. The locations of the three stations
 1114 are shown in Figure 2d. The measurements at Heimaey (Prospero et al., 2012), Alert (Sirois and
 1115 Barrie, 1999), and Trapper Creek (IMPROVE) are averaged for the years 1997 to 2002, 1980 to
 1116 1995, and 2007 to 2011, respectively. The dust concentrations at Trapper Creek only include
 1117 particles with diameter less than 2.5 μm . The other two stations include dust over the whole size
 1118 range.

1119

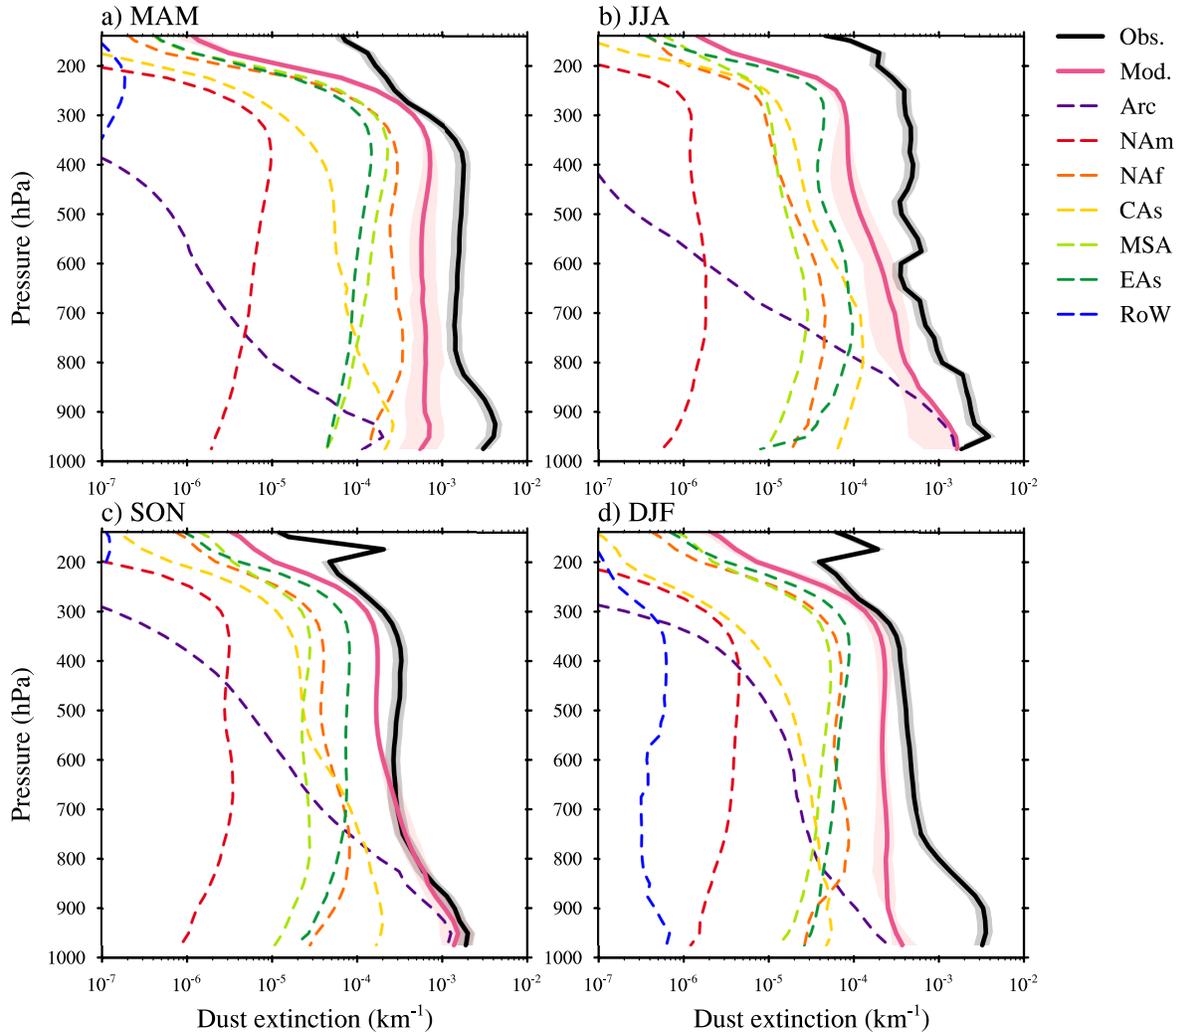

1120

1121 **Figure 4.** Comparison of vertical dust concentrations from ARCTAS flight observations (Jacob
 1122 et al., 2010) (black circle) and CTRL simulation (pink solid line) in a) April and b) July. We
 1123 show median values for observations at each level. The maximum and minimum of the
 1124 measurements at each level are shown by black lines. Contributions from the seven tagged
 1125 sources in CTRL are shown by colored dashed lines. The ARCTAS dust mass concentrations are
 1126 derived from measured calcium and sodium concentrations. The measurements data are
 1127 processed using the same method as Breider et al. (2020). Briefly, we assume a calcium to dust
 1128 mass ratio of 6.8% and further correct the calcium concentrations for sea salt by assuming a
 1129 calcium to sodium ratio of 4%. Only measurements obtained north of 60°N are used for the
 1130 analyses. The low-altitude observations near Fairbanks, Barrow, and Prudhoe Bay are removed.

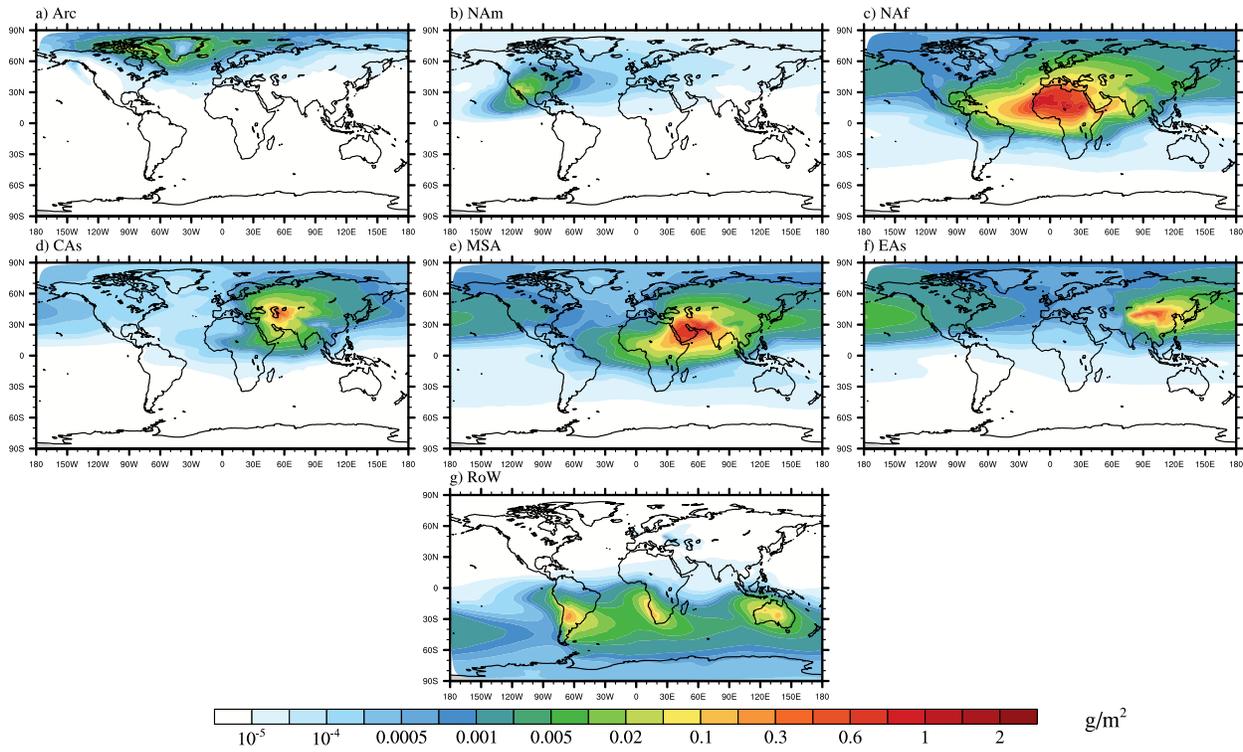

1131 Also, data from below 1 km on 1, 4, 5, 9 July is removed to exclude the influence of wildfire.
1132 The ARCTAS flight campaign was conducted in 2008, while the modeled vertical profiles are
1133 averaged for each April and July from 2007 to 2011, respectively. Following Groot Zwaafink et
1134 al. (2016), the simulation profiles are averaged for the regions north of 60°N and 170°W to
1135 35°W in April and 135°W to 35°W in July. Also, the observations have a cut-off size of 4 μm
1136 and thus is only compared with simulated dust concentrations in the same size range. The pink
1137 shade on each panel represents the standard deviation with respect to time and space for the
1138 simulated total dust concentrations.

1139

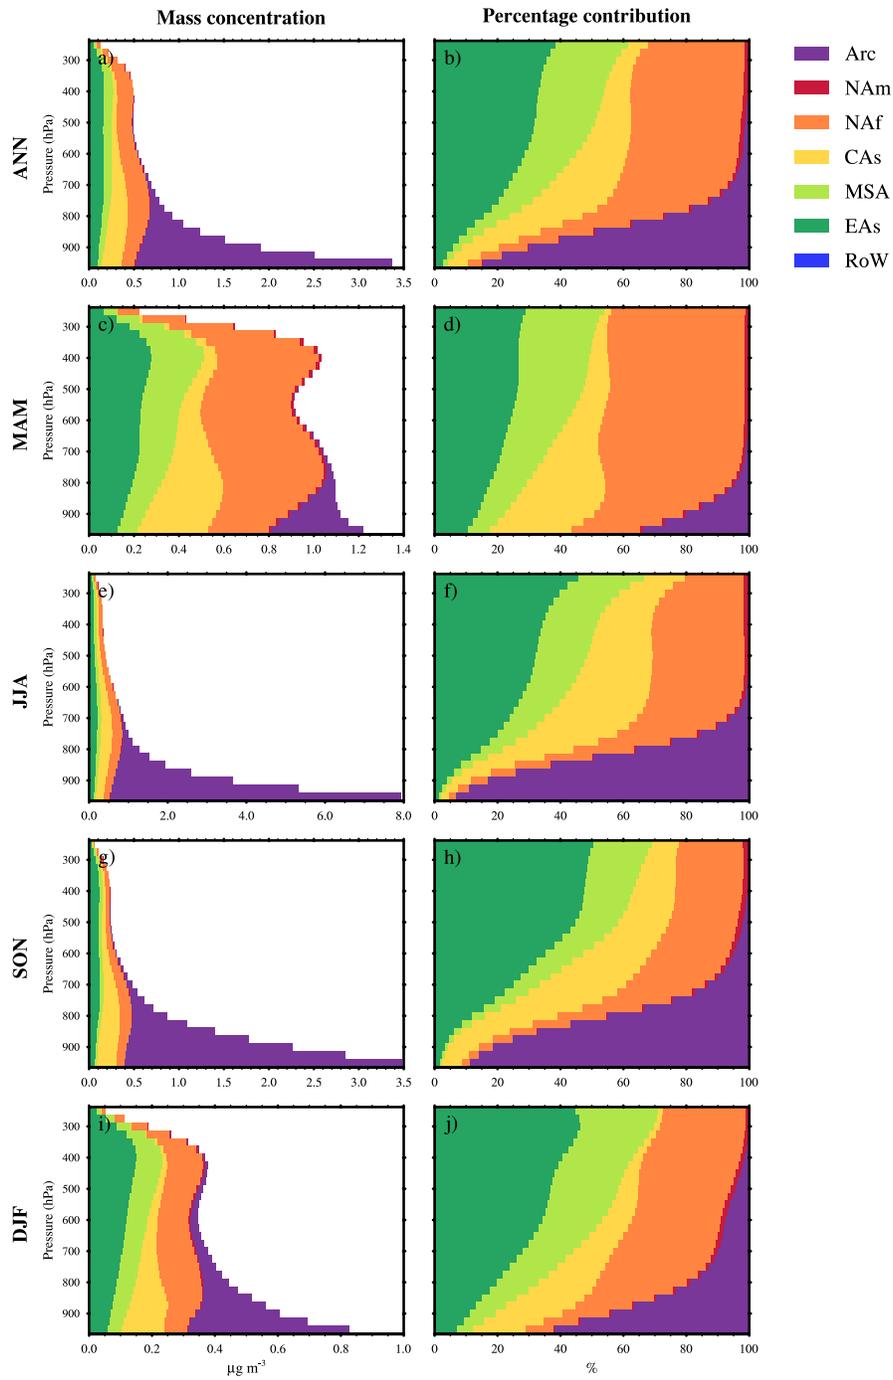

1140

1141 **Figure 5.** Comparison of seasonal CALIPSO retrieved (Luo et al., 2015a, b; Yang et al., 2022)
 1142 (black solid line; with gray shade representing uncertainty) and model simulated (pink solid line;
 1143 with pink shade representing year-to-year variability) dust extinction vertical profiles in the
 1144 Arctic (above 60°N). Contributions from seven tagged sources are shown by colored dashed
 1145 lines. The CALIPSO retrievals are for the year 2007 to 2009, while the model results are
 1146 averaged over the same years. The uncertainties of the CALIPSO retrievals are assumed to be
 1147 20% following Yang et al. (2022).

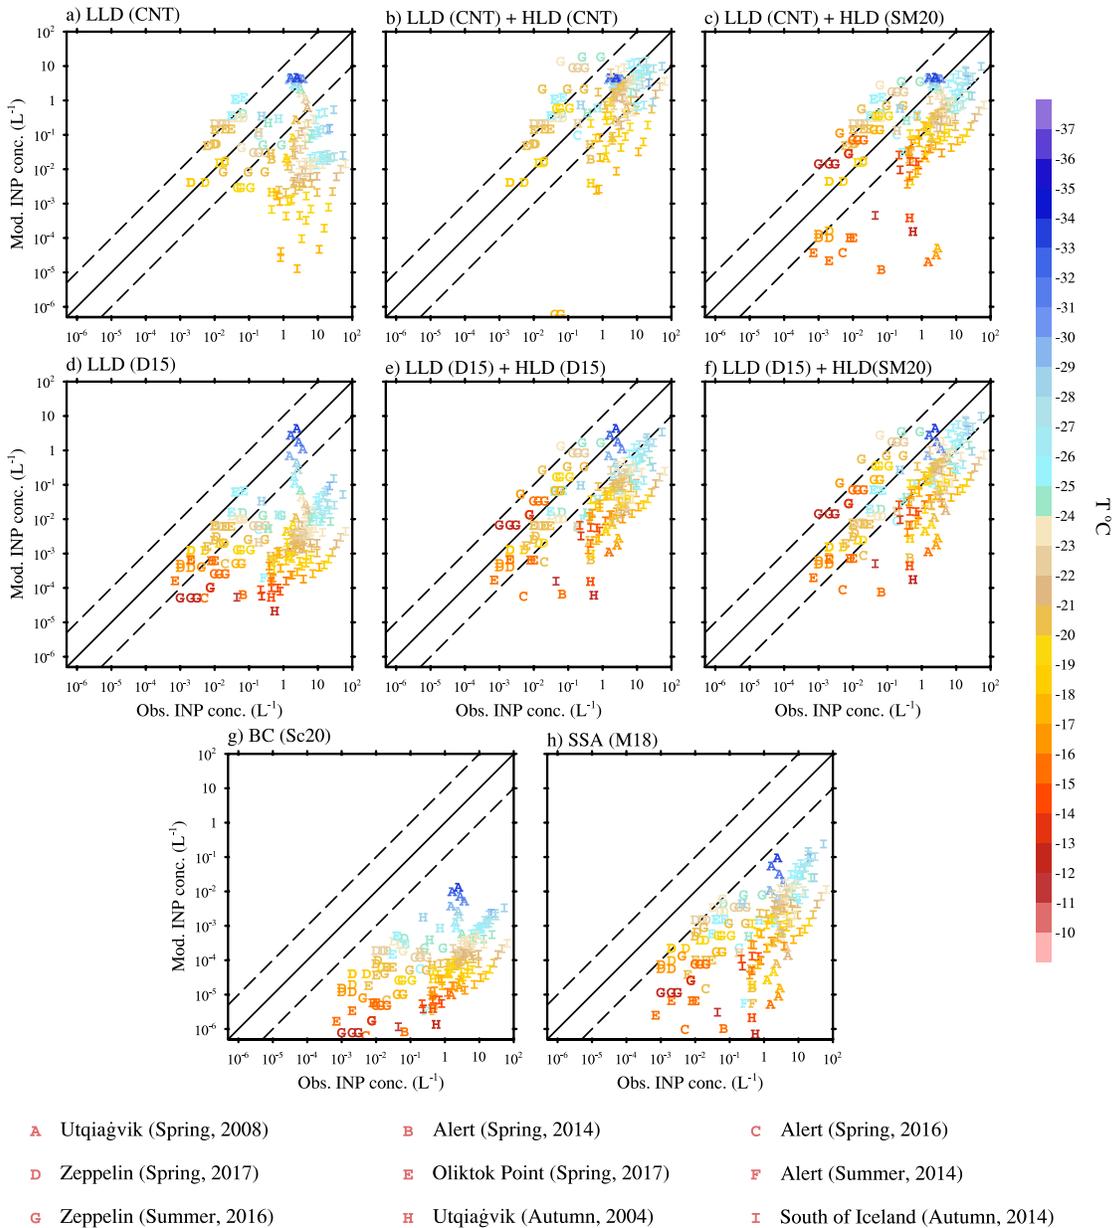

1148

1149 **Figure 6.** Spatial distribution of annual mean (year 2007 to 2011) dust column burdens for
 1150 various tagged sources.

1151

1152 **Figure 7.** Annual and seasonal mean (year 2007 to 2011) Arctic (60-90°N) vertical dust
 1153 concentrations (left panel) and percentage contributions from tagged sources (right panel).
 1154 Different tagged sources are classified by different colors.

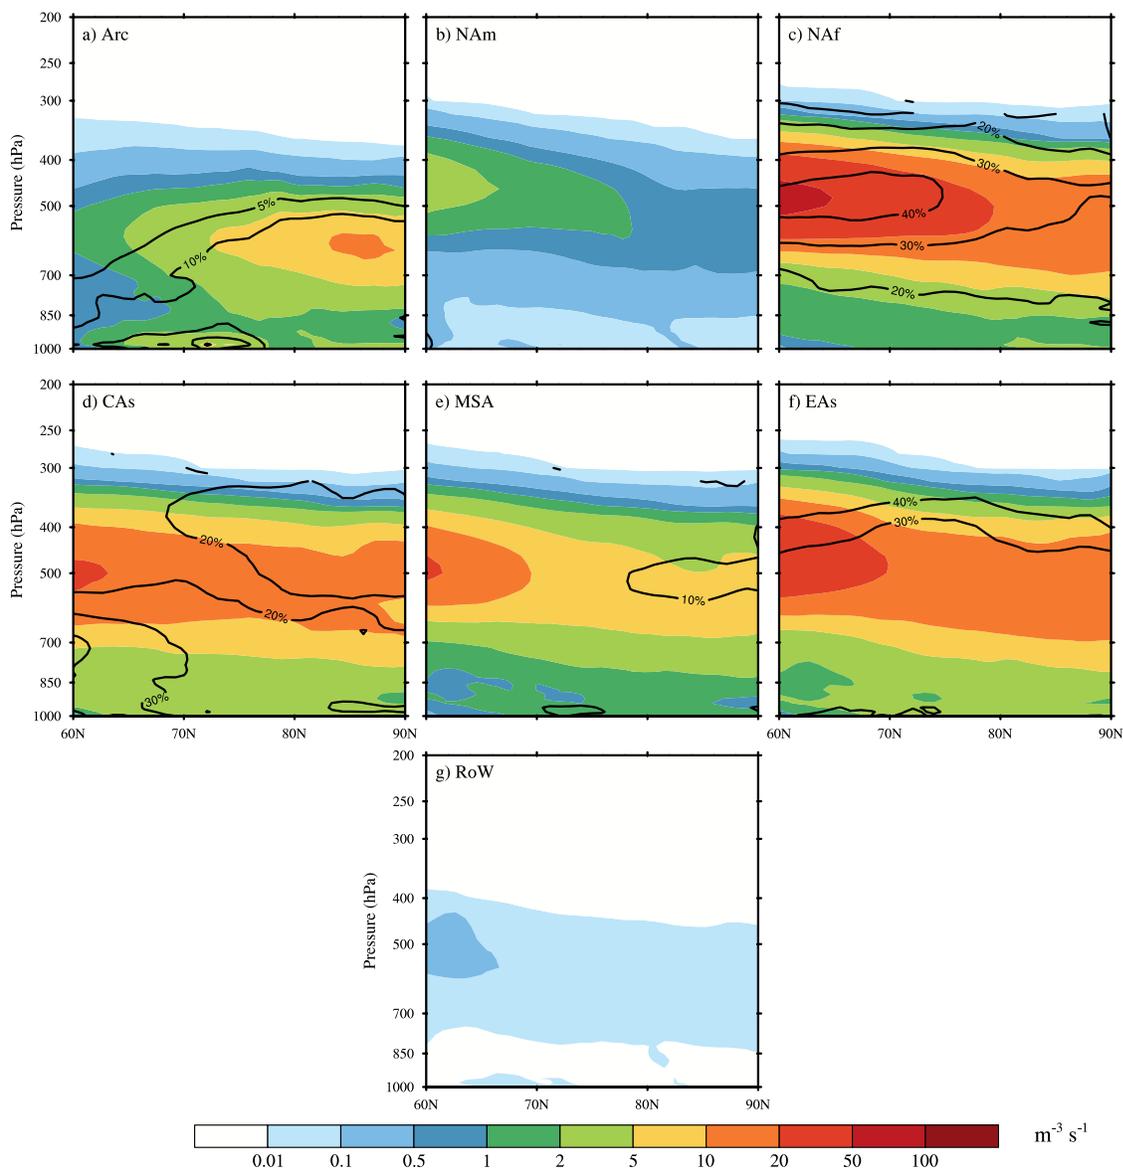

1155

1156 **Figure 8.** Comparison of predicted versus observed INP concentrations in the Arctic. The
 1157 predicted INP concentrations are derived from a) LLD using classical nucleation theory (CNT),
 1158 b) LLD and HLD, both using CNT, c) LLD using CNT and HLD using Sanchez-Marroquin et al
 1159 (2020; SM20), c) LLD using DeMott et al. (2015; D15), d) LLD and HLD, both using D15, e)
 1160 LLD using D15 and HLD using SM20, f) BC using Schill et al. (2020; Sc20), and g) SSA using
 1161 McCluskey et al. (2018; M18). SSA includes both marine organic aerosol and sea salt. Nine INP
 1162 datasets are classified by symbol “A” to “I”, the color of which represents the temperature
 1163 reported in the observations. The observations for datasets “A”, “C”, “E”, “H” are monthly mean
 1164 values. Samples for datasets “D”, “G”, “I” are selected randomly and only 15% of them are
 1165 plotted. Details of each campaign are summarized in Table 3. The modelled INP concentrations

1166 are diagnosed using the observed temperatures and monthly averaged aerosol properties of the
1167 corresponding month from year 2007 to 2011. The INP concentrations for CNT are defined as
1168 the CNT immersion freezing rate integrated by 10 s, following Hoose et al. (2010) and Wang et
1169 al. (2014). Solid line in each panel represents 1:1 comparison, while dashed lines outline one
1170 order of magnitude differences. The unit for INP concentration is L^{-1} .

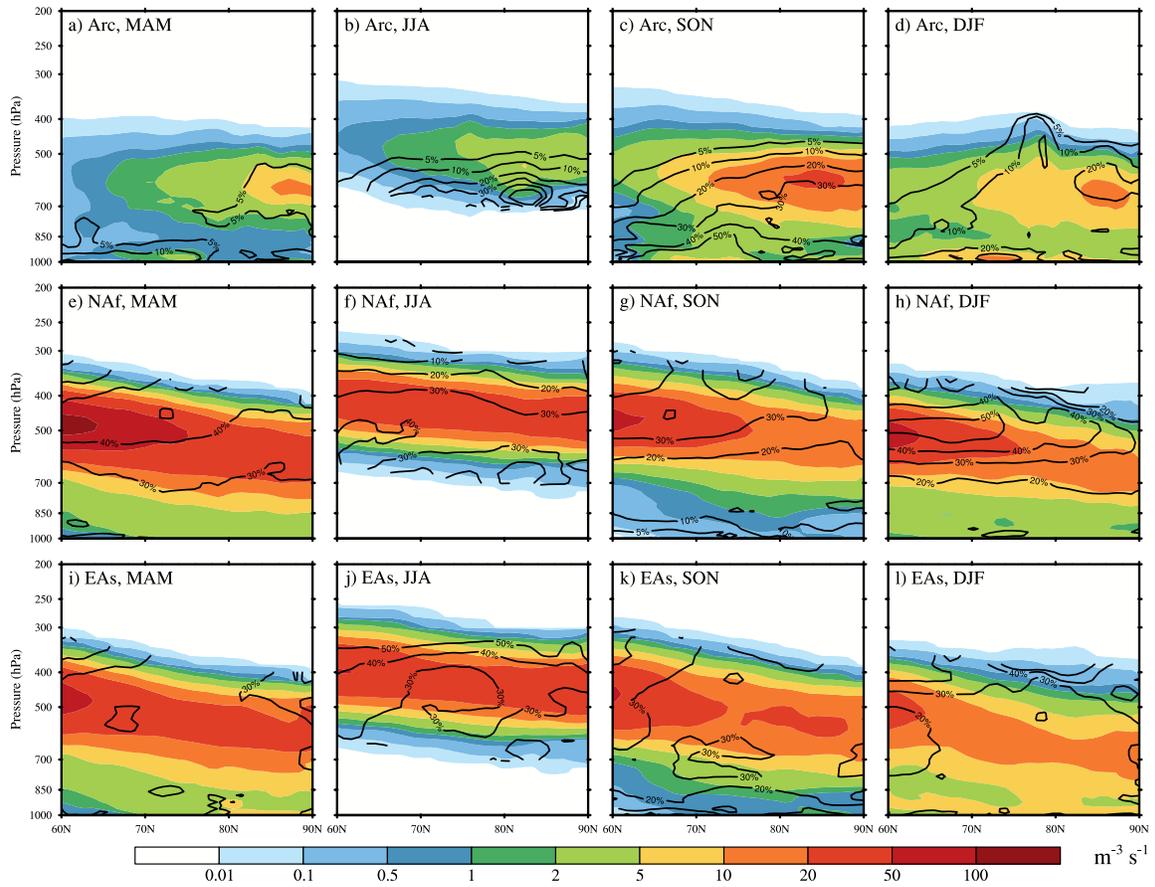

1171

1172

1173 **Figure 9.** Annual and zonal mean (year 2007 to 2011) ambient mixed-phase cloud immersion
 1174 freezing rates (unit: $\text{m}^{-3} \text{s}^{-1}$) in the Arctic for the seven dust sources. Black contours are the
 1175 percentage contributions from each dust source to the total immersion freezing rate.

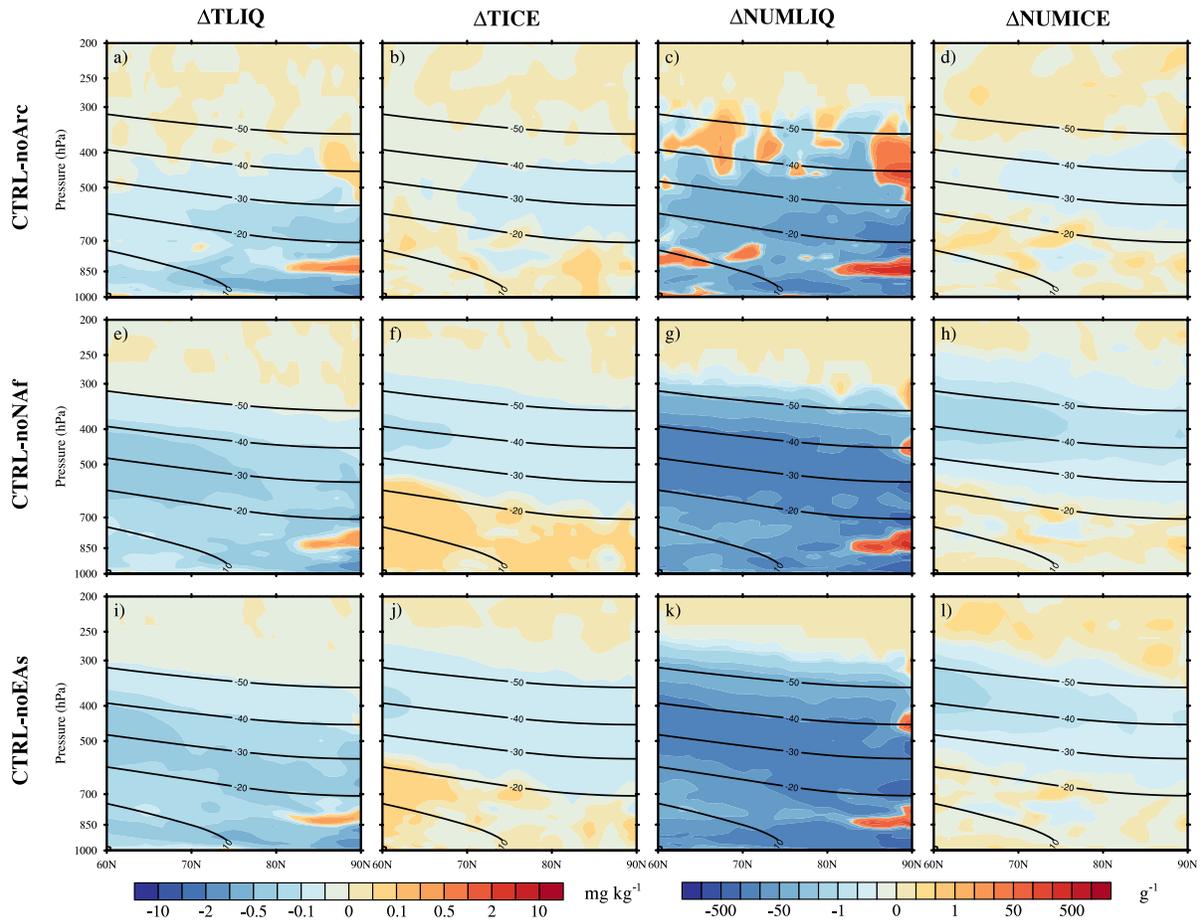

1176

1177

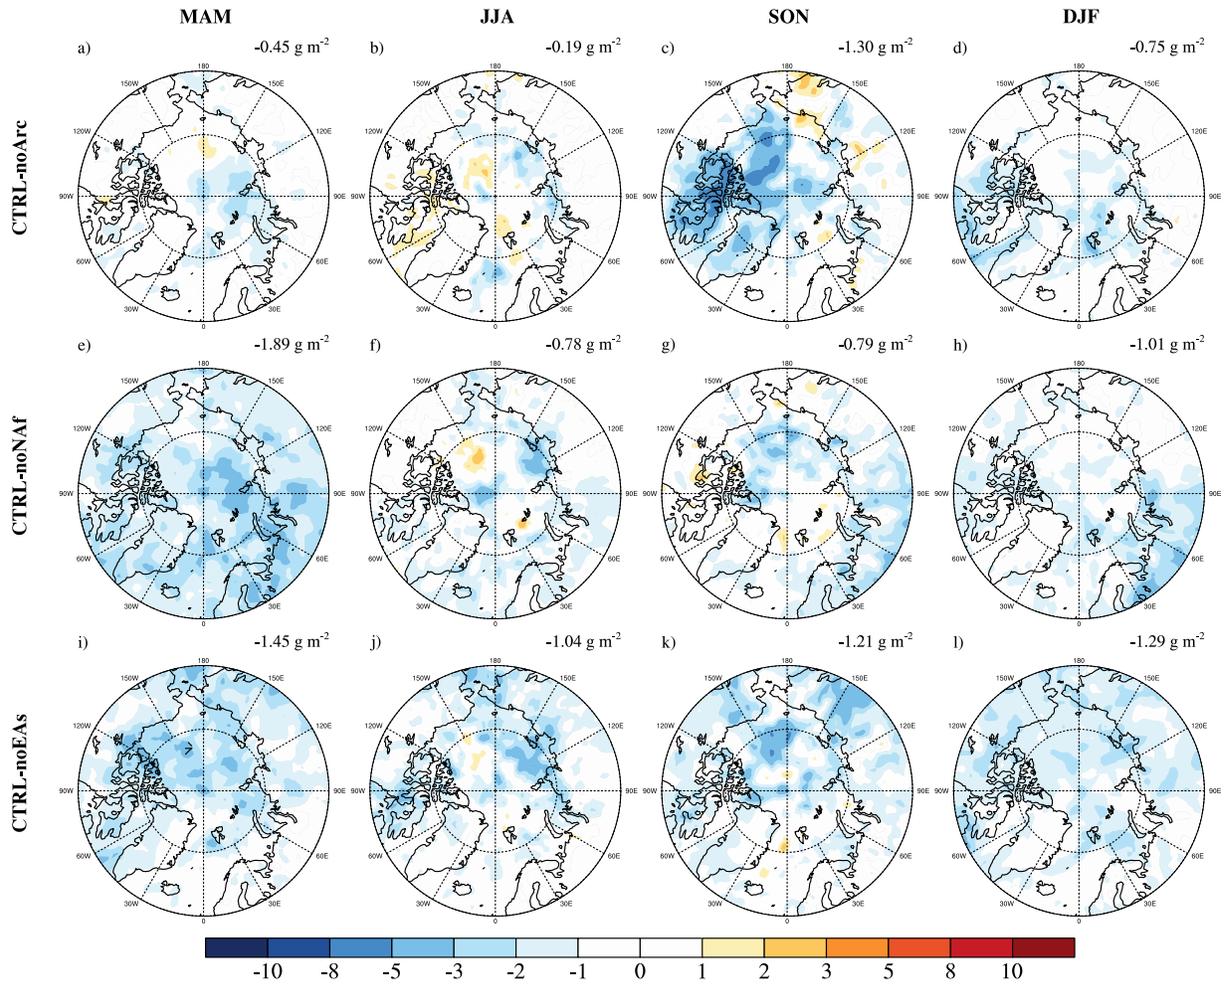

1178 **Figure 10.** Seasonal variations (year 2007 to 2011) of the mixed-phase clouds immersion
 1179 freezing rates (unit: $\text{m}^{-3} \text{s}^{-1}$) over the Arctic for dust emitted from the Arctic (top panel), North
 1180 Africa (middle panel), and East Asia (bottom panel). Black contours are the percentage
 1181 contributions from each dust source to the total immersion freezing rate in the corresponding
 1182 season.

1183

1184

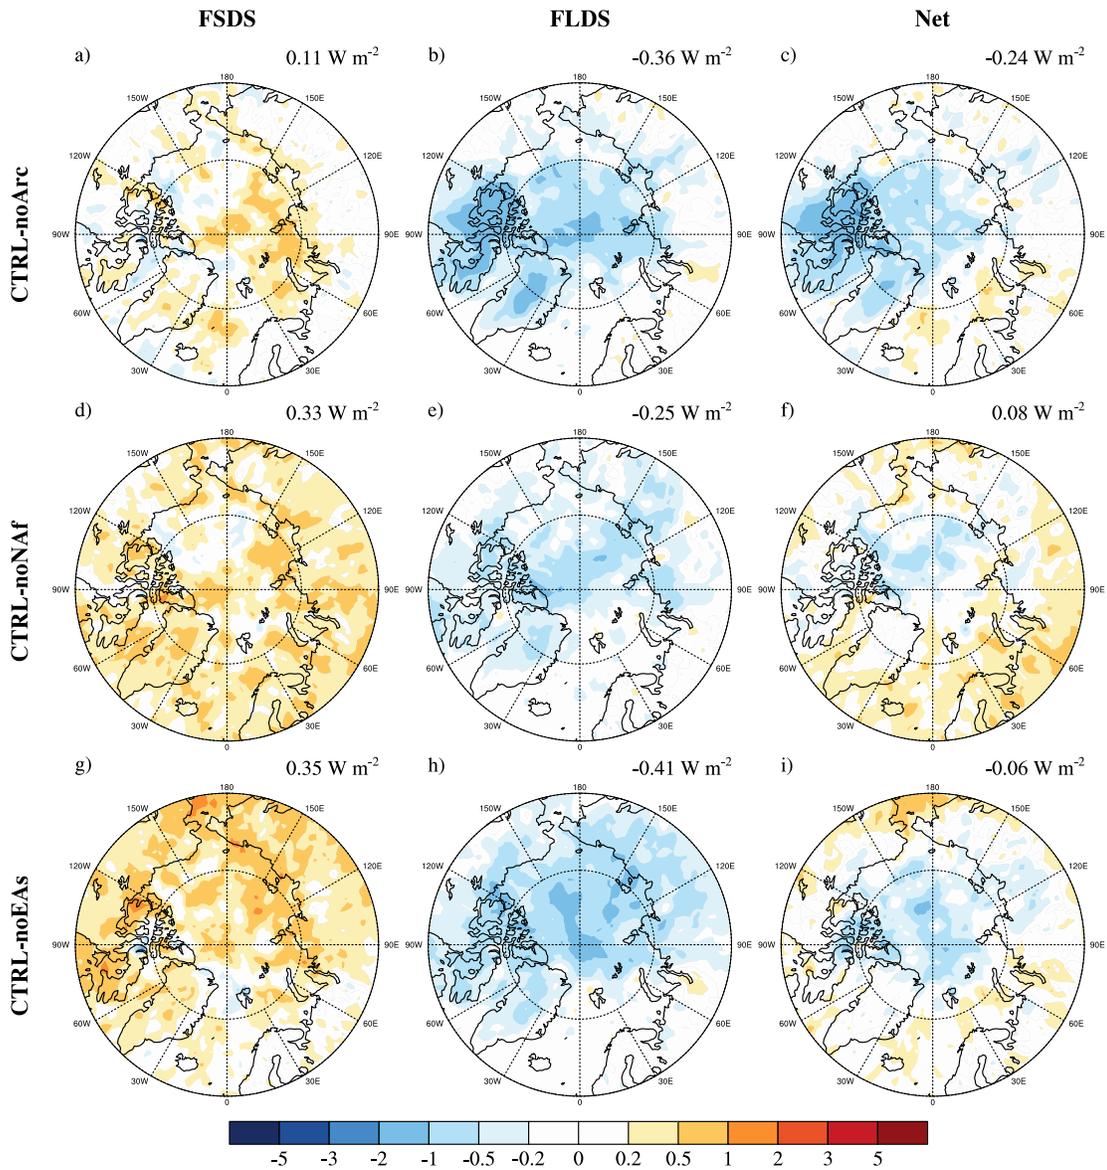

1185 **Figure 11.** Annual and zonal mean differences (year 2007 to 2011) in total liquid water mass
 1186 mixing ratio (TLIQ), total ice mixing ratio (TICE), cloud droplet number concentration
 1187 (NUMLIQ), and cloud ice number concentration (NUMICE) in the Arctic. Black contours are
 1188 zonal averaged temperatures in $^{\circ}\text{C}$. Top, middle, and bottom panels show the differences
 1189 between CTRL and noArc, noNAf, and noEAs, respectively.

1190

1191 **Figure 12.** Seasonal changes (year 2007 to 2011) in LWP (unit: g m^{-2}) caused by dust INPs from
 1192 the Arctic (top panel), North Africa (middle panel), and East Asia (bottom panel). The numbers
 1193 are averaged LWP differences in the Arctic.

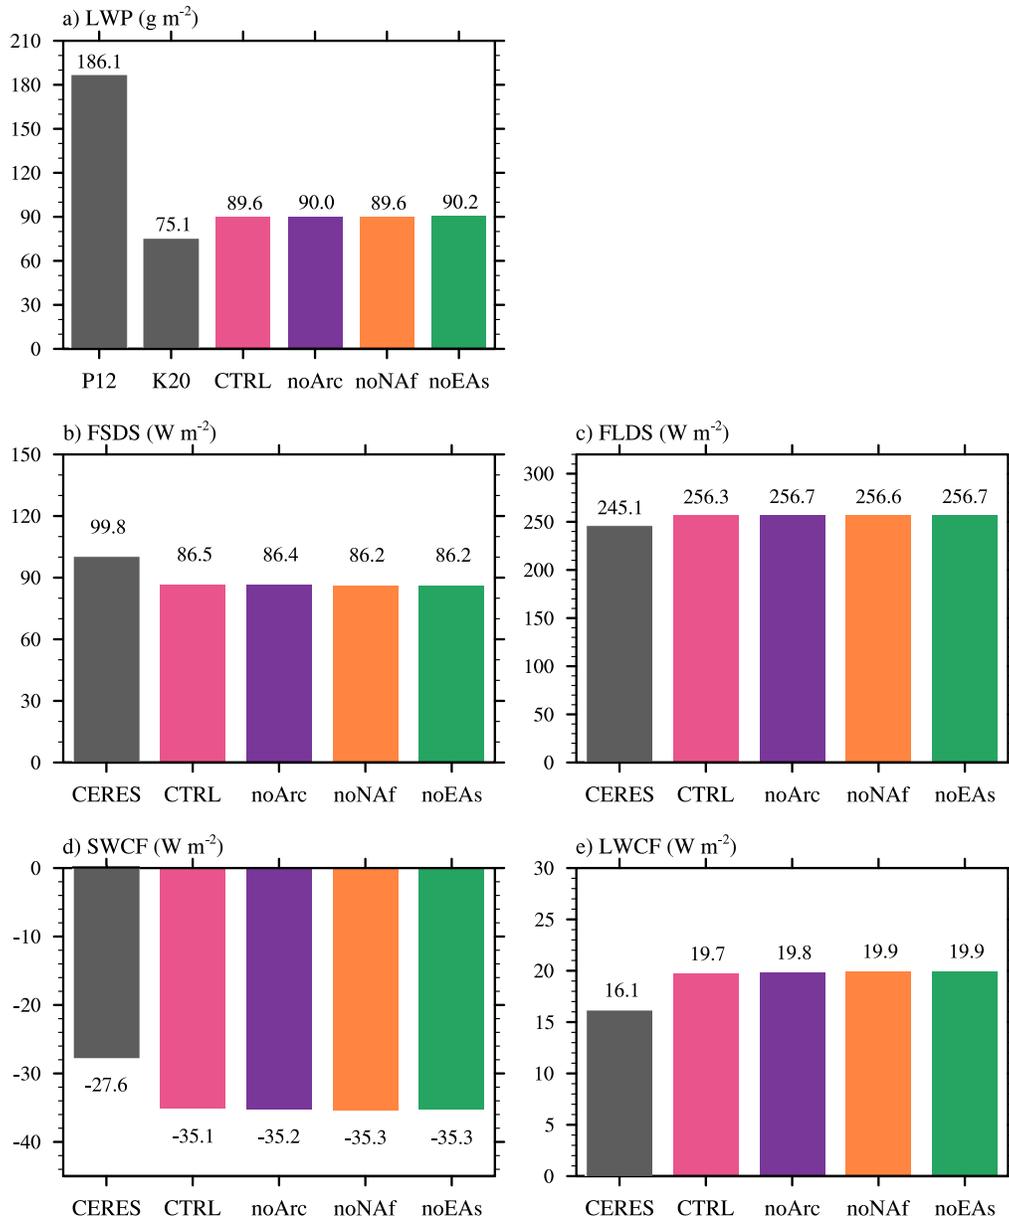

1194

1195

1196 **Figure 13.** Changes in annual mean (year 2007 to 2011) downwelling radiative fluxes at the
 1197 surface (unit: $W m^{-2}$) caused by dust INPs from the Arctic (top panel), North Africa (middle
 1198 panel), and East Asia (bottom panel). Left, middle, and right panels are downwelling shortwave
 1199 (FSDS), longwave (FLDS), and net (FSDS + FLDS) radiative fluxes, respectively. The numbers
 1200 are averaged radiative flux differences in the Arctic.

1201

1202

1203 **Figure 14.** a) Annual mean Arctic (60°N to 80°N in this subplot) averaged LWP over ocean for
 1204 the MODIS observations and the four simulations (2007-2008). Two MODIS datasets are used,
 1205 including the standard product (Pincus et al., 2012; P12; averaged from 2007 to 2008) and an
 1206 improved one (Khanal et al., 2020; K20; averaged from 2007 to 2009). The MODIS simulator is
 1207 used to calculate the simulated LWP. b) - e) Annual mean Arctic (60°N to 90°N in these
 1208 subplots) averaged b) FS DS, c) FL DS, d) SWCF, and e) LWCF for the CERES observation
 1209 (2007-2011) and the four simulations (2007-2011).

1210
